VERTICAL AND HORIZONTAL ASYMMETRIES ARE RELATED TO SLOWER SPRINTING AND JUMP PERFORMANCE IN ELITE YOUTH FEMALE SOCCER PLAYERS

ABSTRACT

Inter-limb asymmetries have been shown to be greater during vertical jumping compared to horizontal jumping. Notable inter-limb differences have also been established at an early age in male youth soccer players. Furthermore, given the multi-planar nature of soccer, establishing between-limb differences from multiple jump tests is warranted. At present, a paucity of data exists regarding asymmetries in youth female soccer players and their effects on physical performance. The aims of this study were to quantify inter-limb asymmetries from unilateral jump tests and examine their effects on speed and jump performance. Nineteen elite youth female soccer players performed a single leg countermovement jump (SLCMJ), single, triple, and crossover hops for distance and a 20 m sprint test. Test reliability was good to excellent (ICC = 0.81-0.99) and variability acceptable (CV = 1.74-5.42%). A one-way ANOVA highlighted larger asymmetries from the SLCMJ compared to all other jump tests ($p < 0.05$). Pearson's correlations portrayed significant relationships between vertical asymmetries from the SLCMJ and slower sprint times (r = 0.49-0.59). Significant negative relationships were also found between horizontal asymmetries during the triple hop test and horizontal jump performance (r = -0.47 to -0.58) and vertical asymmetries during the SLCMJ and vertical jump performance (r = -0.47 to -0.53). The results from this study highlight that the SLCMJ appears to be the most appropriate jump test for identifying between-limb differences with values ~12% showing negative associations with sprint times. Furthermore, larger asymmetries are associated with reduced jump performance and would

25 appear to be direction-specific. Practitioners can use this information as normative data to be

26 mindful of when quantifying inter-limb asymmetries and assessing their potential impact on

27 physical performance in youth female soccer players.

INTRODUCTION

The notion of inter-limb asymmetries refers to the function of one limb in respect to the other and has been a popular source of investigation in recent years. The majority of literature has focused on the prevalence of between-limb differences in multiple testing modalities such as isokinetic dynamometry (14,37), isometric squat or mid-thigh pulls (16,19), back squatting (30,38), and a variety of jumping-based tasks (3,12,27,28). All of the aforementioned methods have been shown to be sensitive when identifying differences between limbs in both athlete and non-athlete populations. Furthermore, it has been stated that inter-limb asymmetries may be a product of the time spent competing in the same sport (18,20). However, their prevalence alone provides limited information as to whether targeted training interventions may be required to minimise their presence. Consequently, understanding whether inter-limb asymmetries have a detrimental impact on physical performance would provide practitioners with more tangible information pertaining to their importance.

Jump protocols are a common modality for testing in youth soccer athletes (11,26,32,41,43), most likely because of their ease of implementation (9) which is an important consideration due to the reduced training age in youth athletes. This is supported by Read et al. (31) who suggested that jump tests not only offer a viable method of quantifying inter-limb asymmetries, but that many have successfully been used to prospectively identify athletes at risk of injury (2,22,35). It was also suggested that unilateral jump tests may be the preferred option when quantifying inter-limb differences due to their enhanced sensitivity for detecting differences (10), which in part may be due to the heightened instability associated with single leg tests. Additional literature has acknowledged that no contribution exists from the opposing limb during unilateral tests; therefore, representing a more accurate interpretation of 'true asymmetries' (4,9). In addition, because the relationship between multi-planar demands

68   of soccer and different jumping tasks is still unclear (21,28), more than one test should be

69   used to assess asymmetries.

70   Consequently, many unilateral jump tests have been incorporated in the literature to date.

71   Single leg countermovement jumps (SLCMJ) and single, triple, and crossover hops for

72   distance have all displayed strong reliability (ICC range = 0.89-0.99) (10,34,36); thus,

73   practitioners can be confident of their consistency during testing. Dos'Santos et al. (15)

74   recently reported that asymmetries during single and triple hops for distance were not

75   associated with slower change of direction speed times. However, the largest imbalance

76   reported can be considered small (6.25%), with larger deficits ($\geq$ 10%) potentially impacting

77   performance (7). Read et al. (33) investigated the effects of maturation on inter-limb

78   asymmetries using the SLCMJ and single leg hop for distance in elite youth male soccer

79   players. They found that SLCMJ landing forces were significantly higher in those who were

80   circa and post-peak height velocity (PHV). Asymmetries during the single leg hop for

81   distance were small, but reduced even further with age. Although useful, the aforementioned

82   evidence relates to male youth players and currently a paucity of data exists concerning youth

83   female soccer players. Thus, the quantification of inter-limb asymmetries from unilateral

84   jump tests and their relationship with physical performance would be a useful addition to the

85   literature for youth female athletes.

