Abstracts of the 32nd Annual Meeting of the European Society of Human Reproduction and Embryology

Helsinki

Finland

3 to 6 July 2016

Abstracts

32nd Annual Meeting of the
European Society of
Human Reproduction and Embryology
Helsinki, Finland
3 to 6 July 2016

Print copies of the meeting abstracts are provided for Conference Delegates only. However, the abstracts are available on-line to all *Human Reproduction/Update/Molecular Human Reproduction* subscribers and are also freely available to all visitors to the following website www.humrep.oxfordjournals.org, and on the ESHRE website: www.eshre.eu

Note to the media: All abstracts are strictly embargoed until the time and date of presentation at the conference.

The opinions or views expressed in this abstracts supplement are those of the authors and do not necessarily reflect the opinions or recommendations of ESHRE. The abstracts have been reviewed by the Congress Scientific Committee and revised accordingly by the authors. The selection of abstracts is based on the scores given by an international panel of peer reviewers.

Dosages, indications and methods of use for products that are referred to in the abstracts by the authors are not necessarily appropriate for clinical use and may reflect the clinical experience of the authors or may be derived from the professional literature of other clinical sources. Because of differences between in-vitro and in-vivo systems and between laboratory animal models and clinical data in humans, in-vitro and animal data may not necessarily correlate with clinical results.

The investigators of these abstracts have stated in their submission letter that prospective studies where patients are involved have institutional Ethics Committee approval and informed patient consent, and that the studies using experimental animals have institutional approval. The Publishers have endeavoured to reproduce faithfully all of the abstracts as accepted by the Conference Organisers, but can accept no responsibility for inaccuracies or omissions caused by the late receipt of abstracts.

EUROPEAN SOCIETY OF HUMAN REPRODUCTION AND EMBRYOLOGY (ESHRE)
COMMITTEES

Executive Committee
(2015 – 2017)

Chairman
Kersti Lundin (Göteborg, Sweden)

Chairman Elect
Roy Farquharson (Liverpool, United Kingdom)

Members
Basak Balaban (Istanbul, Turkey)
Petra De Sutter (Ghent, Belgium)
Mariette Goddijn (Amsterdam, Netherlands)
Georg Griesinger (Luebeck, Germany)
Grigoris Grimbizis (Thessaloniki, Greece)

The cover of *Human Reproduction* shows histone acetylation in two human germinal vesicle (GV) stage oocytes. The upper panels show an early-stage GV oocyte with a non-surrounding nucleolus stained for (A) chromatin (DAPI; blue) and (B) histone acetylation (anti-H4K12ac; red). Note the regions of intense chromatin staining in some areas, whereas others show no acetylation (C; overlay). The lower panels, of a more developed oocyte with a surrounding nucleus stained for chromatin (D) and histone acetylation (E), show more condensed chromatin than in the early-stage oocyte (above), although the oocyte still has some acetylated chromatin as shown in E and overlay (F). For more details see van den Berg *et al.*, pp. 1181–1190.

SESSION 01: KEYNOTE SESSION

Monday 04 July 2016 **Hall 1** **08:30–09:30**

O-001 Human reproduction keynote lecture – Modifiable and non-modifiable risk factors for poor sperm morphology

A.A. Pacey[1]
[1]*University of Sheffield, Oncology and Metabolism Jessop Wing, Sheffield, UK*

Abstract text
The Chemicals and Pregnancy Study UK (CHAPS-UK) is a comprehensive investigation of >2,200 men attending 12 fertility clinics across the UK for their first semen analysis. In two papers published in Human Reproduction in 2012 and 2015, the data was used to investigate how modifiable and non-modifiable lifestyle factors were related to low motile sperm concentration (<12 million motile sperm per ml) and low sperm morphology (<4% normal forms), respectively. This is important because whilst many studies have claimed that men's lifestyle can affect semen quality, the evidence is weak with studies often underpowered and poorly controlled. The design of CHAPS-UK addresses many of these criticisms recruited eligible men, aged 18 years or above, were part of a couple who had been attempting conception without success following at least 12 months of unprotected intercourse and also had no knowledge of any semen analysis before being enrolled.

In our 2012 paper we found that risk factors for low motile sperm concentration, after adjustment for recruitment centre and confounding factors, included a history of testicular surgery [odds ratio = 2.39, 95% confidence interval (CI): 1.75, 3.28], being in manual work [odds ratio (OR) = 1.28, 95% CI: 1.07, 1.53] or not working (OR = 1.78, 95% CI: 1.22, 2.59) and having black ethnicity (OR = 1.99, 95% CI: 1.10, 3.63). Conversely, men who wore boxer shorts (OR = 0.76, 95% CI: 0.64, 0.92) or who had a previous conception (OR = 0.71, 95% CI: 0.60, 0.85) were less likely to be a case. No significant association was found with smoking and alcohol consumption, the use of recreational drugs, a high BMI or having a history of mumps or fever. By contrast, in our 2015 paper we found that risk factors for poor sperm morphology, after adjustment for centre and other risk factors, included: (i) sample production in summer (odds ratio (OR) = 1.99, 95% confidence interval (CI) 1.43–2.72); and (ii) use of cannabis in the 3 months prior to sample collection in men aged ≤30 years (OR = 1.94, 95% CI 1.05 – 3.60). Men who produced a sample after 6 days abstinence were less likely to be a case (OR = 0.64, 95% CI 0.43–0.95). No significant association was found with BMI, type of underwear, smoking or alcohol consumption, or having a history of mumps.

For both analyses, the data had been collected blind to outcome and so exposure information should not have been subject to reporting bias. This is a major strength of the study. In conclusion, both of our analyses of the CHAPS-UK data suggest that common lifestyle choices generally make little contribution to either low motile sperm concentration or low sperm morphology. Therefore, any delay to assisted conception in order to make poorly evidenced changes to lifestyle to improve semen quality is not recommended.

O-002 Long-term consequences of maternal obesity on the health of offspring

J. Eriksson[1]
[1]*Institute of Clinical Medicine, Department of General Practice and Primary Health Care Diabetes and Obesity Research Program Research Programs Unit, Helsinki Yliopisto, Finland*

Abstract text
The Developmental Origins of Health and Disease (DOHaD) hypothesis proposes that several non-communicable diseases – including coronary heart disease and type 2 diabetes – have their origins in prenatal life and in early childhood. The intrauterine *milieu* which is influenced by a large number of factors – including maternal characteristics – affects the developing fetus *via* a number of pathways resulting in the programming of future health outcomes.

Early life programming has mostly been studied in relation to long-term health outcomes in relation to being born with a small body size. However, several more recent studies have been reporting associations between maternal obesity and later health outcomes in the offspring. The prevalence of overweight and obesity are increasing worldwide and within the European Union about one-third of women of reproductive age are overweight, and every fifth is obese. Maternal obesity is associated with immediate adverse maternal and neonatal outcomes including an increased risk of congenital defects and miscarriage. Further there is increasing evidence suggesting that maternal obesity also has long-term consequences for the offspring's later health and wellbeing.

Maternal obesity in pregnancy has been associated with an increased risk of premature death in adult offspring. Further based upon findings from the Helsinki Birth Cohort Study it has been shown that higher maternal pregnancy BMI was associated with an increased risk of cancer, cardiovascular disease, and type 2 diabetes, among the offspring. The association with type 2 diabetes was stronger in women, consistent with the transmission of type 2 diabetes from the mother to her daughters being stronger than transmission to her sons.

Maternal BMI was positively associated with BMI in the offspring as expected. Higher maternal BMI was associated with less favorable body composition in the offspring. There was a significant interaction between birth weight and maternal BMI on offspring body fat percentage in adult life. In mothers with low BMI, a higher offspring birth weight was associated with lower fat percentage, while among those with maternal BMI in the highest fourth, higher offspring birth weight predicted higher body fat percentage in adult life. Our findings suggest that a disadvantageous body composition is programmed in early life, as a consequence of prenatal growth and maternal adiposity. This may in part underlie the association between maternal obesity and later cardiometabolic health in the offspring. These findings support the importance of prevention of overweight in women of childbearing age.

One plausible explanation for an association between maternal obesity, which provides adverse intrauterine experiences, and later health is in utero programming, which may work through environmental, genetic, and epigenetic mechanisms.

SELECTED ORAL COMMUNICATIONS

SESSION 02: OOCYTE HANDLING/ACTIVATION AND EMBRYO CULTURE

Monday 04 July 2016 **Hall 1** **10:00–11:30**

O-003 Influence of the duration between removal of cumulus cells and oocyte retrieval on fertilization and embryonic development

Y. Ishikawa[1], M. Inaba[1], H. Matsumoto[1], S. Mizuno[1], R. Mori[1], M. Ida[1], A. Fukuda[1], Y. Morimoto[2]
[1]*IVF Osaka Clinic, Department of Ob/Gyn, Osaka, Japan*
[2]*HORAC Grand Front Osaka Clinic, Osaka, Japan*

Study question: The aim of present study was to investigate if the timing of cumulus removal post retrieval would be a critical on fertilization and embryonic development.
Summary answer: The present study suggested sufficient time to culture oocytes with intact cumulus cells post-OPU have favorable influence on the embryonic development compared to immediate denudation.
What is known already: The role of cumulus cells surrounding oocytes in the process of maturation, ovulation, and fertilization in mouse has been extensively studied. Prolonged culture of oocyte with intact cumulus cells has been reported to induce apoptotic changes in oocytes. However, the influence of culture duration of oocyte with cumulus cells in human has not been investigated not only on competence of oocyte, but also subsequent embryonic development.
Study design, size, duration: Prospectively randomized study was performed on 667 oocytes retrieved from 54 patients (54 cycles) between October 2013 and May 2015.

Participants/materials, setting, methods: Patients under 39 year old treated by ICSI with controlled ovarian stimulation were randomly divided into 2 groups. Cumulus cells were removed immediately after oocyte retrieval in group A and were removed 120 min after retrieval in group B. ICSI was performed on all matured oocytes and they were cultured to blastocyst stage. The rates of maturation, fertilization, abnormal fertilization, blastocyst and good quality blastocyst were compared between the two groups.
Main results and the role of chance: The rates of maturation, fertilization, abnormal fertilization, and blastocyst between group A and B were 84.2 ± 13.0% vs. 88.1 ± 11.3%, 88.4 ± 10.2% vs. 88.3 ± 11.4%, 5.6 ± 7.3% vs. 4.9 ± 8.4%, 62.8 ± 30.1% vs. 73.8 ± 23.3%, respectively and no significant differences in any category. On the other hand, there was significant difference ($p < 0.05$) in good quality blastocyst rates (33.1 ± 28.4% vs. 52.0 ± 30.9%) between group A and B.
Limitations, reasons for caution: None.
Wider implications of the findings: The present study revealed that culture of oocyte with cumulus cells 2 h or longer improved the quality of resulting blastocyst. Time lag between ICSI and oocyte retrieval might be required to acquire sufficient maturation on cytoplasm of oocyte and beneficial to achieve pregnancy in IVF practice.
Trial registration number: None.

O-004 Late activation with calcium ionophore is associated with chromosome retention by the oocyte following completion of meiosis II and extrusion of the second polar body

R. Blanshard[1], C. Ottolini[2], A. Capalbo[3], S. Natesan[4], A. Handyside[4], E. Hoffmann[1]
[1]*MRC Genome Damage and Stability Centre, Life Sciences, Brighton, UK*
[2]*The Bridge Centre, London, UK*
[3]*GENERA Gynecology-Endocrinology and Assisted Reproduction, Centers for Reproductive Medicine, Rome, Italy*
[4]*Illumina, Reproductive and Genetic Health, Cambridge, UK*

Study question: Does artificial oocyte activation (AOA) with calcium ionophore affect the segregation of chromosomes in the second meiotic division (MII)?
Summary answer: Oocytes activated following a second ionophore exposure, 24 h after initial treatment, were associated with retention of both copies of one or multiple chromosomes at MII.
What is known already: Artificial oocyte activation (AOA) by exposure to calcium ionophore is being increasingly used to overcome partial or complete fertilisation failure after intracytoplasmic sperm injection (ICSI). SNP genotyping and MeioMap analysis of all three products of female meiosis, the first and second polar bodies (PB1 and PB2) and corresponding activated oocytes, has identified six different patterns of chromosome segregation errors. Recently, we used MeioMap analysis in a pilot study of activated oocytes to assess the effects of exposure to calcium ionophore A23187, and found no widespread increase in segregation errors in meiosis II.
Study design, size, duration: Maternal genomic DNA and whole genome amplified products from artificially activated oocytes together with both matching polar bodies, were genotyped for ~300,000 SNPs genome-wide. Informative maternal heterozygous SNPs were phased using a PB2 or oocyte as a reference and the two maternal haplotypes mapped (MeioMapped) in each of the samples, allowing identification of chromosome segregation errors in the first and second meiotic divisions (meiosis I and II).
Participants/materials, setting, methods: With the patients' informed consent, surplus vitrified oocytes arrested at metaphase of meiosis II were thawed and the PB1 was biopsied. The oocytes were then exposed to calcium ionophore for AOA. After resumption of meiosis and extrusion of the PB2, the PB2 was biopsied and the activated oocytes were isolated. Both polar bodies and the activated oocytes were subjected to whole-genome multiple displacement amplification and SNP genotyping by microarray.
Main results and the role of chance: Ten vitrified and thawed MII arrested oocytes from two patients were exposed to calcium ionophore A23187 for AOA. All four oocytes from one patient (maternal age 31 years) but only one out of six oocytes from the second patient (maternal age 29 years) activated and extruded the PB2. The non-activated oocytes were therefore re-exposed to the ionophore 24 h later, of which four then activated.

In the five oocytes which activated after the initial exposure to ionophore, only one chromosome segregation error was identified by MeioMapping resulting in monosomy 17 in the activated oocyte due to non-disjunction at meiosis II. An example of reverse segregation, in which both homologues segregate sister chromatids to both PB1 and oocyte, was also identified for chromosome 15 in a second oocyte; however, the two chromatids segregated normally in meiosis II.

In contrast, one of the oocytes which only activated after a second treatment with ionophore, retained both chromatids in the oocyte for 14 out of 23 pairs. Furthermore, there were five other meiosis II errors totalling 19 out of 115 pairs, all resulting in chromatid retention in the oocyte, which would not be expected by random non-disjunction events ($p = 0.0002$)
Limitations, reasons for caution: The current work is a pilot study of a small number of activated oocytes. Further work is needed to ascertain if retention of chromosomes at meiosis II is caused by repeated exposure to calcium ionophore, or whether the timing of exposure is critical.
Wider implications of the findings: MeioMapping is a powerful tool for the preclinical assessment of novel treatments which may affect human oocytes, and can accurately identify and distinguish abnormalities arising in both meiotic divisions. This is important since, in ART settings, meiosis I is normally completed *in vivo* whereas meiosis II occurs *in vitro*.
Trial registration number: RB, SN and AH (part time) are employed by Illumina (Cambridge, UK), which provided support and a studentship (RB) for the research.

O-005 A prospective randomized controlled trial investigating embryonic development and clinical outcome after using $Ca2^+$ ionophore in cases with previous fertilization arrest

E. Darwish[1], Y. Magdi[2]
[1]*Cairo, Egypt*
[2]*TopLab Co. for ART Laboratories' Consultation and Training, Research and Development, Cairo, Egypt*

Study question: Can A23187 $Ca2^+$ ionophore improve embryonic development in patients with a history of complete fertilization arrest and inability to transit to cleavage stage after ICSI?
Summary answer: In patients with previous history of complete fertilization arrest, using $Ca2^+$ ionophore activation may improve embryonic development which, in turn, may improve clinical outcome measures.
What is known already: Various studies have shown that $Ca2^+$ ionophore activation improved ICSI outcomes in cases with total fertilization failure after ICSI. However, the effect of $Ca2^+$ ionophore activation in selected cases with cleavage failure after successful fertilization was only discussed in a preliminary study that reported a beneficial effect of $Ca2^+$ ionophore activation in reaching more progressed embryonic developmental stages in four women with a history of complete fertilization arrest and inability to transit to cleavage stage during previous ICSI attempts. This study also showed one successful clinical pregnancy ends with delivery of two healthy livebirths with no malformations.
Study design, size, duration: This randomized controlled trial was carried out at a private fertility center between May 2012 and December 2015. This study included 50 ICSI cycles of patients with a history of complete fertilization arrest after conventional ICSI which were randomized into equal two groups. Patients underwent either another conventional ICSI or ICSI combined with $Ca2^+$ ionophore oocyte activation.
Participants/materials, setting, methods: All patients underwent controlled ovarian stimulation with the GnRH agonist and recombinant FSH in a long protocol. In With group, injected oocytes were cultured in 200 µL of incubated $Ca2^+$ ionophore for 15 min after ICSI. All embryo transfers were performed on Day 5. The primary outcomes are the percentage of cleaved embryos on day 3 and blastocysts on day 5. Secondary outcomes were utilization rate, pregnancy and implantation rates.
Main results and the role of chance: There were no statistical differences between Wout group and With group regarding age (30.42 ± 3.89 and 31.92 ± 3.57 years, respectively), female BMI (25.65 ± 5.05 and 25.85 ± 4.8 Kg/m, respectively), duration of infertility (7.52 ± 2.63 and 8.02 ± 2.51 years, respectively), endometrial thickness (10.2 2.09 and 9.7 ± 2.31 mm, respectively), days of stimulation (9.5 ± 0.73 and 9.7 ± 0.65 days, respectively), peak E2 (2611 ± 1279.4 and 2395 ± 1100 pg/ml, respectively), and peak P4 (0.89 ± 0.52 and 0.92 ± 0.48 ng/ml, respectively). The two groups also were similar in the number of oocyte retrieved, and the number of injected MII oocytes. Fertilization 53.23% vs. 72.56%, cleavage 31.7% vs. 82.9%, and blastocyst formation rates 22.3%

vs. 38.7% were statistically different in Wout and With groups, respectively ($p < 0.001$). ICSI cancellation rate was higher in Wout group (28%) as compared to With group (4%), ($p < 0.001$). Due to the difference in blastocyst formation rate between both groups, the mean number of transferred embryos was lower in Wout group as compared to With group. In the With group, a 41.67% clinical pregnancy rate was observed while in the Wout group only 11.1% ($p < 0.001$). Significant differences were observed between the Wout group and With group regarding Implantation rate (13.04% vs. 39.13%).

Limitations, reasons for caution: Small sample size of the study participants is due to the rarity of such cases. Larger prospective trials with an increased number of patients are needed to confirm our findings.

Wider implications of the findings: According to our results we could suggest that $Ca2^{+}$ ionophore activation may provide a useful tool to improve ICSI outcomes in a selected category of patients suffering from previous fertilization arrest after conventional ICSI. Our interesting finding offers a new area for further research.