86   Therefore, the primary aim of this study was to assess the relationship between jumping

87   asymmetries and sprint and jump performance in elite youth female soccer players. This

88   could help to determine whether training interventions might be necessary to rectify existing

89   side-to-side differences. A secondary aim was to quantify inter-limb asymmetries from

90   multiple unilateral jump tests in order to provide an asymmetry profile that is currently

91   lacking in elite youth female soccer players.

METHODS

Experimental Approach to the Problem

After a separate habituation session, data were collected during a single session. The first session allowed players to practice all tests an unlimited number of times until the requirements were fully understood. During data collection, multi-planar jump tests were used to quantify inter-limb asymmetries to represent ecological validity for the population in question, whilst four sets of timing gates were used over 20 m. This enabled split times to be measured for 5, 10, and 20 m sprints and subsequently, multiple relationships to be assessed between asymmetry scores and sprint and jump performance. In addition, test variability was quantified using the coefficient of variation (CV), noting that inter-limb differences are only considered 'real' if greater than test variability (17).

Subjects

Nineteen elite youth female soccer players (age: 10 ± 1.1 years; height: 141 ± 7.9 cm; body mass: 35 ± 7.1 kg), were recruited from a Tier 1 Regional Talent Centre (RTC) of a professional soccer club. Players trained for at least 36 weeks per year and were required to take a minimum of 2 x 30-minute structured strength and conditioning training sessions per week. Emphasis at this age was placed on mastering fundamental movement patterns, building strong foundations, enhancing technical competency, and improving general motor control. All subjects were free from injury at the time of testing and informed consent and PAR-Q forms were completed from all relevant parents or guardians as all participants were under the age of 18. Ethical approval was granted from the London Sports Institute ethics committee, Middlesex University.

115

Procedures

Subjects were tested at the same time of day on two separate testing occasions, each separated by 72 hours. Session one was used to familiarize all subjects with the test procedures, enabling them to practice each jump and sprint test as many times as they wanted; although all players were instructed to practice each test a minimum of five times. The second session was used for data collection and during the jump tests; a particular emphasis was placed on landing mechanics, owing to the increased demand of having to land on one limb. All participants were asked not to participate in any strenuous exercise at least 24 hours prior to testing, and to ensure they wore the same footwear on each occasion to negate the effects of different shoe design and support structures. Both sessions took place on a third generation (3G) pitch, which subjects were used to training on twice weekly. Each jump test consisted of three trials on each limb with 60 seconds rest between trials, and 2-minutes rest between tests, in order to allow for full recovery (34). All tests were conducted in a randomized, counter-balanced order, so as to negate any potential learning effects. Prior to familiarization and testing sessions, all participants completed a standardized warm-up protocol, following the RAMP system as outlined by Jeffreys (23). This consisted of dynamic stretches such as multi-planar lunges, inchworms, and spiderman exercises before progressing into practice jumps and sprints at 60, 80, and 100% of perceived maximum effort. A 3-minute rest period was prescribed between the warm up and the first test.

Single leg countermovement jump (SLCMJ). Subjects stood in an upright position, hands on hips, with feet positioned hip width apart. To begin the test, one leg was lifted off the floor to approximately mid shin height of the standing leg. Subjects then performed a countermovement to a self-selected depth followed by a quick upward vertical movement,

139   triple extending at the ankle, knee, and hip with the intention of jumping as high as possible.

140   The jumping leg had to remain fully extended and hands fixed to hips; any deviation from

141   this required the trial to be re-taken after a 60-second rest period. Jump height was calculated

142   by the flight time method using the "My Jump" iPhone application, which has been shown

143   previously to be a reliable method (1).

144   *Single leg hop (for distance).* Subjects begin by standing on the designated testing leg with

145   their hands on hips and their toes behind the starting line. Subjects were then instructed to

146   hop as far forward as possible and land on the same leg. Upon landing, participants were

147   required to 'hold and stick' their position for two seconds. Failure to stick the landing

148   resulted in a void trial and the jump being retaken after a 60-second rest. This was consistent

149   across all trials for all hop tests. The distance hopped from the starting line to the point where

150   the subject's landing heel hit in the final position was then recorded to the nearest centimetre

151   using a standard measuring tape fixed to the floor (also used for all hop tests).

152   *Triple hop (for distance).* Subjects begin by standing on the designated testing leg, hands on

153   their hips with their toes behind the starting line. Subjects were instructed to take three

154   maximal hops forward (landing on the same leg throughout) with the intention of minimising

155   ground contact times after the first and second hops. When landing from the final hop,

156   subjects were required to 'stick' the landing and hold for two seconds. Failure to stick the

157   final landing resulted in a void trial and the jump being retaken after a 60-second rest. The

158   distance hopped from the starting line to the landing position of the subjects' heel was then

159   measured and recorded to the nearest centimetre.

160   *Crossover hop (for distance).* Subjects began by standing on the designated testing leg, with

161   their toes behind the starting line. If subjects were hopping with their right leg, they started

162   the test on the right side of the measuring tape and vice versa if they started on the left leg.

163   Subjects were instructed to take three consecutive maximal hops forward; each time crossing

164   over an area measuring 15 cm wide landing on the same leg throughout. As per previous hop

165   testing protocols, all subjects were required to stick the final landing for two seconds. Failure

166   to do so resulted in a void trial and the jump being retaken after a 60-second rest. The

167   distance hopped from the starting line to the point where the subject's heel hit on completion

168   of the third jump was measured and recorded to the nearest centimetre.

169   *5, 10, and 20 m Sprints.* Electronic timing gates (Brower Timing Systems, Utah, USA) were

170   positioned at 0, 5, 10, and 20 m to enable multiple splits to be measured during a single sprint.

171   Subjects started the test in a staggered 2-point stance with toes positioned 30 cm behind the

172   start line so as to not break the beam of the timing gates prior to the initiation of the test.

173   When ready, subjects sprinted through the final set of timing gates allowing for 5, 10, and 20

174   m split times which were recorded to the nearest hundredth of a second.

175

176   **Statistical Analyses**

177   All data was initially computed as means and standard deviations (SD) in Microsoft Excel™

178   and all additional analyses computed in SPSS (SPSS Inc., Chicago, IL, USA). All data were

179   checked for normality using the Shapiro-Wilk test and within-session reliability of test

180   measures were computed using intraclass correlation coefficient (ICC) with absolute

181   agreement and the CV. Interpretation of ICC values was in accordance with previous research

182   by Koo and Li, (24) where values > 0.9 = excellent, 0.75-0.9 = good, 0.5-0.75 = moderate,

183   and < 0.5 = poor and CV values were considered acceptable if < 10% (13,40). Inter-limb

184   asymmetries were quantified as the percentage difference between the two limbs (see

185   Equation) rather than using a reference value for limb dominance as has been previously

186   suggested (5,6). A one-way analysis of variance (ANOVA) was used to examine for potential

187 differences in asymmetry between jumping tasks with statistical significance set at $p < 0.05$.

188 Pearson's *r* correlation was utilised to determine the strength of the relationship between

189 asymmetries measured during each jump test and sprint times, and between asymmetry

190 scores and jump performance with statistical significance set at $p < 0.05$.

191

192 *Equation*: 100/Max Value (right and left)*Min Value (right and left)*-1+100 (6)

193

194 **RESULTS**

195 All data were normally distributed ($p > 0.05$) and each test had acceptable between trial

196 consistency with all CV values < 10%, and good or excellent ICC's (Table 1). Mean

197 asymmetry values are presented in Table 1 and the SLCMJ showed greater ($p < 0.05$) side-to-

198 side differences (approximately double) compared to all other jump tests. Correlations

199 between jump tests/asymmetries and sprint tests are shown in Table 2 and correlations

200 between asymmetries and jump performance in Table 3. Results indicated that larger vertical

201 asymmetries were associated ($p < 0.05$) with slower sprint times (Table 2). Asymmetries

202 during the triple hop test were associated ($p < 0.05$) with reduced horizontal jump

203 performance and vertical asymmetries were associated ($p < 0.05$) with reduced vertical jump

204 performance (Table 3). Individual asymmetry data have also been included (Figures 1-4).