Trial registration number: NCT02683031

O-006 Shift in pH during transition to the embryonic genome impacts embryo development

E. Adolfsson[1], M. Meintjes[1], A. Guerami[1], R. Mehta[1], K. Davidson[1], Y. Qing[1]
[1]*Frisco Institute for Reproductive Medicine, Frisco IVF, Frisco, TX, USA*

Study question: Will embryos exposed to a pHe shift during the transition to the embryonic genome develop differently?

Summary answer: The pH shift impacts embryo development. With alkaline–acid shift, the embryos develop slower than controls. With acid–alkaline shift, development is faster.

What is known already: Internal pH (pHi) of embryos is ~ 7.15. When external pH (pHe) changes, pHi of the embryo initially follows. Efforts to keep pHi stable utilizes resources. Even if embryos can survive outside the optimum pHe, quality may be impacted. Some *in vivo* measurements indicate an alkaline–acid gradient for the embryo within the female reproductive system. However, coculture experiments suggest that ciliated oviductal cells generate a relative acidic environment compared to the uterus. Therefore, this study was designed to test a pHe shift in both directions during the transition from maternal to embryonic genome, compared with a control with no shift.

Study design, size, duration: The study is performed using sibling oocytes from patients undergoing IVF/ICSI treatment. The study is ongoing. In this primary analysis a total of 150 oocytes (9 patients, age 30–35) are included. All embryos were cultured at +37°C/5% O2 in the same model incubator equipped with PrimoVision. The only variable was the CO2 concentration. The pH in experimental groups deviated ~ 0.1 from the control group (pH 7.3)

Participants/materials, setting, methods: Patient zygotes were evenly divided into 3 treatment groups: 1) Control in 6% CO_2 throughout, 2) alkaline–acid shift on day 3–5.5% to 6.5% CO_2 and 3) acid–alkaline shift on day 3–6.5% to 5.5% CO_2. Predetermined time-lapse parameters for each zygote were expressed as hours post insemination. Groups were compared using students *t*-test. Primary endpoints were the time-lapse measurements and secondary endpoint was utilization rate.

Main results and the role of chance: The analyses of the first 150 oocytes show that a pHe shift on day 3 does impact embryo development. Initially, the first cell cleavages (t1–t8) were identical between the three groups. For all parameters past the morula stage (tSB, tB, tEB) zygotes exposed to an acid–alkaline pHe shift developed at a faster rate compared with zygotes exposed to an alkaline–acid pHe shift (e.g., tEB; 110 ± 9 h vs. 120 ± 11 h; $p < 0.05$). Furthermore, after the pHe shift, the alkaline–acid group tended to develop slower ($p = 0.07$) and the acid–alkaline group appear to develop faster (not significant) when compared to the control (115 ± 11 h). Due to the progressive decrease in embryo numbers towards the end of the observation period and the initial lower number of patients in this study, *p*-values did not yet reach full statistical significance when comparing with the control. The utilization rate (number of high-quality blastocysts available for cryopreservation and/or transfer) were identical between the groups. However, the acid–alkaline shifting tended to result in proportionally more blastocysts on day 5 compared to the alkaline–acid group (77% vs. 53% blastocyst formation rate, $p = 0.09$) at this early stage of this study.

Limitations, reasons for caution: Changing the CO_2 of the incubator affects not only pHe but also the concentration of H^{+} molecules available for the molecular reactions or gene expression during maternal-zygote genome transition. The differences observed may therefore not solely be attributed to the pH *per se* but also due to the shift.

Wider implications of the findings: Despite embryos ability to adapt and maintain a stable pHi, it is likely that adaptation have consequences on quality. In this study, pH shifting during the maternal-embryo genomic transition impacts embryo development. These minor deviations, possibly mediated through pH dependent gene expression, may have long-term effects.

Trial registration number: Not applicable.

O-007 Prospective randomized study comparing human embryo development in a microwell group culture dish (Primo Vision dish) or in a standard dish with individual droplets

P. Fancsovits[1], C. Pribenszky[2], Ã. Lehner[1], Z. Kaszás[1], Ã. Murber[1], J. Rigó Jr.[1], J. Urbancsek[1]
[1]*Semmelweis University, Division of Assisited Reproduction First Department of Obstetrics and Gynecology, Budapest, Hungary*
[2]*Szent Istvan University, Department of Animal Breeding and Genetics, Faculty of Veterinary Sciences, Gödöllő, Hungary*

Study question: Does embryo culture in the microwell group culture dish improve embryo development and IVF outcome compared to individual microdrop culture in conventional Petridish.

Summary answer: Culture in microwell group culture dish (PrimoVision, Vitrolife) resulted in better fertilization rate, faster embryo development, higher clinical pregnancy rate and better embryo utilization rate.

What is known already: Embryos in human IVF treatment are frequently cultured individually in microdrops allowing individual assessment and follow-up of embryo quality. Culturing more than one embryo in the same microdrop may result in accumulation of autocrine and paracrine factors in culture media having a beneficial effect on embryo development. The microwell group culture dish (Primo Vision dish) contains 9 microwells with a well-to-well distance facilitating paracrine effects and specific well morphology facilitating autocrine effects. The design ensures identification of individual embryos cultured together in the same microdrop.

Study design, size, duration: Five hundred thirty two IVF-ET cycles were enrolled in this prospective randomized study between September 2012 and April 2015. Cycles were randomized using a computer generated table. Oocytes were fertilized by conventional IVF or ICSI. Embryos from 264 cycles were cultured in microwell group culture dish (Study Group) and 268 cycles were allocated into individual cultured (Control) group. Viable embryos were transferred or cryopreserved at cleavage stage.

Participants/materials, setting, methods: IVF cycles were randomized into Study and Control Groups. In the Study Group up to 9 embryos were cultured together in 25 µl culture media. In Control Group embryos were placed into a 25 µl droplet individually. Time-lapse morphology evaluation system was not used in this study, thus embryo development and morphology was assessed by conventional methods. Fertilization rate, embryo morphology, pregnancy rate and embryo utilization rate were compared.

Main results and the role of chance: Cycle characteristics (female age, length of stimulation, gonadotrophin dose, number of oocytes and number of transferred embryos) were similar in the two groups.

Fertilization rate in ICSI cycles – where oocytes were placed into culture dish immediately after sperm injection – was significantly higher in the Study Group compared to the Control Group (70.6% vs. 64.9%, $P = 0.001$). Fertilization rate in conventional IVF cycles was similar in the two groups. Number of blastomeres on Day 3 was also significantly higher in the Study Group compared to Control (7.0 ± 2.2 vs. 6.7 ± 2.3; $P = 0.013$). Clinical pregnancy rate was 50.8% in the Study Group and 40.6% in individual culture ($P = 0.022$). Multiple pregnancy rate was significantly higher in Study Group than in Control Group (28.5% vs. 40.5%; $P = 0.044$). Implantation rate was similar in the two groups (30.1% vs. 27.0%; $P = 0.265$).

A higher proportion of embryos was available for cryopreservation on day 3 in the Study Group (39.7% vs. 32.1%; $P = 0.024$), thus, embryo utilization rate was higher in microwell group culture compared to individual culture (81.3% vs. 74.7%; $P < 0.001$).

Morphology evaluation needed less time in the microwell group culture dish compared to conventional Petridish (144 ± 70 vs. 175 ± 73 s/cycle; $P < 0.001$) which resulted ~ 30 s shorter time outside the incubator.

Limitations, reasons for caution: The higher multiple pregnancy rate in control group reduced the difference in the implantation rate between groups. Further studies are needed to find explanation of the higher multiple pregnancy rate in the control group.
Wider implications of the findings: Using microwell group culture dish has a beneficial effect on IVF outcome and it also allows for individual assessment and following up individual embryo quality. Faster morphology evaluation means shorter time outside the incubator which decreases fluctuation of temperature and pH and also reduces the workload of the embryology laboratories.
Trial registration number: ClinicalTrials.gov: NCT01774006.

O-008 Do not disturb the embryos until day 5: preliminary results of a double blind prospective randomized controlled trial

J. Ten[1], A. Rodriguez-Arnedo[1], J. Guerrero[1], B. Moliner[2], J. Llácer[2], R. Bernabeu[2]
[1]*Instituto Bernabeu, Biology of Reproduction, Alicante, Spain*
[2]*Instituto Bernabeu, Reproductive Medicine, Alicante, Spain*

Study question: To test the hypothesis that avoiding embryo observation until day 5 may produce an improvement in embryo quality and therefore, implantation and ongoing gestation rates.
Summary answer: Maintaining the embryos to the blastocyst stage without assessment or observation on day 2 and 3 does not affect clinical outcomes.
What is known already: In a conventional *in vitro* fertilization (IVF) cycle, daily microscopic observation of embryos outside the incubator is performed to assess their morphology and establish a selection process. However, these observations can produce deleterious effects on embryo development due to environment changes: temperature, pH and osmolarity of the culture media, as well as a negative effect of direct light microscope for observation. Serial shooting by time-lapse systems could also have a negative effect.
Study design, size, duration: This is a double blind (patients and clinicians), randomized controlled trial approved by an Ethics Committee. The objective is to detect a 10% increase in pregnancy rate in the study group (non-embryonic observation, 586 cycles) compared to the control group (conventional observation on day 2 and 3, 305 cycles) in a 3-year period. We present preliminary results of 130 IVF treatments (study group, 67 and control group, 63).
Participants/materials, setting, methods: Couples enrolled in a first IVF treatment using anonymous oocyte donation. After meeting the inclusion (normal uterine cavity) and exclusion (recurrent miscarriage and repeated implantation failure) criteria, couples signed an informed consent and they were randomized in a control or study group. After checking the fertilization, zygotes were cultured in Global Total medium (LifeGlobal, Canada) in a benchtop incubator (Planer, Origio) until day 5. Blastocyst formation rate and clinical outcomes were evaluated.
Main results and the role of chance: We analysed our preliminary data. The number of donated eggs was similar in both groups (11.3 ± 2.1 in the control group and 11.1 ± 2.0 in the study group). There were no significant differences in the fertilization rate in the control group (78.4%) compared to the study group (75.0%), $p = 0.2$. In terms of the number of embryos that reach blastocyst stage on day 5, the results were also similar between the two groups (60.6% vs. 62.1% in the control and study groups, respectively, $p = 0.7$). The number of embryos transferred was 1.5 ± 0.5 in the control group and 1.4 ± 0.5 in the study group, with no significant difference ($p = 0.1$). Regarding implantation rates, embryos that were evaluated on day 2, 3 and 5, had similar implantation potential than those that were cultured until blastocyst and evaluated at this stage of development (47.4% vs. 44.0%, respectively, $p = 0.7$). Finally, the ongoing pregnancy rate (OPR) until the 28th week of gestation was similar in the two groups, with no statistical significance ($p = 0.7$). In the group of no observation, the OPR was 43.1%, and in the conventional control group, 47.5%.
Limitations, reasons for caution: The results obtained at this moment are preliminary, so we need to continue with the trial to confirm our hypothesis.

It seems that there is no negative effect on clinical outcomes when we ignore the information provided by embryos on day 2 and 3 of development.
Wider implications of the findings: One assessment of embryos on day 5 prior to transfer or freezing, gives at this time of the trial, the same clinical results as the conventional workout. This reduces the cost of the treatments and calls into question the predicting value of morphological and kinetic parameters in early embryo development.
Trial registration number: Clinicaltrials.gov: NCT02372279.

SESSION 03: ART IN THE DIFFICULT PATIENT

Monday 04 July 2016 **Hall 5 CB** **10:00–11:30**

O-009 Optimization of the ovarian reserve in Poor Responder patients by ovarian autologous transplantation of mobilized-bone marrow derived stem cells.

A. Buigues[1,2], S. Herraiz[1,2], M. Romeu[2], S. Martínez[2], P. Solves[3], L. Martínez[4], A. Pellicer[1,2]
[1]*Fundación IVI – Universidad de Valencia, Department of Pediatrics-Obstetrics and Gynecology, Valencia, Spain*
[2]*Instituto de Investigación Sanitaria La Fe, Reproductive Medicine Group, Valencia, Spain*
[3]*Hospital La Fe, Hematology Department, Valencia, Spain*
[4]*Hospital La Fe, Radiology Department, Valencia, Spain*

Study question: To evaluate if Bone marrow derived stem cell transplant (BMT) optimizes follicular recruitment in Poor Responder (PR) women and to elucidate the underlying mechanisms.
Summary answer: Forty percent of PR patients increased Antral Follicular Count (AFC) and Anti-Müllerian Hormone (AMH) being this fact associated with soluble factors already present in BMT.
What is known already: Advanced maternal age is a main cause of infertility, in fact both oocyte quantity and quality are seriously impaired in aged patients. These women are known as PR and oocyte donation is their only practical option. Previous studies suggest regenerative effects of BMT in ovarian niche of damaged ovaries and raise the possibility that dormant follicles or somatic cells may benefit from the influence of BM derived cells or soluble factors. This concept is supported by the recovery of fertility in women after BMT. Within BMT, the $CD133^+$ are the most undifferentiated population previously identified at ovaries.
Study design, size, duration: A prospective pilot study with 10 PR women was developed at University and Polytechnic Hospital La Fe between September 2014 and September 2015. Patients were considered as their own control as cells were injected in just one ovary. The contralateral ovary was considered as the control one.
Participants/materials, setting, methods: BM derived stem cells were mobilized to peripheral blood with G-CSF and isolated by apheresis. A volume of aphaeresis containing 5×10^7 $CD133^+$ cells was delivered into one ovarian artery by cathetherism. Serum AMH and AFC were monitored up to 5 months and compared to basal levels.

Soluble factors involved in growth, stem cell signalling and oocyte activation and development as well as the distribution of the stem cell populations contained in BMT were quantified.
Main results and the role of chance: An enhancement of AFC (≥3) in the treated ovary was considered as BMT primary success criteria while two consecutive increases in AMH was the secondary outcome.

BMT improved ovarian reserve function in 40% of the PR patients. Both criteria were accomplished by 30% of the recruited patients while 10% solely reached the AFC increase and 10% the AMH improvement.

Then, the association between AFC and AMH increase and the presence of soluble factors released by BM stem cells was established. Fibroblast Growth Factor-2 (FGF-2) presence in plasma was associated with the improvement in both parameters, being statistically significant for AMH ($r = 0.91$). Thrombospondin (THSP-1) concentration was positively correlated with the enhancement in AFC ($r = 0.98$) while Insulin-like Growth Factor (IGF-1) and Stem Cell Factor (SCF) secretion manifested a negative correlation with this parameter ($r = -0.883$; $r = -0.99$, respectively). Furthermore, SCF level was also associated with AMH ($r = 0.82$).

On the one hand, the $CD133^+CD34^+$ cell population has been proposed as essential to allow BM cell engraftment while the $CD133^+CD34^-$ displayed the most stemness features. Our preliminary data showed a positive influence of higher concentrations of the $CD133^+CD34^+$ cell population on BMT when assessed as AMH improvement, although being not statistically significant ($p = 0.05$).
Limitations, reasons for caution: Pilot study. Confirmation of our preliminary data on a large population should be required.

Wider implications of the findings: We found that autologous BMT using a semi-invasive and easily reproducible technique enhanced AFC and/or AMH levels in PR patients, improving their reproductive potential. This is relevant considering that nowadays oocyte donation is the only practical option for these patients that represent 9–24% of patients attending an ART clinic.
Trial registration number: [NCT02240342]

O-010 Freeze-all in older women: benefit or loss?

S. Lopez[1], K. Lattes[1], R. Vassena[2], M. Brassesco[1], V. Vernaeve[2]
[1]*Clinica CIRH, Barcelona, Spain*
[2]*Clinica Eugin, Barcelona, Spain*

Study question: Does a freeze-all strategy have an impact on reproductive outcomes in women 39 years and older?
Summary answer: A freeze-all strategy yields better clinical pregnancy rates, especially in women of 39 years and older, compared to women receiving a fresh transfer.
What is known already: Currently a freeze-all strategy, i.e., the elective freezing of all embryos from an IVF cycle and cryotransfers at a later time, is mainly employed to prevent ovarian hyperstimulation syndrome (OHSS), or in presence of an unfavorable endometrium. Older IVF patients commonly present a diminished ovarian reserve and sub-optimal oocyte quality. These women usually have their best embryos transferred during a fresh cycle and are therefore exposed to embryo-endometrium asynchrony. Since sub-optimal embryo quality cannot be amended, efforts should be directed towards providing the best endometrial environment for embryos to be transferred to, which might be achieved by a freeze-all strategy.
Study design, size, duration: Retrospective cohort study of 1,697 first embryo transfer cycles, corresponding to 1,469 women, performed between January 2013 and December 2014. Sixty-nine percent ($n = 1,180$) corresponded to fresh embryo transfers and 30.5% were frozen embryo transfer (FET) after a freeze-all strategy. Controlled ovarian hyperstimulation was performed by either a GnRH-antagonist or a long GnRH-agonist protocol. Ovulation was triggered using either a GnRH-agonist ($n = 292$) or hCG ($n = 1,405$).
Participants/materials, setting, methods: Clinical pregnancy rate and miscarriage rates were compared among first embryo transfer, either fresh (FRESH) or frozen (FROZEN). In order to study the effect of freeze-all on older women, data were stratified according to a woman age <39 ($n = 1,056$) or ≥39 years ($n = 641$). Student's *t*-test for independent samples and Chi-square analysis were used. Moreover, logistic regression analyses were performed adjusting for maternal age and number of transferred embryos. A $p < 0.05$ was considered significant.
Main results and the role of chance: Clinical pregnancy rates (CPR) were significantly higher for FROZEN in both age groups. In the <39 years group, CPR for FROZEN vs. FRESH were 44.5% and 38.2%, respectively ($p = 0.044$) and in the ≥39 years group they were 34.9% and 22.7%, respectively ($p = 0.005$). There was no difference in miscarriage rate between groups: 6.4% for FROZEN vs. 7.5% for FRESH in the younger group ($p = 0.49$) and 8.7% vs. 7.6% ($p = 0.66$), respectively, for the older group. The multivariate analysis found a significantly positive effect of performing FROZEN on CPR in both age groups, but the improvement was higher in women 39 years old (OR 1.39; 95% CI 1.07–1.81 in the younger group and OR 1.60; 95% CI 1.04–2.47 in the older group). The freeze-all strategy had no impact on miscarriage rates neither in the younger (OR 0.91; 95% CI 0.55–1.51) or the older group (OR 1.43; 95% CI 0.69–2.97).
Limitations, reasons for caution: The main limitation of our study is its retrospective nature. Further, the reasons for applying a freeze-all strategy might change with the patient age, possibly affecting results.
Wider implications of the findings: Performing a freeze-all strategy seems to yield better reproductive outcomes when compared to a fresh embryo transfer. The increase in clinical pregnancy rates is higher in women 39 years or older. Clinicians should consider a freeze-all strategy in these women in order to improve their reproductive outcomes.
Trial registration number: NA

O-011 Very young women are at risk of having a high embryo aneuploidy rate

G. Eva M.[1], B. Lledo[2], H. Blanca[2], J. Guerrero[3], J.A. Ortiz[2], R. Morales[2], J. Llacer[4], R. Bernabeu[4]
[1]*Instituto Bernabeu, Alicante, Spain*
[2]*Instituto Bernabeu, Molecular Biology, Alicante, Spain*
[3]*Instituto Bernabeu, Reproductive Biology, Alicante, Spain*
[4]*Instituto Bernabeu, Reproductive Medicine, Alicante, Spain*

Study question: Is the prevalence of embryo aneuploidy rate higher in very young women?
Summary answer: Women younger than 22 years old have a higher embryo aneuploidy rate, therefore they have an increased risk of producing chromosomally abnormal offspring.
What is known already: The embryo aneuploidies frequency is estimated to be high and its occurrence is related to maternal and paternal factors. The main factor is female age. It has been demonstrated that increased aneuploidy rates in oocytes and embryos are observed relative to increasing maternal age, in addition, implantation rates have been shown to decrease. Since the introduction of new PGS-techniques more data have been added to elucidate the age-factor effect on aneuploidies. Taking into the account that the average age of women that attend to an IVF clinic is increasing the embryo aneuploidy rate evaluation in very young women remains difficult.
Study design, size, duration: We performed a retrospective observational study (from January 2013 to December 2015). We analysed 1040 blastocyst from 376 comprehensive chromosome screening (CCS) cycles. In order to show the relationship between female age and aneuploidies and also to avoid the confounding effect of male factor 99 polar body chromosome analysis of young women was included in the study.
Participants/materials, setting, methods: PGS was performed to couples who attended with a previous clinical history of repetitive miscarriage, recurrent implantation failure or severe male factor. For PGSv2.0, polar body and trophoectoderm genome was amplified and aCGH performed using Agilent SurePrintG3 8 × 60 K. The association between variables and female age was evaluated by chi-square (SPSSv20.0).
Main results and the role of chance: Results from CCS were obtained in 97.2% of the biopsied embryos (1093/1125). Overall, the embryo aneuploidy rate was 40.6%. The initial analysis was to determine the prevalence of aneuploidy embryos according to the age of the woman. Ages of the women ranged from 19 to 45 years. As expected, the embryo aneuploidy rate increases with age following a fifth order exponential curve. The distribution was statistically significant ($p < 0.05$). The highest embryo aneuploidy rate was observed in 43 years women (83.3%). Within the younger women (<30) the highest embryo aneuploidy rate was observed at 21 years (52.2%). Subsequently, the data were stratified into groups (<21, 22–25, 26–30, >30). The prevalence of aneuploidy was the lowest between ages 22 and 25 (24.1%). Surprisingly, the embryo aneuploidy rate for women younger than 22 years was 40.0%. Statistical significance difference between embryo aneuploidy rate and age ranges was reported ($p < 0.05$). In order to prove this result avoiding confounding factors we analysed the aneuploidies of 99 polar bodies in young women, ranged from 19 to 31 years. To summarize, results were obtained in 93% of the biopsied oocytes. The polar body aneuploidy rate was 18.5%. No difference in the results of polar body aneuploidies and age was shown.
Limitations, reasons for caution: A higher sample size design should be used to corroborate the current findings. In addition, research into the mechanism of maternal aneuploidy and age is needed.
Wider implications of the findings: This investigation reveals that women younger than 22 years show a high embryo aneuploidy rate similar to patients aged 34 years. Moreover, to show this effect in polar body a higher number of analyses is need to reach significance difference.
Trial registration number: No trial.

O-012 Is fertility treatment an additional perinatal risk factor in women over 40 years old?

A. Harlev[1], I. Har-Vardi[1], E. Lunenfeld[1], A. Zeadna[1], I. Bord[1], G. Bar[1], M. Friger[1], R. Sergienko[1], E. Levitas[1]
[1]*Ben-Gurion University of the Negev, Department of Obstetrics and Gynecology, Beer – Sheva, Israel*

Study question: To compare perinatal outcomes in patients aged 40 years and older who conceive by assisted reproductive technologies as compared to patient who conceive spontaneously.
Summary answer: Older women (≥40 years) who conceived *via* ART demonstrate higher rates of pregnancy complications and adverse perinatal outcomes compared with similar women who conceived spontaneously.

What is known already: Advanced maternal age is a well-established risk factor for pregnancy complications including hypertensive disorders (gestational hypertension and pre-eclampsia), pre-gestational and gestational diabetes mellitus, and cesarean section. In addition, advanced maternal age is a risk factor for poor perinatal outcome including perinatal death, preterm delivery, and low birth weight. Assisted reproductive technologies (ART) including both ovulation induction and *in vitro* fertilization (IVF), have long been shown to be independently associated with different adverse perinatal outcome. However, it is less clear whether the mode of conception further adversely affects pregnancy outcomes in women over forty.

Study design, size, duration: A retrospective population-based study comparing pregnancy perinatal outcomes in all singleton pregnancies of women aged 40 years and older delivering at the Soroka University Medical Center between 1988 and 2014 was conducted. A comparison was performed between pregnancies conceived by IVF ($n = 130$, 1.5%), ovulation induction (OI; $n = 234$, 2.6%) and those with spontaneous pregnancies (SP, $n = 8566$, 95.9%). Data was collected from the electronic database and patients charts.

Participants/materials, setting, methods: The study population included all women (>40 years of age) who conceived a singleton pregnancy by IVF or OI and delivered during the study period. The comparison group consisted of all other women (>40) who delivered during the same time period, and conceived spontaneously. Demographic, obstetrical and perinatal data were compared. Multiple regression models were constructed to define independent predictors of adverse perinatal outcome. A p value of <0.05 was considered statistically significant.

Main results and the role of chance: Women in the IVF group were significantly older as compared to OI and SP ($p < 0.001$). Gestational age at delivery was significantly lower in IVF pregnancies (37.2 ± 2.48) compared to OI (37.6 ± 2.29) and SP (38.7 ± 2.49, $p < 0.001$). Pre-eclampsia and gestational diabetes mellitus demonstrated a linear association to conception mode with highest rates in IVF pregnancies and gradually lower in OI and SP. Similarly, higher rates of preterm labor (both <37 weeks and <34 weeks)) were observed in IVF pregnancies compared to OI and SP ($p < 0.001$). Cesarean section rate was significantly higher in IVF pregnancies compared to OI and SP (74.6%, 70.1%, 26.5%, respectively, $p < 0.001$). IVF pregnancies resulted in significantly higher rates of low birth weight (<2500 gr), very low birth weight (<1500 gr), intra-uterine growth restriction, and breech presentation (all $p \leq 0.001$). No association between conception methods and perinatal mortality was observed in both the uni- and multivariate analyses. However, in a multivariate model constructed for prediction of preterm delivery (controlling for maternal age, diabetes, and pre-eclampsia) both IVF and OI demonstrated a significant independent association (OR 3.2, 2.0, respectively, $p < 0.001$). The same was found for growth restriction with an OR of 5.8 for IVF and of 2.0 for OI.

Limitations, reasons for caution: The study is a retrospective population based study with its inherited limitation.

Wider implications of the findings: An increased risk for pregnancy complications and adverse perinatal outcome in pregnancies conceived following assisted reproductive techniques was observed. Pregnancies conceived following IVF treatments are at a higher risk compared with these conceived *via* ovulation induction and spontaneous pregnancies.

Trial registration number: The study is retrospective hence registration was not required. The study was approved by the local IRB committee.

O-013 Predictive value of very low levels of serum Anti-Mã1/4llerian hormone for pregnancy rate

A. Pacheco Castro[1], M. Cruz[2], R. Ferrando[3], C. Iglesias[2], J.A. Garca-Velasco[4]
[1]*IVI Madrid, Andrology, Madrid, Spain*
[2]*IVI Madrid, Reproductive medicine, Madrid, Spain*
[3]*IVI Valencia, Reproductive medicine, Valencia, Spain*
[4]*IVI Madrid, Reproductive medicine, IVI Madrid clinic Director, Rey Juan Carlos University Professor, Madrid, Spain*

Study question: Are serum Anti-Müllerian hormone (AMH) levels a predictor of pregnancy rate?

Summary answer: Serum AMH levels are not predictive of clinical pregnancy rate. Indeed, patients with very low AMH levels have slightly diminished but acceptable pregnancy rate.

What is known already: AMH is an established marker of ovarian reserve and it is strongly correlated with female age. There is no doubt about a positive correlation between serum AMH levels and ovarian response. However, there is no consensus about low AMH values to either recommend or not undergoing ovarian stimulation to infertile patients.

Study design, size, duration: Retrospective, cohort study. This study includes 5570 ICSI cycles performed between 2008 and 2014 Patients were classified in 6 groups according to the serum AMH levels: ≤0.21 ng/ml (Group-I), 0.22–0.8 ng/ml (G-II), 0.81–1.7 ng/ml (G-III), 1.71–3.2 ng/ml (G-IV), 3.21–5.39 ng/ml (G-V) and ≥5.40 ng/ml (G-VI).

Participants/materials, setting, methods: University-affiliated infertility clinic. AMH serum levels were determined in duplicate by using a commercial ELISA kit (Gen-II, Beckman). Data on age, BMI, years of infertility and AFC were collected. Cycles were performed after controlled ovarian stimulation, and for each cycle dose of gonadotropins, duration of stimulation, number of obtained follicles, estradiol serum levels the day of trigger, and clinical results after embryo transfer were recorded. All variables were statistically analyzed by using the SPSS software.

Main results and the role of chance: Strong significant differences in female age (from 39.2 ± 0.3 in G-I to 35.7 ± 0.4 in G-VI), AFC (from 1.93 ± 0.2 in G-I to 6.35 ± 1.1 in G-VI), FSH dose (from 1606 ± 95 in G-I to 1392 ± 53 in G-VI), oocytes retrieved (from 2.9 ± 0.3 in G-I to 14.0 ± 2.0 in G-VI) and mature oocytes (from 2.9 ± 0.3 in G-I to 14.0 ± 2.0 in G-VI) were found between groups. By contrast, the years of sterility, BMI and days of stimulation were similar in all the groups.

Regarding clinical results, neither implantation rates (28.9% in G-I, 25% in G-II, 29% in G-III, 28.8% in G-IV, 30.5% in G-V and 35.3% in G-VI) nor abortion rate (27.9%, 26.8%, 31%, 28.8%, 25.7% and 22.1%, respectively) showed significant differences between groups. Although clinical pregnancy rates were significantly different in the groups, the very low serum AMH level group retained a significant chance of reproductive outcome (45.3%, 48.1%, 47.4%, 45.2%, 48.0% and 54.1%, respectively). However, ROC curve showed no predictive value of AMH related to clinical pregnancy.

Limitations, reasons for caution: Due to the retrospective design, we cannot rule out patients with very low AMH levels that decided not to do ovulation stimulation. Thus, prospective validation is required.

Wider implications of the findings: Serum AMH levels are closely related to female age and it is a very robust marker of ovarian reserve and ovarian response to gonadotropins. By contrast, it has no predictive value for clinical pregnancy, and even patients with very low serum AMH levels still have a reasonable reproductive outcome.

Trial registration number: Not applicable

O-014 Perinatal outcomes following oocyte donation versus autologous IVF: analysis of 99,111 singleton live births

M. Kamath[1], B. Antonisamy[2], S.K. Sunkara[3]
[1]*Christian Medical College and Hospital, Reproductive Medicine, Vellore, India*
[2]*Christian Medical College and Hospital, Department of Biostatistics, Vellore, India*
[3]*Queens Hospital, Barking Havering and Redbridge University Hospitals, Gynaecology and Reproductive Medicine, Essex, UK*

Study question: Does oocyte donation influence perinatal outcomes of preterm birth (PTB) and low birth weight (LBW) compared to autologous IVF treatment.

Summary answer: There was an increased risk of adverse perinatal outcomes of PTB and LBW following oocyte donation compared to autologous IVF treatment.

What is known already: There has been an increasing burden of poor ovarian response following IVF attributed to women delaying childbearing and consequently women of advanced age seeking IVF. However, little information is available regarding maternal or infant outcomes following oocyte donation. There is a higher risk of pregnancy complications following assisted reproductive treatments (ART) compared to spontaneously conceived pregnancies attributed to the underlying infertility itself or embryo specific epigenetic modifications due to the *in vitro* fertilisation techniques. It is a matter of interest if oocyte donation influences obstetric outcomes and whether use of donor oocytes affects perinatal outcomes compared to pregnancies following autologous IVF.

Study design, size, duration: Anonymous data were obtained from the Human Fertilization and Embryology Authority (HFEA), the statutory regulator of

assisted reproduction treatment (ART) in the UK. The HFEA has collected data prospectively on all ART performed in the UK since 1991. Data from 1991 to 2011 involving a total of 524,489 fresh oocyte donor and autologous IVF cycles resulting in 99,111 singleton live births were analysed.
Participants/materials, setting, methods: Data from all women who underwent either fresh donor oocyte or autologous IVF cycles during the study period were analysed to compare perinatal outcomes of PTB, early PTB, LBW and very LBW following singleton live births. Logistic regression analysis was performed adjusting for female age category, year of treatment, number of previous IVF cycles, type of infertility, causes of infertility, number of oocytes retrieved and initial multiple vs. singleton gestation leading to singleton live birth.
Main results and the role of chance: The unadjusted odds of PTB (OR 2.24, 95% CI 1.71 to 2.93), early PTB (OR 1.97, 95% CI 1.13 to 3.44), LBW (OR 1.98, 95% CI 1.50 to 2.63) and very LBW (OR 1.60, 95% CI 1.15 to 3.0) were significantly higher with donor oocyte compared to autologous IVF. There was a significant increase in the risk of adverse perinatal outcomes of PTB and LBW following oocyte donation after adjusting for potential confounders such as female age category, treatment period, previous IVF cycles, type of infertility, cause of infertility, number of oocytes retrieved and initial multiple vs. singleton pregnancy leading to singleton live birth: PTB adjusted odds ratio (aOR) 2.29, 95% CI 1.73 to 3.03 and LBW aOR 2.0, 95% CI 1.50 to 2.69. The aOR for early PTB was 1.63, 95% CI 0.91 to 2.91 and aOR for very LBW was 1.29, 95% CI 0.67 to 2.49.
Limitations, reasons for caution: Although the analysis was adjusted for a number of important confounders, the dataset had no information on confounders such as smoking, body mass index (BMI) and the medical history of women during pregnancy to allow adjustment.
Wider implications of the findings: Analysis of this large dataset suggests that there is increased risk of PTB and LBW following oocyte donation. This information is useful to counsel women and for clinicians managing pregnancies resulting from oocyte donation IVF.
Trial registration number: not applicable

O-015 Prediction model for live birth in intracytoplasmic sperm injection using testicular extracted sperm

L. Ramos[1], A. Meijerink[1], M. Cissen[2], M. Mochtar[3], K. Fleischer[1], I. Thoonen[1], A. de Melker[3], A. Meissner[3], S. Repping[3], M. vd Wely[3], D. Braat[1]
[1]Radboud University Medical Center, Obst. & Gynecology. Div. Reproductive Medicine intern 791, Nijmegen, Netherlands
[2]Jeroen Bosch Hospital, Department of Obstetrics and Gynaecology, 's Hertongenbosch, Netherlands
[3]Academic Medical Center, Center for Reproductive Medicine, Department of Obstetrics and Gynaecology, Amsterdam, Netherlands

Study question: Which parameters have a predictive value for live birth in couples undergoing intracytoplasmic sperm injection using testicular extracted sperm (TESE-ICSI)?
Summary answer: Female age, a first or subsequent cycle, male luteinising hormone, male testosterone, sperm motility and the initial aetiology of azoospermia were relevant predicting parameters.
What is known already: In reproductive medicine prediction models are used to predict treatment success, but no prediction model currently exists for live birth after TESE-ICSI.
Study design, size, duration: A retrospective cohort study between 2007 and 2015 in two academic hospitals including 1559 TESE-ICSI cycles. The prediction model was developed using data from one centre and validation was performed with data from the other centre.
Participants/materials, setting, methods: All couples undergoing TESE-ICSI treatment for the first time. In the development set, we included 526 couples undergoing 1006 TESE-ICSI cycles. We included 289 couples undergoing 553 TESE-ICSI cycles in the validation set. Multivariable logistic regression models were constructed in a stepwise fashion ($p < 0.2$ for entry). The external validation was based on discrimination and calibration.
Main results and the role of chance: A total of 224 couples (22.3%) with a live birth in the development set were included. The occurrence of a live birth was associated with lower female age, first TESE-ICSI cycle, lower male LH, higher male testosterone, the use of motile spermatozoa for ICSI and having obstructive azoospermia as an initial aetiology of azoospermia. The area under the receiver operating characteristic (ROC) curve was 0.62. From validation data, the model had moderate discriminative capacity (c-statistic 0.67, 95% confidence interval: 0.62–0.72) but calibrated well, with a range from 0.06 to 0.56 in calculated probabilities.
Limitations, reasons for caution: Data about the motility of spermatozoa during TESE is lacking. Therefore, we used data about the motility of the spermatozoa used for ICSI after freeze–thawing. In counselling before start of ICSI treatment, those two options (motile spermatozoa available for ICSI or not) should be taken into account.
Wider implications of the findings: This model enables the differentiation between couples with low and couples with high chance to reach a live birth using TESE-ICSI. As such it can help counselling patients and in clinical decision making.
Trial registration number: Not applicable.

O-016 Prediction model for obtaining spermatozoa with TESE in men with non-obstructive azoospermia

M. Cissen[1], A. Meijerink[2], K. d'Hauwers[3], A. Meissner[4], N. van der Weide[5], M. Mochtar[5], A. de Melker[5], L. Ramos[2], S. Repping[5], D. Braat[2], K. Fleischer[2], M. van Wely[5]

[2]Radboud university medical center, Obstetrics and Gynaecology, Nijmegen, Netherlands
[3]Radboud university medical center, Urology, Nijmegen, Netherlands
[4]Academic Medical Center, Urology, Amsterdam, Netherlands
[5]Academic Medical Center, Obstetrics and Gynaecology, Amsterdam, Netherlands

Study question: Can we build a prediction model for successful testicular sperm extraction in men with non-obstructive azoospermia and will the model be accurate after external validation?
Summary answer: Our prediction model including six variables was able to predict the chance of obtaining spermatozoa with TESE.
What is known already: Only a few models have been developed that predict the chance of obtaining spermatozoa with TESE, and none of them have been validated externally.
Study design, size, duration: We performed a prospective nationwide cohort study. Data of 1371 TESE procedures were collected between June 2007 and June 2015 in the fertility centres of the Radboud university medical center in Nijmegen and the Academic Medical Center in Amsterdam.
Participants/materials, setting, methods: All men with NOA undergoing their first TESE procedure were included. Primary endpoint was the presence of spermatozoa in the testicular biopsies. We constructed a model for the prediction of successful sperm retrieval, using univariable and multivariable binary logistic regression analysis and the dataset from one centre. This model was then validated using the dataset from the other centre. The area under receiver operating characteristic curve was calculated and model calibration was assessed.
Main results and the role of chance: There were 599 (43.7%) successful sperm retrievals after a first TESE procedure. The prediction model, build after multivariable logistic regression analysis, demonstrated that higher male age, higher levels of serum testosterone and lower levels of FSH and LH were predictive for successful sperm retrieval. Diagnosis of idiopathic NOA and an AZF-c deletion were predictive for unsuccessful sperm retrieval. The area under the curve was 0.69 (95% CI: 0.66 to 0.72). The difference between the mean observed chance and the mean predicted chance was less than 2.0% in all groups, indicating good calibration. In external validation, the model had moderate discriminative capacity (area under the curve 0.65, 95% CI: 0.62 to 0.72) and moderate calibration, the predicted probability never differed more than 9.2% of the mean observed probability.
Limitations, reasons for caution: This model is limited to use prior to the first TESE procedure only.