DISCUSSION

The aims of this study were to test for the presence of asymmetries during vertical and horizontal jump tests in elite youth female soccer players and examine relationships between asymmetries measured in these different tasks and sprint and jump performance. Results indicated that asymmetry is task-dependent as the SLCMJ produced significantly greater between-limb differences compared to all horizontal hop tests. Significant relationships were also present between asymmetries in the SLCMJ and sprint times measured across distances of 5, 10, and 20 m. No significant relationships were found between asymmetries during horizontal hop tests and any of the sprint distances measured. Significant negative relationships were also found for horizontal asymmetries in the triple hop test and horizontal jump performance, and asymmetries in the SLCMJ and vertical jump performance.

The first point to consider from these results is that the SLCMJ produced significantly greater asymmetries than all other jump tests which is in agreement with previous research. Lockie et al. (25) reported asymmetries of 10.4 and 5.1% during the SLCMJ and single leg broad jump respectively (also called single leg hop for distance). It is possible that vertical jumping may be more sensitive at identifying asymmetries given that the results in the present study and that of Lockie et al. (25) found inter-limb differences ~50% greater than any horizontal jump test. Furthermore, the sample used in Lockie's study were adult male team sport athletes and with a similar trend now found in the present study (from a completely different sample), these results require an explanation. Intuitively, this seems quite difficult to fully explain; however, considering children learn and practice horizontal hopping activities (such as hop scotch) from an early age (39,42), it could be argued that these movement patterns are practiced more than unilateral vertical jumping for youth athletes. This may explain why inter-limb differences are notably less in horizontal jumping tasks; however, further research is still warranted to fully corroborate this theory.

234 In addition to significantly larger inter-limb differences from the SLCMJ, this was the only

235 asymmetry that had significant correlations with sprint times (Table 2). Furthermore, all *r*

236 values from the SLCMJ asymmetry scores are positive, indicating that larger asymmetries

237 may be indicative of slower sprinting; noting that the fastest time is always desirable in sport.

238 Consequently, practitioners who measure between-limb asymmetries from jump tests should

239 be mindful of differences ~12% and aim to quantify whether they are associated with any

240 decrements in performance. This seems prudent advice given the notion that asymmetries >

241 10% have been suggested to potentially impact physical and sports performance (7,9) and the

242 results of the present study are in agreement with this consensus. Cumulatively, given that the

243 SLCMJ appears more sensitive at identifying inter-limb differences and shows stronger

244 relationships to decrements in sprint speed compared to horizontal hops, these results indicate

245 that the SLCMJ may be the most appropriate jump test to identify the prevalence of inter-

246 limb asymmetries in athletes.

247 When examining the role of inter-limb differences on jump performance, the results show

248 interesting findings (Table 3). Firstly, asymmetries from the triple hop test were significantly

249 associated with reduced performance in all horizontal jump tests, but no significant

250 correlations were found with the SLCMJ. In addition, asymmetries from the SLCMJ were

251 also significantly associated with reduced jump performance during vertical jumping only.

252 Recent literature has indicated that determinants of unilateral jump performance are

253 direction-specific (29), and it would appear that asymmetries may follow this trend as well.

254 Although anecdotal, it seems logical to assume that if asymmetries are minimised during

255 unilateral tests that jump performance may also improve (in the same direction). Given that

256 no contribution exists from the non-jumping leg during unilateral tests (9), a larger

257 asymmetry will naturally result in one limb performing poorly in respect to the other. What is

258 apparent from the present study is that horizontal jumping appears unaffected by vertical

259 asymmetries, and vice versa. Thus, with inter-limb differences being direction-specific, it is

260 suggested that soccer practitioners consider monitoring asymmetries in multiple directions

261 (9,31) with a view to reducing these differences to potentially enhance jump performance.

262 A further consideration relates to the individual nature of asymmetries. Firstly, it is

263 interesting to note that the single effort tests showed the greatest individual variation in

264 asymmetry scores (SLCMJ range = 0.0-36.4%; single leg hop range = 0.7-25%) compared to

265 the repeated effort tests (triple hop range = 0.3-14.2% and crossover hop range = 0.6-11.7%)

266 (Figures 1-4). Previous research has highlighted that the single leg hop is able to detect larger

267 asymmetries than other commonly used alternatives such as the triple hop or crossover hop

268 tests (35). Thus, it is plausible that between-limb differences may 'even out' during repeated

269 efforts by virtue of momentum being built throughout the test, although further research is

270 again required to fully corroborate this theory. In addition, there was variation in the direction

271 of asymmetry across tests for individual subjects (Figures 1-4). It is worth noting that this too

272 appears to be test-specific with only two subjects demonstrating larger scores on the same leg

273 for each test. This further highlights the individual nature of asymmetries and the requirement

274 for multiple tests (9,31) in order to better understand their prevalence and interaction with

275 physical performance.