Wider implications of the findings: This model can help in clinical decision making in men with NOA by reliably predicting the chance of obtaining spermatozoa with TESE.
Trial registration number: Not applicable

O-017 Meaning of DNA fragmentation in relation to the sperm source and ART outcome

T. Paniza[1], T. Cozzubbo[1], S. Chow[1], S. Cheung[1], Q.V. Neri[1], M. Goldstein[2], Z. Rosenwaks[1], G.D. Palermo[1]
[1]Weill Cornell Medicine, Reproductive Medicine, New York, NY, USA
[2]Weill Cornell Medicine, Urology, New York, NY, USA

Study question: We question whether sperm chromatin integrity differs among spermatozoa isolated from different sections of the male genital tract and how it affects reproductive outcome.
Summary answer: Progression through the male genital tract increases chances for oxidative aggression and consequent sperm chromatin fragmentation (SCF), this may be obviated by utilizing testicular spermatozoa.
What is known already: During the later stages of spermiogenesis DNA breakage is physiologically induced to allow tight chromatin compaction. While most spermatozoa undergo DNA repair, additional reactive oxygen species (ROS) are the main cause for DNA injury. The buffering capacity of seminal antioxidants is the only agent protecting the DNA integrity of spermatozoa in the ejaculate. Therefore, retrieving spermatozoa from the epididymis or testis may bypass such an insult on the chromatin.
Study design, size, duration: Over 27 months, men with extremely high SCF in their ejaculates ($n = 64$) underwent surgical sampling, often bilateral, from vas deferens, epididymis, and testis. SCF was assessed by terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) and clinical outcome was recorded for each sperm source for men undergoing ICSI.
Participants/materials, setting, methods: Ejaculates processed in standard fashion were assessed for SCF by TUNEL. Surgical samples were minced and smeared for SCF evaluation and were cryopreserved for later use with ICSI. DNA fragmentation was measured by TUNEL on specimens isolated from all sites. TUNEL was assessed utilizing a commercial kit (In Situ Cell Death Detection Kit, Roche). At least 500 spermatozoa were evaluated per site under fluorescent microscopy with an adopted threshold of 15%.
Main results and the role of chance: Of the original 64 patients, 51 were treated by ART with an average SCF of 31.0 ± 19% (range 26.0–96.0). In 9 men aspiration of the vas deferens resulted in 16.7 ± 8% SCF (range 5.8–30.0) while in 32 men epididymal sampling yielded 17.3 ± 8% SCF (range 7.0–34.8) and in 64 the SCF on testicular spermatozoa was 12.3 ± 6% (range 2.0–27.0). The SCF progressively decreased as TUNEL was performed proximally from the ejaculate toward the vas deferens ($P = 0.05$), the epididymis ($P = 0.01$), and testis ($P = 0.01$). ART outcome with ICSI utilizing these surgical sources yielded a clinical pregnancy of 26.7%, while with the ejaculated counterpart only 14.6%. Based on these preliminary findings a subgroup of patients ($n = 19$), with SCF of 40.1 ± 18 bypassed the prerequisite cycle with ejaculated spermatozoa. By opting to directly undergo TESE with ICSI a clinical pregnancy rate of 29.0% per cycle was achieved that translated to 55.6% per couple treated.
Limitations, reasons for caution: Patients need to be informed of risks regarding surgery, anesthesia, and be aware that even with surgical spermatozoa a pregnancy may not occur. Thus, engaging counseling should be conducted since many of these men have spermatozoa in their ejaculate. These data are still preliminary and require an evidence-based consensus.
Wider implications of the findings: DNA integrity assessment on the spermatozoa isolated at different levels of the male genital tract evidenced that oxidative stressors progressively compromise DNA integrity toward the ejaculate. Couples unable to achieve a pregnancy using ejaculated spermatozoa with compromised DNA may benefit from undergoing testicular retrieval for diagnostic and therapeutic purposes.
Trial registration number: N/A

O-018 Parameters predicting successful sperm retrieval in men with non-obstructive azospermia undergoing primary and repeated microdissection testicular sperm extraction

M.M. Basar[1], A.P. Cil[2], S. Selimoglu[3], Y. Kumtepe-Colakoglu[4], S. Kahraman[2]
[1]Memorial Sisli Hospital, Urology and Andrology, Istanbul, Turkey
[2]Memorial Sisli Hospital, ART and Reproductive Genetics, Istanbul, Turkey
[3]Memorial Sisli Hospital, ART and Reproductive Genetics-Andrology Laboratory, Istanbul, Turkey
[4]Memorial Sisli Hospital, ART and Reproductive Genetics-Embriology Laboratory, Istanbul, Turkey

Study question: What are the predictive parameters for the microdissection testicular sperm extraction (m-TESE) outcome in men with non-obstructive azoospermia (NOA) undergoing primary and repeated m-TESE
Summary answer: Prior unsuccessful m-TESE and low testicular volume were the significant negative predictors in repeated m-TESE cases but there were none for primary cases.
What is known already: M-TESE is the recommended method for sperm retrieval and the sperm retrieval rate is around 50% in primary m-TESE cases. Chromosome Y microdeletion is the only prognostic parameter useful in predicting m-TESE outcome but we still need other predictive factors. There are a limited number of studies which have evaluated preoperative parameters predicting m-TESE success. One of these studies concluded that history of Klinefelter Syndrome and orchiopexy are the most significant predictors, whereas the other suggested inhibin-B levels to be predictive of m-TESE outcome.
Study design, size, duration: A total of 518 men with NOA undergoing primary ($n = 225$) and repeated ($n = 293$) m-TESE procedures between October 2011 and September 2015 were evaluated retrospectively. Serum hormone levels (gonadotropins, total testosterone, estradiol and Inhibin-B), genetic investigations as well as detailed physical examinations were done. If the patients had hyper/hypogonadotropic hypogonadism, hyperprolactinemia, Testosterone/E2 ratio less than 0.10 in addition to having previous unsuccessful m-TESE operation, medical treatment was offerred for 5–6 months.
Participants/materials, setting, methods: Parameters such as age, total testicular volume (TTV), hormone levels before and after treatment, and previous m-TESE results were compared between men with successful and unsuccessful m-TESE within the primary and repeated m-TESE groups. A multivariate logistic regression analysis was used to determine the independent parameters correlated with m-TESE outcome for each group.
Main results and the role of chance: Overall sperm retrieval rate (SRR) was 44.8%, of which the ratio was 43.6% in primary and 45.7% in repeated m-TeSe groups. Age (33.6 vs. 36.2) and E2 levels (29.2 vs. 34.2) were significantly different between primary and repeated m-TESE groups. Age was positively and E2 levels were negatively correlated with the increasing number of prior m-TESE. All of the parameters were similar between patients with successful and unsuccessful m-TESE in primary micro-TESE group, whereas patients in repeated m-TESE group with successful outcome were older, had significantly higher TTV and 84.7% of the patients had prior successful m-TESE ($p < 0.001$) (Table1). After multivariate logistic regression analysis, higher TTV and prior successful m-TESE were correlated with successful m-TESE outcome in repeated m-TESE group, but age did not. However, none of the parameters were predictive of the successful m-TESE outcome in primary m-TESE group.
Limitations, reasons for caution: We did not find Inhibin B as a significant predictor of m-TESE outcome in contrast to a prior study. This might be due to the limited number of serum Inhibin B measurements in our study population. Therefore, importance of this hormone needs further evaluation especially for primary m-TESE cases.
Wider implications of the findings: This is the first study evaluating parameters predictive of TESE outcome in both primary and repeated m-TESE cases. According to our results patients with prior failed m-TESE and low TTV showing testicular atrophy due to testicular tissue damage should be councelled regarding the decreased chances of success after repeated procedures.
Trial registration number: None

O-019 Clinical freeze preservation of whole human testicular tissue: the practicality of pre-freeze *in vitro* culture (IVC) at 30Â°C to insure good post-thaw sperm motility

C. Rothman[1], C.A. Sims[2], M.C. Schiewe[2]
[1]California Cryobank, Los Angeles, CA, USA
[2]California Cryobank, R&D Lab, Los Angeles, CA, USA

Study question: Can testicular tissue be processed in a simplistic and effective manner that promotes progressive sperm motility to enhance and optimize overt post-thaw sperm viability?

Summary answer: The cryopreservation of small testicular tubular masses following extended IVC (48–96 h) effectively stimulated pre-freeze and post-thaw sperm motility while reducing technician processing time and labor.
What is known already: Frozen-thawed testicular sperm has been effectively used for two decades, resulting in live births rates similar to fresh testis sperm. It has been shown that the use of intermediate temperature conditions (30°C ± 2°C) can promote and extend the motility potential of immature testicular sperm, whereas 21°C IVC conditions fail to optimize motility potential (% and progression) and 37°C maximizes metabolic activity which reduces longevity. IVC itself, as well as effective cryopreservation, reduces the urgency to synchronize surgical procedures (i.e., testicular biopsies and oocyte retrievals). Meanwhile, the ease of handling whole tissue masses minimizes the time and labor of processing.
Study design, size, duration: Over a 24 month interval between 2014 and 2015, 40 adult men (24–62 years old) were scheduled to have testicular tissue frozen for possible future ICSI use. A retrospective analysis was performed to demonstrate the efficacy of our whole tissue freeze preservation/IVC methodology for cryobanking purposes. We assessed sperm motility patterns for up to 1 week and compared pre-freeze and post-thaw total and progressive sperm motility patterns, contrasting differences by ANOVA ($p < 0.05$).
Participants/materials, setting, methods: Surgically recovered testicular tissue was transported to the lab in sperm wash medium under insulated ambient conditions. Needle dissected, small tubular masses were placed into individual cryovials (0.5 ml medium), or a test piece was shred and cultured under oil in a heated Styrofoam box (30°C ± 1°C), along with the vials. Upon daily assessments of motility (I = twitching to IV = rapid progression), when greater than 10–20% progressive motility was attained, samples were frozen. Test thaws were performed/evaluated at +3 h.
Main results and the role of chance: Testicular tissue freeze preservation services were provided to men scheduled for either a Vasovasostomy surgery ($n = 32$, 84%) or to assist NOA/Anejaculatory Cancer patients ($n = 8$). Only two of the latter NOA patients failed to yield sperm, thus 95% of the clients had tissue cryopreserved. Total and progressive motility significantly elevated by +48 h IVC (46.8% and 12.4%) compared to 26.4% and 5.2% at +3 h and 32.5% and 5% at +24 h, respectively. Total motility peaked at +96 h (52.1%), while progression elevated ($p < 0.05$) to 20.3% and 24.5% by +96 and 120 h, respectively, and remained high at +168 h (20+%). Mean pre-freeze total and progressive sperm motilities declined ($p < 0.05$) from 44.4% ± 2.0% SE and 13.3% to 32.1% ± 2.2 and 6.7%, respectively, post-thaw. The reduced motility recovery rate of both total (73%) of progressive (50%) movements, are generally lessened by additional overnight IVC considering the median pre-freeze IVC interval was +72 h. The motility patterns of pre-freeze/equilibrated (3 h, 37°C), post-thaw samples were: I = 18.7%/17%; II = 12.8%/8.4%; 9.6%/5.1%; and IV = 3.7%/1.6%, respectively. Overall, excellent conservation of sperm viability was achieved, with minimal pre-freeze processing, by cryopreserving whole testicular tissue pieces in a 13.4% glycerol solution and five equal mixed dilutions.
Limitations, reasons for caution: Testicular freeze-preservation of Vasovasotomy patients is essentially an insurance policy to prevent a possible second surgery in case the reversal fails to be effective and future IVF treatment is required. Any concerns regarding IVC- or cryo-related reactive oxidative stress DNA fragmentation have been proven negligible (Schiewe et al., 2016).
Wider implications of the findings: Whole testicular tissue freezing following IVC promoting motility enhancement has proven be a highly effective, while minimizing excessive and laborious processing procedures. The availability of overtly motile sperm, simplifies valuable Embryology time to isolate viable sperm to ICSI oocytes in a timely manner.

O-020 Choosing the appropriate insemination method according to sperm DNA fragmentation level

S. Chow[1], T. Paniza[1], T. Cozzubbo[1], S. Cheung[1], Q.V. Neri[1], M. Goldstein[2], Z. Rosenwaks[1], G.D. Palermo[1]
[1]*Weill Cornell Medicine, Reproductive Medicine, New York, NY, USA*
[2]*Weill Cornell Medicine, Urology, New York, NY, USA*

Study question: We question if sperm chromatin fragmentation (SCF) can guide toward the appropriate ART method in couples with idiopathic infertility and history of poor IUI outcome.
Summary answer: This study provides a DNA fragmentation-based algorithm that allows appropriate allocation of resources and guides patients towards the appropriate infertility treatment.
What is known already: During the later stages of spermiogenesis DNA breakages are physiologically induced to allow tight chromatin compaction and only those spermatozoa with repaired chromatin reach the ejaculate. Throughout the male genital tract oxygen-free radicals, mostly from decaying spermatozoa and other cells, are the main cause of DNA damage and responsible for the impaired ART outcome. Therefore, in men with adequate semen parameters but poor reproductive outcome, a SCF assessment may guide towards the most effective ART treatment.
Study design, size, duration: Over a 27-month period, couples were allocated to the appropriate ART treatment according to the level of SCF. The clinical pregnancy rate was evaluated according to SCF cohort and in the relation to each insemination method.
Participants/materials, setting, methods: Infertile couples ($n = 551$) underwent standard semen analysis according to WHO criteria (2010) and resulted in adequate semen parameters for IUI and ART. Couples that failed IUI were then screened for chromatin fragmentation by TUNEL and/or SCSA® on their ejaculates. In-house TUNEL assessment evaluates 500 spermatozoa under fluorescent microscopy and patients were only deemed abnormal when sperm DFI reached ≥15%. SCSA® assessment was performed by an external laboratory and analyzes 5000 spermatozoa (abnormal >25%).
Main results and the role of chance: A total of 551 couples underwent 1363 cycles and included women with an average age of 37.7 ± 4 years and men with a mean age of 39.8 ± 5 years. The overall average sperm concentration was 50.0 ± 29 million with a motility of 49.9 ± 14% and morphology of 3.1 ± 2%. Based on the control, we expect an intrauterine insemination (IUI) clinical pregnancy rate of 17.9%, but the study cohort evidenced a clinical pregnancy rate of just 3.4%. The patients from this cohort presented a TUNEL of 26.1 ± 18% and SCSA DFI of 39.5 ± 26%. Men with normal SCF were subsequently treated by *in vitro* insemination and reported a pregnancy rate of 22.1%. Once we controlled for an eventual confounding female factor (female age ≤35 years), a remarkably higher pregnancy rate of 36.8% ($P < 0.001$) was reached. On the other hand, couples with abnormal DFI were treated exclusively by ICSI also yielding a higher pregnancy rate at 21.7%, and 28.9% with females 35 years old ($P < 0.001$). For those patients that failed ICSI with ejaculated spermatozoa, we offered a testicular sampling. In 38 couples that consented, the SCF of testicular spermatozoa was 12.3 ± 6%, remarkably lower than 39% SCF in the ejaculate, and a pregnancy rate of 26.7% ($P < 0.001$).
Limitations, reasons for caution: Patients need to be informed of risks regarding surgery, anesthesia, and the possibility that even with TESE a pregnancy may not occur. Thus, engaging counseling should be conducted since these men have spermatozoa in their ejaculate. These data are still preliminary and a clinical consensus has not been reached.
Wider implications of the findings: IVF is successful in men with intact sperm chromatin. When sperm SCF is compromised in the ejaculate, ICSI is the most suitable insemination method. In men with high DNA fragmentation in their ejaculate and pursuant pregnancy failure, surgical sampling yields spermatozoa with lower SCF and higher changes of pregnancy.

Monday 04 July 2016 **Hall 3 AB** **10:00–11:30**

O-021 Genome-wide DNA methylation and mRNA expression profiling in eutopic endometrium, disease tissue and fat: implications for endometriosis research

N. Rahmioglu[1], A. Drong[1], H. Lockstone[1], C. Lindgren[1], C. Becker[2], K. Zondervan[3]
[1]*University of Oxford, Wellcome Trust Centre for Human Genetics, Oxford, UK*
[2]*University of Oxford, Nuffield Department of Obstetrics and Gynaecology & Endometriosis Care Centre, Oxford, UK*

[3]University of Oxford, Wellcome Trust Centre for Human Genetics & Nuffield Department of Obstetrics and Gynaecology & Endometriosis Care Centre, Oxford, UK

Study question: What implications does variability in transcriptomic/epigenomic profiles in whole tissues relevant to endometriosis have for "omics" study designs?
Summary answer: Inter-individual variation is greater than intra-tissue and technical variability in all three tissues, and we identify menstrual phase as the strongest covariate.
What is known already: Of the nine genetic loci associated with endometriosis, most are intergenic with unclear functional roles. Integrated analysis of genomic with transcriptomic and epigenomic data can help identify biological-pathways perturbed by these genetic variants. Studies in other disease areas have shown that these investigations need to be conducted in tissue relevant to disease. For endometriosis this is endometrium, which is not included in large profiling initiatives such as GTex and NIH-Epigenome-Roadmap. However, the utility of tissue-based profiling for endometrium requires further exploring, as it is a heterogeneous tissue composed mainly of glandular epithelial and stromal cells subject to cyclic endocrine influences.
Study design, size, duration: The prospective ENDOX study recruits women undergoing laparoscopy for symptoms suggestive of endometriosis or tubal sterilisation. Twenty-four women (8 endometrioma cases; 8 with peritoneal endometriosis; 8 controls) provided 48 tissue samples using WERF EPHect protocols (16 eutopic and 16 ectopic endometrium, 16 subcutaneous adipose tissue).
Participants/materials, setting, methods: Subjects were not using hormones in the previous 3 months and had regular cycles; controls were frequency-matched to cases on menstrual phase. Tissues were split for DNA vs. RNA extraction. In each extraction arm, the 32 eutopic and ectopic endometrium and 8/16 adipose tissue samples were split prior to extraction; 10% of samples were analysed in duplicate. DNA and RNA samples (n = 96 each) were analysed using Illumina 450Kmethylation and H12 expression arrays, respectively.
Main results and the role of chance: Hierarchical-cluster-analysis showed distinct methylation profiles per tissue type; peritoneal-disease-tissue and endometrioma samples also clustered distinctly, suggesting different methylation signatures. Intra-tissue variability was investigated through analysis of split samples of the same tissue, while technical variation was assessed through replicates. The principal-component-analysis demonstrated that the inter-individual (biological and environmental) variation was greater than intra-tissue (cellular heterogeneity) and technical (experimental) variation in all three tissues. This was supported by variance-component-analysis of the top 10% most variable methylation probes, which showed that inter-individual variance explained the majority of the overall methylation variance. Menstrual phase was the covariate most significantly correlated with methylation patterns in eutopic endometrium and fat, but not in ectopic endometrium. Smoking showed a strong correlation with methylation profiles of fat and ectopic disease tissue. Analysis of the eutopic endometrium gene expression data supported the findings of greater inter-individual variation compared with intra-tissue and technical variation, while menstrual phase was also the most important covariate. Power calculations showed that to have 80% power for detection of differentially methylated/expressed variants with effect size >0.4, minimum 500 tissue samples are required. As an outset, differential expression analysis adjusted by menstrual phase between cases and controls identified 3 loci with fold change expression >4.
Limitations, reasons for caution: This a pilot study performed to test parameters affecting tissue profiling variability and their implication for larger study designs. Due to the size of the study, the effects of more subtle covariates would not have been detected. Any significant differential expression/methylation result need to be replicated in a larger study.
Wider implications of the findings: This is the first study investigated tissue expression and methylation profiling variability in tissues relevant to endometriosis. These results enable appropriate study design of future large-scale collaborative studies.
Trial registration number: N/A

O-022 Co-expression of the estrogen receptor beta splice variant isoform 5 (ERÃŸ5) with estrogen receptor alpha selectively augments estrogen responsiveness of endometrial epithelial cells

P.T.K. Saunders[1], N. Itani[2], A. Esnal-Zufiaurre[1], C. Fitzgerald[2], D. Gibson[1], H. Critchley[2], F. Collins[1]
[1]University of Edinburgh The Queen's Medical Research Institute, Centre for Inflammation Research, Edinburgh, UK
[2]University of Edinburgh The Queen's Medical Research Institute, Centre for Reproductive Health, Edinburgh, UK

Study question: Does the ERβ5 variant protein play any role in endometrial function or malfunction?
Summary answer: ERβ5, an isoform which lacks an intact ligand binding pocket may alter the response of epithelial cells to oestrogens by forming heterodimers with ERα.
What is known already: Oestrogens play an essential role in regulation of endometrial function during the menstrual cycle. Their biological effects are classically mediated *via* oestrogen receptors that act as ligand-activated transcription factors. Two oestrogen receptors have been identified; oestrogen receptor alpha (ERα) and beta (ERβ). Multiple isoforms of the ERβ protein have been described: mRNAs encoding full length (ERβ1) and truncated variants (ERβ2 and ERβ5) are present in normal endometrium but protein expression has not been described. ERβ5 protein is highly expressed in epithelial cells in endometrial adenocarcinomas. ERβ5 cannot bind E2; its role in mediating cell responses to E2 is poorly understood.
Study design, size, duration: Endometrial biopsies collected from women with written informed consent and local research ethics committee approval (LREC/07/S1103/29) were processed for immunohistochemistry. ERα-positive Ishikawa cells were used to investigate the impact of with ERβ1 or ER5 on E2 responses. An ERβ5 receptor protein with a yellow fluorescent protein "tag" (ERβ5-YFP) was used in fluorescence recovery after photobleaching (FRAP) experiments. Transcription assays were conducted in cells cotransfected luciferase cDNA under the control of an oestrogen response element (ERE-luc).
Participants/materials, setting, methods: Immunohistochemistry was performed on NBF-fixed paraffin-embedded endometrial tissue. Ishikawa cells were used as a model of endometrial epithelial cells. FRAP was conducted using a Zeiss LSM 510 laser scanning confocal microscope with images captured at 3 s intervals after bleaching. Cells used in reporter assays were engineered to express different ratios of ERα and ERβ5. Reporter gene activity was measured after treatment of cells with vehicle control (ethanol) or E2 10^{-8} M for 24 h.
Main results and the role of chance: ER5 was immunolocalised to epithelial and stromal cells; region/stage-dependent variation in epithelial cells was observed. In cells transfected with YFP-ERβ5, treatment with E2 identified two populations of cells: a) cells in which treatment with E2 had no impact, b) cells in which E2 treatment affected mobility of ER protein. In these cells, treatment with E2 resulted in rapid redistribution of the protein, reduced intra-nuclear mobility and a redistribution of the receptor into a punctate pattern (70% of cells 30 min after addition of E2). As ERβ5 lacks an intact ligand binding pocket and we have previously shown mobility was unchanged in cells which do not express full length ER proteins, we investigated whether punctate redistribution was a result of ERβ5 forming heterodimers with ERα. When the ratio of ERα and ERβ5 was altered in Ishikawa cells, the response of an ERE-driven reporter gene to E2 was significantly increased in cells with an increased ratio of ERβ5:ERα. The increase in E2-dependent reporter gene activation was abrogated by the antiestrogen Raloxifene. Responses to the ERα-selective agonist PPT mimicked those of E2. In contrast cotransfection with ERβ1 reduced E2 dependent reporter gene activity.
Limitations, reasons for caution: Immunohistochemistry on fixed tissue sections only reflects receptor location and abundance at a single point in time. Ishikawa cells that are commonly used as a model cell for endometrial epithelium were originally established from an endometrial adenocarcinoma.
Wider implications of the findings: ER5 is expressed in both normal endometrium and also in endometrial and other cancers: these novel data suggest we should re-evaluate its role in modulating estrogen-responsiveness in cells where it is coexpressed with ERα. Our results have important implications in understanding the regulation of proliferation in gynecological health and disease.

O-023 Regulation of angiogenesis-related prostaglandin F2α-induced VEGF and CXCL-8 factors in endometriosis

H. Rakhila[1], M. Al-Akoum[1], I. Dubuc[1], C. Doillon[1], A. Gravel[1], N. Lacroix-Pépin[2], M. Leboeuf[3], M. Lemyre[3], A. Akoum[2], M. Pouliot[1]
[1]Research Center, Centre Hospitalier Universitaire de Québec, Immunology and Microbiology, Quebec, QC, Canada
[2]Research Center, Centre Hospitalier Universitaire de Québec, Reproduction, Quebec, QC, Canada

[3]Research Center, Centre Hospitalier Universitaire de Québec, Gynecology and Obstetrics, Quebec, QC, Canada

Study question: How the activation or blockade of the prostaglandin (PG) $F_{2\alpha}$ receptor (FP) might stimulate angiogenesis in ectopic endometrial implantation sites?
Summary answer: $PGF_{2\alpha}$ enhances differential expression of VEGF and CXCL-8 through two variants of FP (FP_A and FP_B) which potentiates angiogenesis by endothelial proliferation and migration.
What is known already: Active angiogenesis and proliferation processes are required for ectopic endometrial tissue growth during endometriosis. Our previous studies showed that eutopic and ectopic endometrium from women with endometriosis exhibit higher expression of key enzymes involved in the $PGF_{2\alpha}$ biosynthetic pathway (e.g., cyclooxygenase-2 (COX-2), aldoketoreductase-C3...), as well as a high expression of PGF_2 receptor (e.g., FP), in endometriotic lesions. It has also been shown that the interaction between $PGF_{2\alpha}$ and its receptor in human endometrial pathologies induces angiogenesis (e.g., adenocarcinoma).
Study design, size, duration: The production of angiogenic factors (VEGF and CXCL-8), with disruption of $PGF_{2\alpha}$ signaling pathways using, inhibitors of FP signaling: COX-2, phospholipase C, protein kinase C or Ca^{2+}chelator, was assessed by RT-qPCR, WB, and ELISA (n = 11). Angiogenesis, proliferation and migration evaluations (n = 3), following exposure to conditioned media of transfected cells either with FP_A or FP_B, following $PGF_{2\alpha}$ treatment using Matrigel® angiogenesis network and scratch wound tests were assessed by microscopy.
Participants/materials, setting, methods: The study was conducted at the CHUQ and in an inflammatory research laboratory. Primary cultures of eutopic stromal cells of control women (n = 7) and matched eutopic and ectopic stromal cells of women with endometriosis (n = 11) were exposed to different concentrations of $PGF_{2\alpha}$. Endometriosis was thus categorized as early (n = 6) or late (n = 5) stages. Of the afflicted patients, 4 were in the follicular phase and 7 in the luteal phase at the moment of sample collection.
Main results and the role of chance: $PGF_{2\alpha}$ stimulated CXCL-8 ($p < 0.05$) and VEGF ($p < 0.05$) protein secretion in endometriotic ectopic stromal cells in the proliferative and secretory phases, without noticeable changes in eutopic endometrial stromal cells of women with or without endometriosis. Cell exposure to $PGF_{2\alpha}$ analog confirmed these previous observations. After 24 h of stimulation, FP antagonism led to an inhibition of the $PGF_{2\alpha}$-induced VEGF ($p < 0.05$) and CXCL-8 ($p < 0.01$) protein secretion, thereby indicating a specific effect of $PGF_{2\alpha}$. Meanwhile, $PGF_{2\alpha}$ increased significantly COX-2 expression while its other enzymes showed no difference. The COX-2 inhibitor NS398 decreased both VEGF and CXCL-8 secretion. Furthermore, in transfected cells either with FP_A or FP_B alone, COX-2 and phospholipase C inhibition suppressed $PGF_{2\alpha}$-induced CXCL-8 secretion ($p < 0.01$ and 0.05, respectively) through FP_A, while only protein kinase C and Ca^{2+} production were involved in VEGF ($p < 0.001$ and 0.001, respectively) through FP_B. Thus, both transcripts, FP_A and FP_B, are required for the $PGF_{2\alpha}$-induced stimulation of VEGF and CXCL-8 production. Finally, $PGF_{2\alpha}$ enhanced angiogenesis through endothelial tubal formation ($p < 0.05$) and proliferation ($p < 0.05$) processes in response to FP_A cells supernatant.
Limitations, reasons for caution: We carried out this study in isolated peritoneal ectopic stromal cells, which doesn't include preservation of histotypic relationships among other endometrial cells.
Wider implications of the findings: These results show for the first time that $PGF_{2\alpha}$ exerts direct and indirect angiogenic effects *via* FP signaling pathways by interacting with ectopic stromal cells and by inducing the secretion of major angiogenic factors. This study provides evidence for a possible new mechanism underlying endometriosis development and pathophysiology.
Trial registration number: Not Applicable

O-024 Seminal plasma mediates metaplasia in endometriosis, *via* transcriptional repressors (SNAIL and ZEB)

M.G.S. Ibrahim[1], S. Dr. Schäfer[1], S. Prof. Kliesch[2], L. Prof. Kiesel[1], M. Prof. Götte[1], A. Dr. Schüring[1]
[1]UKM Kinderwunschzentrum, Klinik für Frauenheilkunde und Geburtshilfe, Muenster, Germany
[2]Center of Reproductive Medicine and Andrology CeRA, Center of Reproductive Medicine and Andrology CeRA, Muenster, Germany

Study question: Can seminal plasma (SP) induce metaplasia in endometriosis (EM)?
Summary answer: SP induces a time dependent metaplasia in endometriotic cells, characterized by a rapid and transient increase in SNAIL1/2 and ZEB2 expression.
What is known already: SP, is rich in growth factors and hormones (e.g., TGFβ1 and estrogen) known to induce tissue metaplasia. Metaplasia may promote the development of EM lesions, and may be a mechanism through which abundant metaplastic myofibroblasts (expressing alpha smooth muscle actin (ASMA)) predominate in the stroma of EM lesions. **Study design, size, duration:** Semen samples were obtained from normozoospermic men (n = 14) as assessed according to WHO criteria 2010. After liquefaction, samples were centrifuged at 3000 rpm for 10 min, and the supernatant was stored at −20C. After thawing at room temperature, SP was pooled and filtered in 0.2 µm mesh and used for *in vitro* experiments in a 1:10 dilution.
Participants/materials, setting, methods: 12Z (endometriotic epithelial) and St-T1b (endometriotic stromal) cell lines (components of EM) were basically characterized *in vitro* by Immunofluorescence, for cytokeratin, vimentin and ASMA.

The effect of 2 h and 6 h incubation with SP 10% on both cell lines was studied with quantitative real-time PCR in comparison to SP-free culture medium in regard to the mRNA expression of metaplasia markers (E-cadherin, ASMA) and metaplasia mediators (SNAIL 1/2, ZEB2, and TWIST). **Main results and the role of chance:** Immunofluorescence characterization: Vimentin was expressed both in 12Z and St-T1b, while cytokeratin was only expressed by 12Z. Very few single ASMA expressing cells were observed in St-T1b, while they were absent in 12Z.

Metaplasia markers: Incubation of 12Z with SP 10% upregulated ASMA expression, but downregulated E-cadherin expression, both pointing to metaplasia. Both effects were observed after 2 h (early effect) and more pronounced after 6 h (late effect) incubation. In St-T1b, the same findings were observed for ASMA, however, in contrast to epithelial 12Z cells; an upregulation of E-cadherin was noticed. In contrary, N-cadherin was down regulated in both cell lines following SP incubation.

Metaplasia mediators: Incubation with SP 10% induced a rapid upregulation of SNAIL1/2 (as early as 2 h incubation), in addition to a more delayed upregulation of ZEB2 expression (as late as 6 h incubation). In contrast, TWIST expression was down regulated in both cell lines. This might suggest a SNAIL-mediated early metaplasia and a ZEB2-mediated late metaplasia, whereas the expression of TWIST does not follow conventional patterns.
Limitations, reasons for caution: Studying metaplasia markers and factors on the level of protein expression as well as blocking metaplasia-inducing growth factors in SP will further elucidate the precise role of SP on the development of EM.
Wider implications of the findings: Other possible effects of SP (being an inducer of metaplasia) on endometriotic cell invasion, migration and cellular viability should be studied. This will help to understand the effect of SP coming in contact with the endometrium or with vaginal EM lesions (during intercourse).
Trial registration number: Irrelevant

O-025 Detection of cancer stem cell phenotype within endometrial mesenchymal stem cells of endometriosis patients

S. Vignesh Srinivasan[1], S. Jo Varghese[1], K. Gemzell Danielsson[1], P. Lalitkumar[1]
[1]Karolinska Institutet, Deptartment of Women's & Children Health, Solna, Sweden

Study question: Endometriosis Associated Cancer (EAC) – can we detect cancer stem cell markers from stem cells in endometrium or endometriotic cyst within endometriosis patients?
Summary answer: We identify a subpopulation of endometrial mesenchymal stem cells (MSC) expressing Cancer Stem cells (CSC) markers in endometriosis patients.
What is known already: EAC is a rare but possible molecular event occurring among 0.7–2.5% of endometriosis patients. Several epidemiological multicentre studies on endometriosis patients showed an increased risk for endometrioid and clear cell ovarian carcinoma. Endometrial stem cells are known to actively regenerate within endometrium and sheds into ectopic sites during retrograde menstruation which are suggested to be involved in the pathogenesis of endometriosis. A variety of molecular events have been correlated previously with the malignant transformation of endometriotic cyst such as alterations in genes

TP53, BCL-2, PTEN, ARID1A, CTNNB1. Unfortunately, early molecular events that contribute to tumor progression in EAC remain undefined.
Study design, size, duration: Endometrial (n = 18; P-EnSC) and endometriotic cyst (n = 11; EndoSC) biopsies were collected from patients undergoing surgery for endometriotic cystectomy. These patients were not under hormonal treatment or any intrauterine device for atleast three months prior to surgery. Also, endometrium from healthy fertile volunteers (n = 17; H-EnSC) was collected as control. Biopsies were enzymatically digested and sorted for MSC markers CD90, CD73 and CD105 by flowcytometry (FACS). MSC were characterized and used for analysis of putative CSC. subpopulations.
Participants/materials, setting, methods: *In vitro* monolayer cells from P-EnSC and P-EndoSC were compared against H-EnSC for cell cycle distribution. Also, they were checked for putative CSC population after growing them as 3D-multicellular spheroids for two generations and compared with H-EnSC for expression of CSC markers CD44, CD133, ALDH1A1, CD117, ABCG2; pluripotent markers OCT3/4, SOX2, NANOG using real-time-PCR and FACS. Colocalization of CSC markers were analysed using confocal imaging. Paired and unpaired t test were used for statistical analysis.
Main results and the role of chance: We observed an unique G1/S cycling cell-cycle distribution as previously reported with CSC, exclusively by increased early-S and late-S phase ($P < 0.05$) among both P-EnSCs and P-EndoSC on comparing H-EnSC with 5-Bromodeoxyuridine in DNA of newly dividing cells. Coincidentally, P-EnSC also showed higher expression of proliferative Ki67 marker and low expression of antiapoptotic gene BCL2 ($P < 0.05$) comparing H-EnSC indicating re-activation of a quiescent subpopulation. FACS sorting of P-EnSC and P-EndoSC with known endometrial and ovarian CSC markers CD44, CD133, ALDH1A1, CD117 and ABCG2 on monolayer cultured MSCs revealed existence of such rare CSC populations (~0.01–0.1%) in patient samples but they failed to survive in our long term culture. Hence, we enriched P-EnSC, P-EndoSC and H-EnSC into 3D-tumor spheroids which exhibited significant increase in expression of pluripotent markers OCT3/4, SOX2, NANOG, and CSC marker CD133/PROM1 between P-EnSC and H-EnSC spheroids ($P < 0.01$). Moreover, SOX2 were exclusively upregulated with P-EndoSC comparing P-EnSC, indicating possibility of dedifferentiation of MSC into CSC populations within endometrioma ($P < 0.05$, $P < 0.01$, $P < 0.01$, respectively). Further characterization by FACS between groups showed clonal expansion of $CD44^+CD133^+$ populations of P-EndoSC spheroids ($P < 0.01$). Validation with confocal imaging revealed increased expression of CSC markers $CD44^+CD133^+$ among P-EndoSC spheroids with higher colocalization index (0.91).
Limitations, reasons for caution: We included only endometriosis patients without any hormonal treatment. Although it improves the quality of results, it limits the overall sample size. Also, we tried to adopt a physiologically relevant *in vitro* model; however, an *in vivo* approach would have led to better understanding of transformation events leading to EAC.
Wider implications of the findings: Our study demonstrates for the first time the link between ovarian cancer and endometriosis at cellular level by identifying CSC phenotypes within both endometrium and endometriotic cyst. This would help in screening patients who exhibit CSC phenotypes and offer prophylactic measures to reduce their cancer risk.
Trial registration number: Not Applicable

O-026 Hypoxia and hypoxia inducible factor-1 in the human and murine endometrium: a role in the pathogenesis of prolonged, heavy menstrual bleeding

J.A. Maybin[1], A. Murray[1], P.T.K. Saunders[2], N. Hirani[2], P. Carmeliet[3], H.O.D. Critchley[1]
[1]*University of Edinburgh, The Queen's Medical Research Institute, MRC Centre for Reproductive Health, Edinburgh, UK*
[2]*University of Edinburgh, The Queen's Medical Research Institute, MRC Centre for Inflammation Research, Edinburgh, UK*
[3]*KU Leuven, VIB, Laboratory of Angiogenesis and Neurovascular link, Leuven, Belgium*

Study question: Are hypoxic conditions and/or the activation of hypoxia inducible factor (HIF)-1α required for efficient endometrial repair at menstruation?
Summary answer: Hypoxia and hypoxia inducible factor-1α are required for efficient endometrial repair at menstruation and an aberrant hypoxic response results in prolonged, heavy menstrual bleeding.
What is known already: Heavy menstrual bleeding (HMB) is a common, debilitating condition that often requires surgical intervention. There is an unmet need for new, efficient medical therapies that lack hormonal side effects.
Following progesterone (P)-withdrawal in the late secretory phase, vasoconstriction of spiral arterioles is thought to lead to local hypoxia in the luminal endometrium. However, the presence and role of endometrial hypoxia has been the subject of intense debate. Hypoxia was shown to have no effect on endometrial breakdown but its role in subsequent repair (reepithelialisation and stromal expansion) remains unknown. Inefficient endometrial repair at menses may contribute to prolonged, HMB.
Study design, size, duration: Human case–control studies were performed with ethical approval and written consent to determine the presence of HIF-1α across the menstrual cycle in women with (>80 ml) and without (<80 ml) HMB (minimum n = 4 per group/cycle stage). A cohort design was utilised in murine studies to determine if lack of hypoxia or deficient HIF-1α was a risk factor for HMB (minimum of n = 6 per group).
Participants/materials, setting, methods: Endometrial biopsies were collected from healthy women. Those with fibroids, endometriosis, irregular cycles or taking hormones were excluded. Menstrual blood loss was objectively measured (modified alkaline-haematin method). HIF-1α was detected by Western blot and downstream targets by PCR.