276 When measuring asymmetries, practitioners should also be mindful of the scores in relation

277 to test variability (CV). Exell et al. (17) suggest that asymmetries can only be considered real

278 if inter-limb differences are greater than the variability during test protocols. In the present

279 study, all CV values were < 10% which is considered acceptable (13) and with each jump test

280 demonstrating a greater asymmetry score than the CV, these between-limb differences can be

281 considered real. Despite the prevalence of these asymmetries, it should be reiterated that only

282 differences in the SLCMJ were associated with sprint decrements; thus, their reduction could

283 be considered a viable aim during targeted training interventions. Furthermore, additional

284 factors such as technique and strength may be more prominent reasons why sprint decrements

285 exist (43); thus, coaches should consider the relevance of these when aiming to optimise

286 sprint performance.

287 When interpreting the findings of the current study, practitioners should be mindful of some

288 limitations. Firstly, these results are only applicable to youth female soccer players and future

289 research should aim to provide comparisons across gender and sports where possible. In

290 addition, the impact of jumping asymmetries on physical performance metrics should be

291 investigated across multiple age groups in youth female athletes; thus, highlighting the

292 impact that maturation may have. Read et al. (33) noted that landing force asymmetries

293 during the SLCMJ increased during maturation, but asymmetries in distance from the single

294 leg hop test actually decreased, and it would be useful to consider these results across

295 multiple age groups in female athletes.

296

297 **PRACTICAL APPLICATIONS**

298 Unilateral jump tests are easy to administer and ecologically valid, especially for team sport

299 athletes. The SLCMJ appears to be the most appropriate test for identifying inter-limb

300 asymmetries in youth female soccer players and these differences are associated with slower

301 sprint times. Consequently, practitioners should be mindful of between-limb differences > 10%

302 considering the impact this may have on physical performance. This threshold may be used

303 cautiously to determine if training interventions are deemed necessary for the reduction of

304 asymmetry. Currently, little is known about strategies for the reduction of asymmetries;

305 however, recent literature highlighted that a combination of bilateral and unilateral strength

306 and jump training will likely assist in minimizing these differences (8). However, it was also

307 acknowledged that further interventions are required in order to fully comprehend the optimal

308   methods associated with the reduction of asymmetries; thus, further research is needed in this

309   area.

465   Table 1: Mean scores (standard deviation), mean asymmetry percentages, and reliability data

466   for each jump test ($N = 19$)

Test	Mean ± SD	Asymmetry %	CV (%)	ICC (95% CI)
SLCMJ (R)	9.79 ± 2.56	12.54*	2.82	0.99 (0.97-0.99)
SLCMJ (L)	9.29 ± 2.79		3.51	0.99 (0.97-0.99)
SLH (R)	119.21 ± 17.40	6.79	3.94	0.88 (0.76-0.95)
SLH (L)	120.58 ± 14.84		4.18	0.81 (0.64-0.91)
THOP (R)	377.42 ± 52.14	6.81	3.65	0.86 (0.76-0.95)
THOP (L)	378.26 ± 45.04		3.37	0.92 (0.83-0.96)
XHOP (R)	319.58 ± 54.43	5.81	5.42	0.83 (0.67-0.93)
XHOP (L)	326.21 ± 60.43		3.66	0.94 (0.88-0.98)
5m	1.33 ± 0.15	-	3.69	0.91 (0.84-0.99)
10m	2.21 ± 0.22	-	2.72	0.94 (0.89-0.99)
20m	3.85 ± 0.36	-	1.74	0.96 (0.94-0.99)
* denotes significantly higher asymmetry value than all other jump tests ($p < 0.05$)				
CV = coefficient of variation, ICC = intraclass correlation coefficient, CI = confidence intervals, SLCMJ = single leg countermovement jump, SLH = single leg hop, THOP = triple hop, XHOP = crossover hop, R = right, L = left, m = metres