Mice do not naturally menstruate. Ovariectomy, administration of estradiol/progesterone and induction of decidualisation enabled modeling of endometrial shedding/repair allowing manipulation of hypoxia and HIF in this *in vivo* model. Endometrial repair was quantified by histological grading.
Main results and the role of chance: HIF-1α was present in nuclear protein extracts from human endometrium, but limited to tissue exposed to P-withdrawal (perimenstrual). Women with HMB had significantly decreased endometrial HIF-1α at menstruation when compared to women with normal loss ($P < 0.05$). Downstream targets of HIF-1 (VEGF/CXCR4) were also decreased in women with HMB at menses ($P > 0.001$). Of note, women with HMB bled for 2 days longer on average than those with normal bleeding ($P < 0.01$).

We detected a transient hypoxic episode in murine endometrium during menstruation using pimonidazole (marker of O_2 <10 mmHg), which localised to the denuded surface. We prevented endometrial hypoxia during menses using a hyperoxic chamber (75% O_2), confirmed by absent pimonidazole staining. This unique model demonstrated menstrual hypoxia is necessary for (1) sufficient endometrial HIF-1α induction, with decreased HIF-1α protein in mice exposed to hyperoxia and (2) efficient endometrial repair, as evidenced by a decreased endometrial repair histoscore at 24 h in mice incubated in hyperoxia vs. normoxia ($P < 0.05$).

We genetically (HIF-1α heterozygote vs. wild type mice) or pharmacologically (i.p., injection of echinomycin vs. vehicle) reduced endometrial HIF-1α during menstruation in the mouse model of simulated menstruation. This also resulted in significantly delayed endometrial repair, due to aberrant endothelial cell function and delayed epithelial cell proliferation.
Limitations, reasons for caution: We acknowledge the number of human samples studied is small due to our strict classification and stringent exclusion criteria. The mouse model of simulated menses is not a natural model of menses but does mimic human endometrial changes and maintains endometrial architecture and cell–cell interactions critical for efficient menstruation/repair.
Wider implications of the findings: Herein, we demonstrate that hypoxia/markers of hypoxia are present in the human and murine menstrual endometrium. Prevention of this hypoxic episode, or of the subsequent stabilisation of HIF-1α, significantly delays endometrial repair. Correction of this defect could result in a novel, efficient medical treatment for women with HMB.

SESSION 06: WHAT DOES GENOTYPE MEAN TO THE EMBRYO?

Monday 04 July 2016 **Hall 3 DE** **10:00–11:30**

O-027 Genetic diseases and aneuploidies can be detected with a single blastocyst biopsy: a new clinical successful approach.

E. Cursio[1], M.G. Minasi[1], A. Ruberti[1], A.M. Lobascio[1], V. Casciani[1], A. Colasante[1], F. Scarselli[1], T. Riccio[1], K. Litwicka[1], M.T. Varricchio[1], A. Biricik[2], F. Spinella[2], F. Fiorentino[2], E. Greco[1]

[1]European Hospital, Centre for reproductive medicine, Rome, Italy
[2]Genoma, Molecular biology, Rome, Italy

Study question: Is a single blastocyst biopsy efficient in detecting both genetic diseases and aneuploidies, limiting negative effect on embryo implantation potential and guaranteeing good clinical outcomes?
Summary answer: Genetic diseases and aneuploidies can be detected with a single biopsy without negative influence on blastocyst implantation and developmental potentials and allowing good clinical outcomes.
What is known already: Initially, preimplantation Genetic Diagnosis (PGD) was used in fertile patients who have the risk of transmitting genetically inheritable diseases to their offspring. Later, after the introduction of different techniques allowing the analysis of all the 24 chromosomes, the same procedure was applied to investigate the genetic status of the embryos (preimplantation Genetic Screening, PGS) obtained from infertile patients. The efficiency of performing routinely PGS in all the categories of patients with the aim to select the embryo(s) with the highest implantation potential, it is still an issue under intense debate in the literature.
Study design, size, duration: This consecutive case series study was performed from October 2011 to December 2015. Clinical and biological outcomes from 963 blastocysts obtained in 264 PGD cycles for monogenic diseases or translocations were analyzed. When the blastocyst resulted transferable after the PGD analysis, also its ploidy status by mean of PGS was detected using the same biopsy sample. Mean female age was 35.26 ± 4.16 years old. All biopsies were performed at blastocyst stage with array comparative genomic hybridization.
Participants/materials, setting, methods: All mature oocytes retrieved were injected and cultured individually until the blastocyst stage at 37°C, 6% CO_2, 5% O_2. When the blastocyst was formed, it was biopsied and vitrified, waiting for the genetic results. The frozen–thawed embryo-transfer was performed in a subsequent cycle. Sometimes, when the blastocyst was obtained within the morning of day-5 of culture, it has been maintained in culture in order to perform a fresh embryo-transfer on day-6, after receiving the genetic report.
Main results and the role of chance: A total of 2389 mature oocytes were injected with a fertilization rate of 75.1% (N = 1795); 1780 embryos were obtained with a blastocyst formation rate of 54.1% (N = 963); 952 of them were biopsied from day-4 to day-7 of culture. After the genetic analysis, 269 blastocysts resulted transferable, both for monogenic disease or translocation and for their ploidy status, 31 mosaic, 52 no result and 600 not transferable, for the genetic disease and/or for their ploidy status. A total of 174 embryo-transfer were performed, 53 fresh and 121 cryopreserved, where 184 healthy or carrier euploid blastocysts were transferred. In cryopreserved embryo-transfer, 130 out of 135 (96.3%) warmed blastocysts survived. The clinical pregnancies, the heart beats, the miscarriages and the ectopic pregnancies were 82 (47.1%), 85 (implantation rate of 46.2%), 17 (9.8%) and 1 (0.6%), respectively. To date, 53 deliveries occurred whit 56 healthy babies born, 28 males and 28 females; 11 pregnancies are still ongoing. In addition, there are still 111 transferable blastocysts cryopreserved obtained from 49 cycles, that could lead to further improved clinical outcomes. Finally, it will be possible to perform a second biopsy on the no results blastocysts, with the hope to recover other transferable ones.
Limitations, reasons for caution: A higher cycle cancellation rate than expected could be found due to the double kind of genetic analysis performed. For this reason, particular care should be taken in drafting and explaining informed consent, and in particular the risks related to this approach, in order to avoid patients' drop out.
Wider implications of the findings: When the biopsy have to be performed in order to prevent the transmission of a hereditary disease, it should be mandatory to analyze also the genetic status of the blastocyst, avoiding useless embryo-transfers in this particular category of patients. Blastocyst seems to be the more convenient stage to perform biopsy.
Trial registration number: Not applicable

O-028 Clinical outcome derived after tranfer of embryos with chromosomal mosaicism

F. Fiorentino[1], A. Biricick[2], S. Bono[2], E. Greco[3], M.G. Minasi[3], A. Ruberti[3], F. Spinella[2]
[1]GENOMA – Molecular Genetics Laboratory Centre for Preimplantation Genetic Diagnosis, Rome, Italy
[2]GENOMA, Molecular Genetics Laboratory, Rome, Italy
[3]European Hospital, Reproduction Medicine, Rome, Italy

Study question: Can optimized protocol for chromosomal mosaicism determination be applied for aneuploidy screening of human embryos to detect potentially transferrable mosaic embryos?
Summary answer: The adoption of optimized protocol improves the detection of embryos with chromosomal mosaicism and identification of embryos capable to implant and result in normal pregnancies.
What is known already: Aneuploidy screening of embryos at blastocyst stage can be jeopardized by the presence of chromosomal mosaicism, a phenomenon characterized as a mixture of diploid and aneuploid cell lines in the same embryo. Although many of such embryos do not implant, some may undergo through a natural mechanism of aneuploidies rescue during development resulting in euploid embryos. However, technical limitations have precluded accurate detection of mosaicism after preimplantation genetic screening of embryos preventing, in some case, transfer of only viable mosaic embryos (false positive) or, in the opposite scenario, transferring undetected mosaic embryos (false negative) instead of, if available, euploid embryos.
Study design, size, duration: This study was organized into two steps. The first involved the analysis of 195 experimental samples composed with different euploid and aneuploid single cell ratios (10–90%) to obtain reference curves for chromosomal mosaicism. In the second step, embryos obtained from 1525 PGS cycles, performed from May 2013 to April 2015 were analysed. The clinical outcome (implantation, miscarriage, and live birth rate) after euploid and mosaic embryos transfer was evaluated.
Participants/materials, setting, methods: All embryos were cultured to blastocyst stage; trophectoderm biopsy was performed on day-5 of development. Experimental and clinical samples were analysed with array-comparative genomic hybridization (array-CGH) and Next-Generation Sequencing (NGS) methodologies accomplished by BlueFuse Multi (BFM) analysis software. Percentage of chromosomal mosaicism was determined based on reference curves in both mosaic and full aneuploidy embryos. Designated mosaic embryos were offered to patients without euploid embryos available.
Main results and the role of chance: Based on reference curves 2191 euploid, and 3019 aneuploid embryos were detected. The remaining 452 were classified as mosaic embryos including 117 (13%) of samples predicted to be uniformly aneuploidy by BFM automatic call. Following transfer of 993 euploid embryos in 941 women (mean age 38.4 years range 20–48), 610 had positive hCG levels: 507 pregnancies continued, confirmed by at least one fetal sac and heart beat (54% clinical pregnancy rate/ET), 95 were biochemical and 46 miscarried. Following transfer of 39 mosaic embryos in 38 women (mean age 37 ± 4 years, range 29–44), 13 resulted in healthy babies (33.3%). Of these, 7(54%) were from blastocysts with 40% mosaicism, 4 (31%) from 50% and 2 from blastocysts with 30% mosaicism. Twelve of babies born (92.4%) were from blastocysts with a single or double monosomies, one (7.6%) was from a single trisomy.
Limitations, reasons for caution: Although clinical results have documented high pregnancy outcomes following transfer of mosaic embryos scored with a chromosomal mosaicism curve, a randomized controlled trial confirming its clinical effectiveness is advisable before recommending widespread application.
Wider implications of the findings: Our results indicate that adoption of a proper reference curve able to discriminate full euploid or aneuploidy from mosaic embryos may represent a strategy to avoid the discarding of viable embryos and offer IVF-patients with only aneuploid embryos, a chance of success
Trial registration number: No external funding was sought for this study

O-029 The clinical significance of segmental aneuploidy in human oocytes and preimplantation embryos

D. Babariya[1,2], E. Fragouli[1,2], S. Alfarawati[1], K. Spaeth[1,2], A. Raberi[1,2], S. Taylor[1], N. Kubikova[1], D. Wells[1,2]
[1]Reprogenetics UK, Institute of Reproductive Sciences, Oxford, UK
[2]Nuffield Department of Obstetrics & Gynaecology, University of Oxford, Oxford, UK

Study question: What is the incidence, origin and significance of segmental aneuploidy in oocytes and embryos? Does the presence of partial chromosome errors affect embryo implantation ability?
Summary answer: Segmental aneuploidy is frequent in embryos. The nature of such abnormalities should be considered when selecting embryos for transfer, after preimplantation genetic screening (PGS).

What is known already: PGS has been proposed as a tool for embryo selection, distinguishing embryos affected by lethal aneuploidies from those that are euploid and potentially viable. The adverse impact of aneuploidy involving entire chromosomes, in terms of reduced likelihood of embryo implantation and increased miscarriage risk, is well-established. However, losses or gains of chromosomal fragments, resulting in segmental aneuploidies, are also common during preimplantation development. The clinical relevance of segmental aneuploidies is unclear at this time. Given the high frequency of segmental aneuploidy, investigations to determine the impact of this class of abnormality in the context of IVF outcome are urgently required.
Study design, size, duration: Cytogenetic data was obtained from oocytes and embryos of 690 IVF patients who requested PGS for various reasons, most commonly advanced female age or previously unsuccessful IVF treatments. A total of 4,068 samples including 452 human oocytes, 1,726 cleavage stage and 1,890 blastocyst stage embryos were investigated. The data was obtained over a period of 3 years, from 2012 to 2015.
Participants/materials, setting, methods: Both the first and second polar bodies were examined from the oocytes included in this study. Analysis at the cleavage stage involved testing of single blastomeres, while blastocysts were assessed by investigating trophectoderm biopsy specimens (~5 cells). The biopsied material was subjected to whole genome amplification followed by comprehensive chromosome analysis using well-validated microarray comparative genomic hybridisation (aCGH) or next generation sequencing (NGS) methods.
Main results and the role of chance: Segmental aneuploidy was identified in 10.39% of oocytes (47/452), 24.29% of cleavage stage embryos (428/1726) and 15.59% of blastocysts (207/1327). Thus, the incidence of segmental aneuploidy increased dramatically after fertilisation ($p < 0.0001$), but declined from the cleavage to the blastocyst stage ($p < 0.0001$). The high levels of segmental abnormality at the cleavage stage, relative to levels seen in oocytes, suggests that most segmental aneuploidies are derived from the sperm, or spontaneously arise during the first few mitotic divisions post-fertilisation. Approximately 75% of the chromosomes breaks associated with segmental aneuploidies occurred along the chromosome arms, while ~25% occurred at or near centromeres. Additionally, distinct chromosome breakage hotspots were found at specific locations on individual chromosomes, some corresponding to known chromosomal fragile sites. The NGS method utilised is able to detect mosaic chromosome abnormalities with high sensitivity (i.e., aneuploidy restricted to a subset of the biopsied cells). Analysis of 563 trophectoderm biopsies using NGS revealed that three-quarters of segmental abnormalities were present in mosaic form (122 vs. 43, respectively). In some cases embryos with mosaic abnormalities were transferred. Clinical follow-up conclusively demonstrated that embryos with mosaic segmental errors had a higher chance of producing ongoing pregnancies than those with mosaic for whole chromosomal aneuploidy ($p = 0.0021$).
Limitations, reasons for caution: The scoring of segmental aneuploidy using different techniques for PGS (such as aCGH, real-time PCR and NGS) across different laboratories is currently without consensus. This issue needs to be addressed. Some widely used PGS methods are unable to accurately detect segmental abnormalities, leading to contradictory reports in the literature.
Wider implications of the findings: Understanding the impact of segmental aneuploidies will lead to improved clinical management. Data on the origin of the defect (meiotic/mitotic), and the site of chromosomal breakage, can provide an indication of the likelihood of mosaicism. This information is relevant to embryo viability and the potential to produce a healthy child.
Trial registration number: Not applicable

O-030 Embryos showing mosaicism in trophoectoderm cells can achieve good pregnancy rates

R. Morales[1], B. Lledó[1], J.A. Ortiz[1], J. Ten[2], J. Llácer[3], R. Bernabeu[3]
[1]*Instituto Bernabeu, Biotech, Alicante, Spain*
[2]*Instituto Bernabeu, Reproductive Biology, Alicante, Spain*
[3]*Instituto Bernabeu, Reproductive Medicine, Alicante, Spain*

Study question: Should embryos carriers of mosaicism in trophoectoderm cells be discarded?
Summary answer: Transfer of mosaic embryos leads to a lower but relatively good clinical pregnancy rate.
What is known already: There is a high incidence of chromosomal abnormalities in human embryos that leads to failure of IVF cycles. The chromosomal mosaicism, which consists of a mixture of diploid and aneuploid cells, is a common phenomenon in IVF-derived embryos. Classification of mosaic embryos as aneuploid embryos is a controversial topic, since the association between mosaicism in trophoectoderm cells and inner mass cells is unknown. Moreover, it seems that there is a mechanism by which mosaicism could be corrected. To clarify this issue the outcomes of transfer cycles with mosaic and euploid blastocysts were compared.
Study design, size, duration: We retrospectively reanalyzed array-CGH results from trophoectoderm biopsies of day 5 and 6 blastocysts (from October 2014 to December 2015). A total of 816 embryos were included. We considered a mosaic embryo when the percentage of mosaicism, calculated by the log2 ratio, was higher than 25%. The mosaic embryos ($n = 107$) were classified in two groups according to the number of chromosomes with mosaicism: 1 chromosome ($n = 48$) and two or more chromosomes ($n = 59$). **Participants/materials, setting, methods:** Chromosomal comprehensive screening was performed to couples who attended the Instituto Bernabeu for advanced maternal age, abnormal sperm FISH and/or a history of recurrent miscarriage or implantation failure. Array-CGH analysis was performed using Agilent SurePrint G3 8 × 60 K CGH microarrays with previous whole genome amplification of genomic DNA. The main outcome measures were implantation rate, pregnancy rate and biochemical and clinical miscarriage rate. The differences between groups were evaluated using the Fisher's exact statistical test (SPSSv20.0).
Main results and the role of chance: The array-CGH results from trophoectoderm biopsies of day 5 and 6 blastocysts ($n = 816$) were reanalysed. We detected chromosomal mosaicism in 107 blastocysts (13.1%). Moreover, 49.4% of the analysed embryos were euploid, 30.9% aneuploid and the remaining 6.6% without diagnosis. In the mosaic group, 57.9% were euploid embryos with mosaicism and 42.1% were also aneuploid. In the euploid-mosaic embryos, the frequency of embryos with mosaicism in only 1 chromosome was 51.6% vs. 48.4% for those with mosaicism in 2 or more chromosomes.

The outcomes of the cycles were compared between cycles where only mosaic embryos were transferred and cycles where euploid embryos were transferred. Although the outcomes of transfer cycles seem to be lower among the mosaic group, the differences with regard to pregnancy rate, implantation rate, miscarriage rate and ongoing pregnancy rate were considered not quite statistically significant. However, significant differences were observed in the clinical pregnancy rate (20.6% in mosaic group vs. 38.9% in euploid group; $p = 0.042$). In the mosaic group, according to the number of chromosomes with mosaicism, the embryos with mosaicism in 2 or more chromosomes showed a lower pregnancy rate compared with the embryos with mosaicism in 1 chromosome (23.5% vs. 64.7%; $p = 0.016$).
Limitations, reasons for caution: It is unknown if the mosaicism detected in a biopsied embryo is confined only to trophoectoderm, and moreover if the embryo is able to correct it. More data are needed to conclude which mechanisms are involved in the development of these mosaic embryos.
Wider implications of the findings: Our data show that the transfer of mosaic embryos affects the outcomes of the IVF cycles. Even so, the mosaic embryos have a relatively good IVF success rate and therefore they should not be discarded in couples that don't have euploid embryos for transfer.
Trial registration number: No clinical trial

O-031 Incidence, origin and type of aneuploidy seen in human preimplantation blastocysts: concurrent analysis using single nucleotide polymorphism (SNP) arrays and next generation sequencing (NGS)

M. Konstantinidis[1], K. Ravichandran[1], R. Prates[1], L. Ribustello[1], P. Colls[1], D. Wells[2], S. Munne[1]
[1]*Reprogenetics, Livingston, NJ, USA*
[2]*Reprogenetics UK, Institute of Reproductive Sciences, Oxford, UK*

Study question: What is the incidence and origin of aneuploidy in human preimplantation blastocysts and what are the types of aneuploidies observed?
Summary answer: Aneuploidy of maternal meiotic origin was most common and displayed an equal distribution of monosomies and trisomies. Paternal-derived aneuploidy was mostly associated with chromosome loss.
What is known already: The incidence of aneuploidy in human gametes and embryos has been studied in the past and has been shown to be strongly correlated with increasing maternal age. It is known that aneuploidy in human embryos can be of meiotic (gamete) origin or be mitotic (arising after fertilization). In the past, phenomena and processes contributing to meiotic and mitotic

chromosome errors have tended to be studied separately. A comprehensive investigation looking into all the different types of aneuploidy simultaneously, and within the same cohort of samples, could provide valuable data, offering a thorough insight into this biologically and clinically important phenomenon.
Study design, size, duration: Single nucleotide polymorphism (SNP) arrays and next generation sequencing (NGS) were used in parallel to screen over 8,700 chromosomes from 190 *in vitro* fertilized embryos (blastocysts). These embryos were generated by 31 couples (average maternal age 33.87 ± 0.80 years) undergoing preimplantation genetic diagnosis (PGD) for single gene disorders in conjunction to comprehensive chromosome screening. The SNP arrays were used for PGD *via* a linkage-based (Karyomapping, Illumina, USA) approach, while NGS was used for aneuploidy detection.
Participants/materials, setting, methods: Embryos were biopsied at the blastocyst stage and the trophectoderm samples obtained were subjected to multiple displacement amplification. Karyomapping was then used to generate data from 300,000 SNPs per embryo. Next generation sequencing was carried out using the VeriSeq PGS assay (Illumina). A MiSeq desktop sequencer was utilized for NGS. BlueFuse Multi analysis software was used for interpretation of results obtained from Karyomapping and VeriSeq PGS assays.
Main results and the role of chance: Results were generated from 179 embryos of which 54.8% were identified as containing at least one chromosomal abnormality; 45.4% of the embryos exhibited only meiotic abnormalities, 39.2% had only mitotic abnormalities and the rest had both types of aneuploidy. Of a total of 164 aneuploidy events, 52.4% were determined to be meiotic in origin and 47.6% mitotic in origin. Maternal meiotic events (81.4%) eclipsed paternal meiotic events (18.6%). While maternal meiosis consisted of an equal number of events leading to gain and loss of chromosomes, paternal meiotic errors were more likely to involve loss of chromosomes (93.75% vs. 6.25%), with almost half of these being partial losses.

We also looked into the incidence of meiotic errors according to maternal age (calculated as No. of embryos with meiotic errors vs. overall No. of embryos per age group). It was determined that meiotic errors increase with increasing female age with highest predominance being at ages ≥40 years. Specifically, the incidence of meiotic errors was determined to be 14.2% for <34 age group, 26.4% for 35–39 age group and 73.7% for ≥40 years; incidence was significantly higher for ages 40 years ($P < 0.001$). However, mitotic errors did not increase with age.
Limitations, reasons for caution: In order to have robust data concerning the incidence of aneuploidy affecting individual chromosomes, an even larger dataset would be required. The current research can only be used to assess general trends.
Wider implications of the findings: Maternal meiotic errors dominated and increased with age, explaining the higher rates of implantation failure and miscarriage experienced by older women. Mitotic errors, potentially producing mosaicism, were also common. Interestingly, aneuploidy of male meiotic origin was characterized by a preponderance of monosomies, suggesting a different mechanism to their female counterparts.

O-032 Mutations in TUBB8 cause a multiplicity of phenotypes in human oocytes and early embryos

L. Wang[1], Y. Zheng[2], L. Bin[2], S. Qing[1], F. Ruizhi[1], S. Xiaoxi[3], K. Yanping[2]
[1]*Fudan University, Life Sciences, Shanghai, China*
[2]*Shanghai Jiao Tong University, The Ninth Hospital, Shanghai, China*
[3]*Fudan University, Shanghai Ji Ai Genetics and IVF Institute, Shanghai, China*

Study question: What phenotype of human oocytes and early embryos can caused by TUBB8 mutations
Summary answer: *TUBB8*mutations can cause oocyte meiotic arrest or embryos developmental arrested by either dominant negative effects or tubulin deficiency
What is known already: TUBB8 is unusual in that it exists only in primate species, where its biological function was unknown. Recently, we identified seven missense mutations in TUBB8 in patients with oocyte maturation arrest. We found that TUBB8 is uniquely expressed in oocytes and the early embryo, where it is the preponderant β-tubulin isotype. Based on an assessment of their effects upon expression in HeLa cells, yeast cells, mouse and human oocytes, we concluded that these mutations exert their effects *via* dominant negative effects on microtubule behavior. These findings uncovered an essential role for TUBB8 in human oocyte maturation and female fertility.
Study design, size, duration: Patients with oocyte maturation arrest were referred from the reproductive medicine center at Ninth Hospital affiliated with Shanghai Jiao Tong University and Shanghai Ji Ai Genetics from January 2014 to December 2015.
Participants/materials, setting, methods: Patient genomic DNA samples and those from their family members and controls were extracted. All exons and splicing sites of *TUBB8* were amplified and sequenced. Oocytes obtained from donors undergoing routine clinical ICSI were viewed by phase contrast and polarization microscopy with an OLYMPUS IX71 inverted microscope system. Folding kinetics of wild type and mutant were evaluated and transfected into HeLa cells to evaluate microtubule phenotypes
Main results and the role of chance: We report eight new inherited or de novo *TUBB8*mutations and a recurrent de novo *TUBB8* mutation that cause female infertility in nine independent families. Seven of these (S176L, I210V, T238M, V255M, R262W, T285P, and N348S) are missense, and are structurally predicted to interfere with various aspects of microtubule behavior. With the exception of R262W, these mutations cause varying degrees of microtubule disruption upon expression in cultured cells as a result of dominant negative effects. In spite of lacking a detectable spindle or containing an impaired spindle, oocytes harboring three of these mutations (I210V, T238M and N348S) can extrude the first polar body. Moreover, they can be fertilized, although the ensuing embryos become developmentally arrested. These data underscore the independent nature of human oocyte meiosis and differentiation. We also describe two infertile patients carrying homozygous *TUBB8*mutations (p.T143Dfs*12 and p.(E27_A33del)) that render the protein folding and assembly incompetent. Surprisingly, oocytes from these patients have identifiable spindles, although in at least one case these had an abnormal morphology. These observations imply that such spindles are assembled from pre-existing non-TUBB8 tubulin heterodimers expressed at an earlier developmental stage, and that tubulin deficit can contribute to meiotic arrest.
Limitations, reasons for caution: TUBB8 mutations need to be evaluated in larger sample of patients with human oocyte meiotic arrest. Corresponding oocytes and embryos phenotypes incurred by TUBB8 mutations should be deeply evaluated
Wider implications of the findings: Currently, in IVF/ICSI clinics, only morphologically MII oocytes identified by extrusion of the first polar body are selected for fertilization. Our observations provide an additional criterion that can be applied for evaluating the quality of oocytes selected for fertilization in the future.
Trial registration number: Not applicable

O-033 Results of the ESPART randomized controlled trial investigating recombinant luteinizing hormone supplementation for controlled ovarian stimulation in poor ovarian responders aligned with the Bologna criteria

P. Humaidan[1], W. Chin[2], D. Rogoff[3]
[1]*The Fertility Clinic – Skive Regional Hospital Faculty of Health, Aarhus Universi, Skive, Denmark*
[2]*EMD Serono Research & Development Institute, Inc., an affiliate of Merck KGaA, Darmstadt, Germany, Global Biostatistics & Epidemiology, Billerica, MA, USA*
[3]*EMD Serono Research & Development Institute, Inc., an affiliate of Merck KGaA, Darmstadt, Germany, Global Clinical Development Center, Billerica, MA, USA*

Study question: Does fixed-ratio combination recombinant-human follicle-stimulating hormone (r-hFSH) plus recombinant-human luteinizing hormone (r-hLH) increase the number of oocytes vs. r-hFSH in Bologna criteria-aligned poor ovarian responders?
Summary answer: No significant difference in the number of oocytes retrieved between poor ovarian responders receiving fixed-ratio combination r-hFSH plus r-hLH and those receiving r-hFSH was seen.

What is known already: At present no "gold standard" protocol for controlled ovarian stimulation (COS) in women with poor ovarian response (POR) exists; nevertheless, evidence from previous meta-analyses have suggested that the addition of r-hLH to r-hFSH may be beneficial for COS in this population. However, clinical trials included in the meta-analyses used a variety of definitions for POR, reducing their comparability. Subsequently, the ESHRE Bologna criteria have been set, in an attempt to identify a standardized population for inclusion in clinical trials investigating POR.
Study design, size, duration: The Efficacy and Safety of Pergoveris in Assisted Reproductive Technology (ESPART) study is a phase III, randomized, single-blind, parallel-group, active-comparator trial, comparing the number of oocytes retrieved following COS in 939 women randomized (1:1) to receive either fixed-ratio r-hFSH plus r-hLH (2:1 ratio) or r-hFSH monotherapy. It is the largest RCT to date in patients with POR and includes follow-up to the assessment of live birth rate, over a single assisted reproductive technologies (ART) cycle.
Participants/materials, setting, methods: Patients meeting ≥2 of the following (aligned to ESHRE Bologna criteria) were included: age >40–<41 years; previous cycle with ≤3 oocytes retrieved with conventional stimulation; anti-Müllerian hormone (AMH) level 0.12–1.3 ng/mL. Following downregulation, 462 women were randomized to COS with r-hFSH/r-hLH and 477 to COS with r-hFSH. The primary endpoint was number of oocytes retrieved. Secondary and other outcomes included biochemical, clinical and ongoing pregnancy rates, embryo implantation rate and live birth rate.
Main results and the role of chance: The mean age of patients was 38.3 years, mean AMH level was 0.59 ng/mL, and mean antral follicle count was 4.8. 83% of patients had at least one previous ART cycle with ≤3 oocytes retrieved. In the overall Modified Intention-to-Treat population (and supported by the Per Protocol population), there was no significant difference in the mean [standard deviation] number of oocytes retrieved in the r-hFSH plus r-hLH group (3.3 [2.71]) compared with the r-hFSH group (3.6 [2.82]; $P = 0.054$). The biochemical pregnancy rate was significantly lower in the r-hFSH plus r-hLH group compared with the r-hFSH group (17.3% vs. 23.9%, respectively), however, no significant difference was seen between the groups for clinical pregnancy rate (14.1% vs. 16.8%), ongoing pregnancy rate (11.0% vs. 12.4%) and live birth rate (10.6% vs. 11.7%). The incidence of adverse events was comparable between the treatment groups, occurring in 25.8% and 33.3% of women treated with r-hFSH/r-hLH and r-hFSH, respectively, and no new safety concerns were identified. When subgroups of patients were investigated according to the individual Bologna criterion defined in the study (age, AMH level and ART history) separately, no subpopulation was identified that benefitted from the addition of r-hLH to r-hFSH.
Limitations, reasons for caution: Although a definition of POR aligned with the ESHRE Bologna criteria was used, some degree of clinical heterogeneity still existed within the population which may have impacted the outcome.
Wider implications of the findings: This study demonstrated that, in the worst prognosis patient, with POR aligned with the Bologna criteria, no benefit from fixed-ratio r-hLH supplementation during COS was seen.
Trial registration number: ClinicalTrials.gov identifier: NCT02047227; EudraCT Number: 2013-003817-16.

O-034 Are AMH level and AFC useful predictors of outcomes in poor ovarian responders? A post hoc analysis of the ESPART randomized controlled trial

W. Chin[1], J. Hubbard[2], P. Humaidan[3]
[1]*EMD Serono, Global Biostatistics & Epidemiology, Billerica, MA, USA*
[2]*EMD Serono, Global Clinical Development Center, Billerica, MA, USA*
[3]*Aarhus University, Faculty of Health, Skive, Denmark*

Study question: Are anti-Müllerian hormone (AMH) levels and antral follicle count (AFC) associated with outcomes in poor ovarian responders (PORs), aligned with the Bologna criteria?
Summary answer: In PORs, AMH levels and AFC were associated with the number of oocytes obtained, but not with ongoing pregnancy or live birth rates.
What is known already: In the general infertility population undergoing assisted reproductive technologies (ART) both AMH level and AFC are associated with the number of oocytes retrieved. This association has not previously been investigated in Bologna PORs. The ESPART study aimed to demonstrate superiority of a fixed-dose combination r-hFSH + r-hLH compared with r-hFSH in women with poor ovarian response aligned with the Bologna criteria (≥2 of the following: >40–<41 years; previous cycle with ≤3 oocytes retrieved with conventional stimulation; AMH level 0.12–1.3 ng/mL). No difference was observed between groups with regards to number of oocytes retrieved, ongoing pregnancy rates and live birth rates.
Study design, size, duration: Regression models investigating the number of oocytes retrieved, ongoing pregnancy and live birth rates were developed using ESPART study data. For the number of oocytes retrieved, a Poisson regression model was used with AMH level, AFC and age as explanatory variables. Logistic regression models for ongoing pregnancy rate and live birth rate included these terms and also the number of oocytes retrieved as explanatory variables. Association between terms was investigated using the Pearson correlation coefficient.
Participants/materials, setting, methods: The intention-to-treat population from ESPART was used (939 patients; r-hFSH + r-hLH, $n = 462$; r-hFSH, $n = 477$). The mean age was 38.3 years, the mean AMH level was

0.59 ng/mL and the mean AFC was 4.8. The mean number of oocytes retrieved was 3.3 and 3.6 in patients receiving r-hFSH + r-hLH and r-hFSH, respectively. There were 51/462 (11.0%) and 59/477 (12.4%) ongoing pregnancies with r-hFSH + r-hLH and r-hFSH, respectively, and 49/462 (10.6%) and 56/477 (11.7%) live births, respectively.
Main results and the role of chance: In this population of PORs ($n = 939$), the AMH level and AFC were strongly associated with the number of oocytes retrieved ($P < 0.0001$ for both), whereas age was not ($P = 0.082$). The AMH level was associated with AFC (Pearson correlation coefficient = 0.346; $P < 0.0001$). Age and the number of oocytes retrieved were strongly associated with ongoing pregnancy rate ($P = 0.003$ and <0.0001, respectively) and live birth rate ($P = 0.006$ and <0.0001, respectively), whereas AMH level and AFC were not associated with ongoing pregnancy rates ($P = 0.102$ and 0.096, respectively) or live birth rates ($P = 0.163$ and 0.096, respectively). Overall there was a trend for higher ongoing pregnancy and live birth rates in patients with AMH levels >0.5 and ≤1.1 ng/mL. Ongoing pregnancy rates were 9.8% (46/472), 14.2% (52/366) and 10.5% (10/95) in patients with AMH levels ≤0.5, >0.5–≤1.1 and >1.1 ng/mL, respectively; live birth rates were 9.3% (44/472), 13.7% (50/366) and 9.5% (9/95), respectively. Likewise, when only patients with AMH levels of ≤1.1 ng/mL were included ($n = 838$), comparable outcomes were obtained from the regression models, with AMH levels and AFC being associated with number of oocytes retrieved ($P < 0.0001$ for both) but not with ongoing pregnancy ($P = 0.137$ and 0.339, respectively) or live birth rates ($P = 0.212$ and 0.292, respectively).
Limitations, reasons for caution: Although a regression model can indicate associations between baseline characteristics and outcomes, this does not confirm a causal relationship. Furthermore, the ESPART study inclusion criteria were aligned with the Bologna criteria, but not identical to them. Therefore, these results may not be applicable to the strict Bologna criteria POR population.
Wider implications of the findings: This analysis suggests that although AMH level and AFC may provide guidance on controlled ovarian stimulation outcomes, in this population they do not predict the live birth rate. Age, however, was related to live birth rate and, therefore, should be considered when informing patients about outcomes.
Trial registration number: ClinicalTrials.gov identifier: NCT02047227; EudraCT Number: 2013-003817-16.

O-035 Optimization of outcome through individualized dosing in predicted poor responders undergoing IVF/ICSI; the OPTIMIST randomized controlled trial, NTR2657

Study question: Does an individualized dose of gonadotropin based on the antral follicle count (AFC) improve live birth rates in predicted poor responders undergoing IVF/ICSI?
Summary answer: Individualized dosing of gonadotropin based on the AFC does not improve the 18 months cumulative live birth rate in predicted poor responders.
What is known already: It is common practice to adjust the gonadotropin dose when a poor response is predicted based on ovarian reserve tests or after a poor response in a previous cycle. However, evidence such dose adjustments is limited.
Study design, size, duration: A multi-center cohort study in women starting their first IVF/ICSI cycle. Women with a predicted poor response (AFC < 11 follicles sized 2–10 mm) were randomized between an adjusted (225 (AFC 8–10) or 450 IU FSH (AFC < 8)) and standard dose of 150 IU FSH. Primary outcome was ongoing pregnancy leading to live birth <18 months after randomization. We needed to include 300 women to demonstrate a 15% gain in live birth rate (two-sided alpha-error 0.05, power 80%).
Participants/materials, setting, methods: Of 1503 women included in the cohort, 501 (33%) were predicted poor responders of which 238 were randomized to an adjusted (N = 107 received 450 IU FSH; N = 131 received 225 IU FSH) and 263 women to a standard dose. Following strict, predetermined criteria, limited dose adjustment in subsequent cycles was allowed in the standard treatment group only.

Pregnancies achieved <18 months after randomization and that are still ongoing at present are considered as live births (N = 39).
Main results and the role of chance: Women were included between May 2011 and May 2014. Baseline characteristics were comparable amongst groups. The rate of cumulative ongoing pregnancies leading to live birth rate from any transfer of fresh or frozen/thawed embryos within 18 months did not differ between adjusted and standard treatment (41% vs. 41%, corresponding to a RR of 1.0 [CI 95% 0.8–1.2]). Average time to positive pregnancy test leading to live birth was comparable in both groups (5.1 months for the adjusted group vs. 4.5 months in standard treatment, p = 0.334)

In first cycles (fresh and frozen/thawed embryos), no difference between groups was seen in live birth rate (18% in adjusted treatment vs. 18% in standard treatment, RR 1.0[95% CI 0.7–1.5]). A higher number of oocytes was retrieved in the adjusted dose group (7.6 vs. 6.5, mean difference 1.1[95% CI of the difference 0.2–2.0]). Also, in the first cycle, overall cycle cancellation rate was lower in the adjusted treatment group (8% vs. 23% in the standard treatment group, RR 0.3 [95% CI 0.2–0.6]). First cycles were mostly cancelled due to a poor response; 7% in the adjusted treatment group vs. 21% in the standard treatment group, RR 0.32 [95% CI 0.19–0.54].
Limitations, reasons for caution: Although we provided ultrasound training and guidelines, no quality control system was operational for AFC-measurements. Despite reported sufficient inter-observer reproducibility, categorization may have been imprecise. Stratified randomization, however, will have ensured comparability.

Secondary outcomes were based on first cycle data. Complete cumulative data will be available at the ESHRE meeting.
Wider implications of the findings: AFC-based individualized gonadotropin dosing in predicted poor responders does not improve live birth rates and should therefore not be clinical practice. In the first cycle, adjustment led to more oocytes and fewer cancellations, without influencing live birth rates or time to pregnancy, suggesting extra oocytes do not produce quality advantage.
Trial registration number: Registered at the "Dutch Trial Registry" (www.trialregister.nl). Registration number: NTR2657.

O-036 Optimization of outcome through individualized dosing in predicted hyper responders undergoing IVF/ICSI; The OPTIMIST randomized controlled trial, NTR2657

[10]Rijnstate Hospital, Obstetrics and Gynecology, Arnhem, Netherlands
[11]VU Medical Center, Obstetrics and Gynecology, Amsterdam, Netherlands
[12]Academic Medical Center, University of Amsterdam, Obstetrics and Gynecology, Amsterdam, Netherlands

Study question: Does an individualized dose of gonadotropins based on the antral follicle count (AFC) improve live birth rates in predicted hyper responders undergoing IVF/ICSI?
Summary answer: Gonadotropin dose adjustment in predicted hyper responders does not influence live birth rates, while it increased first cycle cancellations for a reduction in mild/moderate OHSS.
What is known already: Exaggerated ovarian response to gonadotropin stimulation for IVF may result in increased rates of cycle cancellation, the occurrence of complications such as the ovarian hyperstimulation syndrome (OHSS), and even slightly jeopardize live birth rates. In daily practice, lower gonadotropin doses are often administered to predicted hyper responders for safety reasons. However, no knowledge is available on whether such individualized gonadotropin dosing does indeed improve safety and increase efficacy and efficiency compared to a standard dose.
Study design, size, duration: A nationwide, multi-center cohort study in women scheduled for a first IVF/ICSI treatment. Women with a predicted hyperresponse based on their AFC (>15 follicles) were invited to participate in an RCT comparing an adjusted dose (100 IU FSH) to standard treatment (150 IU FSH). Since this RCT was embedded in a cohort study assessing over 1500 women, we expected to randomize 300 couples. Primary outcome was ongoing pregnancy leading to live birth within 18 months after randomization.
Participants/materials, setting, methods: Women were included between May 2011 and May 2014. From the 1503 women included in the cohort study, in 531 (35.3%) a hyperresponse was predicted and they were randomized to receive the adjusted fixed dose (100 IU, N = 258) or standard fixed dose; (150 IU, N = 273). Following strict, predetermined criteria, small dose adjustments were allowed in subsequent cycles.

Pregnancies achieved <18 months after randomization and that are still ongoing at present, are considered as live births (N = 39).
Main results and the role of chance: Baseline characteristics were comparable. The primary outcome, ongoing pregnancy rate from any transfer of fresh or frozen/thawed embryos leading to live birth <18 months after randomization, was 68% in the adjusted vs. 68% in the standard group (RR 1.0[95% CI 0.89–1.12]). Average time to positive pregnancy test leading to live birth was comparable in both groups (4.6 vs. 4.6 months, p = 0.749). In the first cycle (fresh and frozen/thawed embryos), live birth rates were 33% vs. 37% (RR 1.1(95% CI 0.9–1.4]).

In firsts cycles, the number of retrieved oocytes was significantly lower in the adjusted group (8.9 and 13.3, mean difference −4.4[95% CI−5.4–3.3]). Overall cycle cancellation rate in the first cycle was higher in the adjusted dose group (25% vs. 13%, RR 1.94[95% CI 1.3–2.8]). Cancellation rates for poor response were 22% vs. 3% (RR 6.8[95% CI 3.5–13.5]) and cancellation rates for hyperresponse were 2% vs. 8% (RR 0.2[95% CI 0.1–0.6]). After the first cycle, mild OHSS occurred in 3% of women in the adjusted and in 12% of women in the standard group (RR 0.27[95% CI 0.13–0.57]), while moderate OHSS did not occur in the adjusted group compared to 3% in the standard

group (RR 0.01[95% CI 1.01–1.05]). Incidence of severe OHSS was comparable (1.2% vs. 1.1%).

Limitations, reasons for caution: Although we provided ultrasound training and guidelines, no quality control system was operational for AFC-measurements. Despite reported sufficient inter-observer reproducibility, categorization may have been imprecise. Stratified randomization, however, will have ensured comparability.

Secondary outcomes were based on first cycle data. Complete cumulative data will be available at the ESHRE meeting.

Wider implications of the findings: In women with a predicted hyperresponse scheduled for IVF/ICSI, an adjusted dose does not affect live birth rates or time to pregnancy, despite a clearly reduced ovarian response. While dose adjustment limited the occurrence of mild/moderate OHSS, it also increased the cancellation rate and therefore cost-effectiveness should be further assessed.

Trial registration number: Registered at the "Dutch Trial Registry" (www.trialregister.nl). Registration number: NTR2657.

Study question: Is ovarian reserve testing with the antral follicle count (AFC) and subsequent dose adjustment of gonadotropins cost-effective in women undergoing IVF/ICSI?

Summary answer: Ovarian reserve testing with the AFC and subsequent dose adjustment of gonadotropins is not more cost-effective than a standard dosing strategy in women undergoing IVF.

What is known already: While it has become common practice to assess ovarian reserve in women scheduled for IVF/ICSI and subsequently adjust the gonadotropin dose in case of a predicted poor or hyperresponse, it is unknown whether such a policy is cost-effective.

Study design, size, duration: We performed a multi-center cohort study with two embedded clinical trials in women starting their first IVF/ICSI cycle. We then developed a model comparing costs and effects of two strategies: (I) AFC measurement with gonadotropin dose adjustment (ORT strategy) or (II) standard dosing (SD) strategy. We calculated the number of live births, the number of cycles, the amount of FSH used and the number ovarian reserve tests performed for both strategies.

Participants/materials, setting, methods: Women with a predicted poor response (AFC < 11 follicles sized 2–10 mm) were randomized between an adjusted (225 (AFC 8–10) or 450 IU FSH (AFC < 8)) and standard dose of 150 IU FSH, while women with a predicted hyper response (AFC > 15) were randomized between an adjusted (100 IU FSH) and standard dose of 150 IU FSH. Women with a predicted normal response (AFC 11–15) received a standard dose of 150 IU FSH.

Main results and the role of chance: Between May 2011 and May 2014, we included 1503 women in the cohort, of whom 471 (31%) had a predicted normal response, 501 (34%) a predicted poor response and 531 (35%) a predicted hyper response. Both the ORT and SD strategy resulted in comparable ongoing pregnancy rates leading to live birth of 56%. The mean total number of cycles per patient was 1.8 in the ORT strategy and 1.9 in the SD strategy. The reduction of cycles for the ORT strategy was mainly achieved in the predicted poor responders (1.7 cycles/patient for the ORT strategy vs. 2.1 cycles/patient for the SD strategy). The mean number of 600 IU multidose FSH pens applied per patient was 7.0 in the ORT strategy and 4.8 in the SD strategy. This resulted in an average total cost per patient of €4,149 in the ORT strategy and €4,121 in the SD strategy.

Limitations, reasons for caution: Although we provided ultrasound training and guidelines, no quality control system was operational for AFC-measurements. Despite reported sufficient inter-observer reproducibility, categorization may have been imprecise.

Wider implications of the findings: From a cost-effectiveness perspective, AFC-based dosing has no advantage over standard dosing. However, in the ORT strategy, predicted poor responders underwent less cycles to achieve the same number of live births. In addition, safety aspects related to the prevention of hyperresponse may influence the final valuation of AFC-based dosing.

Trial registration number: Registered at the "Dutch Trial Registry" (www.trialregister.nl). Registration number: NTR2657.

O-038 Testosterone pre-treatment in poor responders treated with GnRH analogues and gonadotrophins for *in vitro* fertilization: a meta-analysis

J. Bosdou[1], E. Kolibianakis[1], C. Venetis[2], T. Tarlatzi[1], K. Chatzimeletiou[1], L. Zepiridis[1], B. Tarlatzis[1]
[1]*Aristotle University of Thessaloniki, 1st Department of Obstetrics and Gynecology, Thessaloniki, Greece*
[2]*University of New South Wales, Dept. of Women's and Children's Health. St George Hospital, School of Women's and Children's Health, Kogarah, Australia*

Study question: Does pre-treatment with testosterone improve the probability of pregnancy in poor responders undergoing ovarian stimulation for *in vitro* fertilization (IVF)?

Summary answer: Testosterone pre-treatment in poor responders undergoing ovarian stimulation for IVF is associated with a significant increase in the probability of clinical pregnancy and live birth.

What is known already: Testosterone pre-treatment has been administered in poor responders undergoing ovarian stimulation for IVF, on the premise that it increases ovarian sensitivity to follicle stimulating hormone (FSH), leading to an improved ovarian response. Several relevant randomized controlled trials (RCTs) have been recently published, evaluating such an intervention without, however, leading to solid conclusions, mainly due to their small sample size.

Study design, size, duration: A literature search was performed until January 2016 aiming to identify RCTs evaluating testosterone pre-treatment in poor responders. Outcome measures included achievement of pregnancy, duration of stimulation, number of cumulus oocyte complexes (COCs), number of 2-pronuclei (2pn) oocytes and number of embryos transferred.

Participants/materials, setting, methods: Five eligible RCTs were identified including 362 patients evaluating testosterone pre-treatment in the form of transdermal (n = 4) or oral (n = 1) testosterone. The dose of transdermal testosterone ranged from 10 mg to 12.5 mg for 15 to 21 days, while testosterone was given per os at a dose of 40 mg/d for 48 days.

Main results and the role of chance: Testosterone pre-treatment was associated with a significantly higher probability of clinical pregnancy (RR: 2.44, 95% CI: 1.47 to 4.03) and live birth (RR: 2.12, 95% CI: 1.20 to 3.76). Moreover, it was associated with significantly lower total dose of gonadotrophins (WMD: −299.73 IU, 95% CI: −552.57 to – 46.89), significantly more COCs (WMD: +0.87 COCs, 95% CI: +0.18 to +1.57) and more 2pn oocytes (WMD: +1.04 2pn oocytes, 95% CI: +0.66 to +1.42). In patients pre-treated with testosterone compared to those who were not, no significant differences were observed in duration of stimulation (WMD: −0.57 days, 95% CI: −1.18 to +0.04, respectively) and in the number of embryos transferred (WMD: +0.15 embryos, 95% CI: −0.06 to +0.36, respectively).

Limitations, reasons for caution: The definition of poor ovarian response as well as the protocols of the proposed interventions and ovarian stimulation protocols varied among studies. Moreover, due to the limited number of studies identified, a meaningful evaluation of clinical heterogeneity was not feasible.

Wider implications of the findings: Currently, based on the limited available evidence, testosterone pre-treatment seems to increase clinical pregnancy and live birth rates in poor responders undergoing ovarian stimulation for IVF.

However, further studies are necessary to increase our confidence to the currently available evidence as well as the precision of the estimates.

O-039 Naïve pluripotent stem cells: the key to success for *in vitro* gametogenesis?

J. Hanna[1]
[1]*The Weizmann Institute of Science, The Department of Molecular Genetics, Rehovot, Israel*

Abstract text
The identity of somatic and pluripotent cells can be epigenetically reprogrammed and forced to adapt a new functional cell state by different methods and distinct combinations of exogenous factors. The aspiration to utilize such ex vivo reprogrammed pluripotent and somatic cells for therapeutic purposes necessitates understanding of the mechanisms of reprogramming and elucidating the extent of equivalence of the *in vitro* derived cells to their *in vivo* counterparts. In my presentation, I will present my group's recent advances toward understanding these fundamental questions and further detail our ongoing efforts to generate developmentally unrestricted human naive pluripotent cells. I will conclude by highlighting new avenues for utilizing epigenetic reprogramming to naïve pluripotency for unraveling critical gene regulatory mechanisms acting during early mammalian development and highlighting prospects for new platforms for human primordial germ cell and mature gamete developmental modelling.

O-040 Trophoblast stem cells to model earliest steps of placental development

P. Latos[1], A. Murray[1], V. Perez-Garcia[1], C. Senner[1], M. Hemberger[1]
[1]*The Babraham Institute, Epigenetics Programme, Cambridge, UK*

Abstract text
Trophoblast Stem Cells (TSCs) are an invaluable biomedical research tool to study early processes in placental development that are instrumental for pregnancy progression, healthy reproductive outcome and long-term wellbeing. Despite the importance of these processes for normal development, our understanding of the characteristics and requirements of TSCs, and the cues that drive self-renewal and differentiation, remain poorly understood. This is likely the reason why culture conditions for the long-term maintenance of human TSCs have still not been optimized.

Our efforts are focused on gaining a much more refined understanding of murine TSCs so to pave the way towards successful hTSC derivation. Here, we report on our newest insights into the transcriptional and epigenetic regulation of TSCs. We find that their self-renewal capacity is tightly controlled by a stoichiometry-sensitive network made up of the three interacting transcription factors Eomes, Elf5 and Tfap2c. All three factors, when present at approximately equal levels, promote TSC self-renewal. However, a shift in balance towards higher levels of Elf5 and Tfap2c promotes TSC differentiation by re-distributing the chromatin binding sites and activating a differentiation-promoting programme. These findings reveal that the stem cell state of TSCs is exquisitely labile, which may explain the difficulties to maintain their self-renewal potential. At the same time, we are pursuing a CRISPR-Cas9-driven knockout screen in TSCs to determine the origins of developmental abnormalities that may have a placental origin. These efforts demonstrate that our appreciation of the gene complexity required for normal placentation lags far behind that of the embryo itself, and indicates that a significant number of gene mutations causing embryonic defects may indeed be secondary to an abnormal placenta.

O-042 FSA exchange lecture: Validation of next-generation sequencing for testing chromosome aneuploidy in preimplantation embryos

P. Coleman[1], M. MARTIC[1], S. STOCK-MYER[1], L. WILTON[1],
[1]*Melbourne IVF, Preimplantation Genetics, Melbourne, Australia*

Abstract text
Aim: A variety of techniques for 24-chromosome analysis are currently available for clinical use in preimplantation genetic diagnosis for aneuploidy PGD-A. ArrayCGH (comparative genomic hybridisation) was the first widely available technology used for aneuploidy testing on embryos in PGD programs. Next generation sequencing (NGS) based aneuploidy testing has recently been introduced. Here we present the application of an NGS based chromosome testing system (Illumina, USA) on single cells and trophectoderm (TE) samples.
Method: Aliquots of whole genome amplified (Sureplex, Illumina, USA) DNA from either single cells or TE samples that had been previously analysed using arrayCGH were coded and subjected to NGS. The chromosome status of these samples was analysed with no knowledge of the previous arrayCGH result. Data was then unblinded and concordance determined.
Results: Amplified products from 170 single blastomeres and 8 TE samples were analysed by NGS. Results were obtained on 100% of amplified products. In each case the result obtained by NGS confirmed the clinical result diagnosed by array CGH (sample concordance 100%). Individual chromosome concordance was 99.97% (4271/4272).
Conclusion: This study has demonstrated that NGS can provide 24-chromosome aneuploidy results for single cells and TE samples with a high level of consistency to established array CGH methodologies. Our PGD laboratory is now participating in a world-wide randomised clinical trial to validate the clinical effectiveness of NGS technology.

As a result of our validation of this system we are now using NGS clinically for aneuploidy diagnosis and have processed and reported over 1000 samples.

O-044 Oocyte on crutches

C. Andersen Yding[1]
[1]*Copenhagen University Hospital Rigshospitalet, Section 5712- Laboratory of Reproductive Biology, Copenhagen, Denmark*

Abstract text

In the early/mid-1990s ICSI was developed for severe male infertility and enabled men to become farther with few or immotile sperm cells by facilitating fertilization of oocytes. Now the time has come for female counter part, the oocyte, to undergo development enhancing measures to help women who would otherwise have difficulties in becoming mothers. The mechanisms that cause oocytes to have difficulties to sustain fertilization and further development are now slowly being unraveled. Alongside comes new potential methods that may be employed to overcome these difficulties. Together with these very sophisticated ways of manipulating oocytes and indeed cellular components of oocytes or other cells have allowed development of experimental methods, which we have only seen the very first start of.

A major cause for the development of these new techniques is the fact that women wait too long to have children. The quality of the oocytes becomes reduced with age and one the main challenges for today's fertility clinics are reproductive aged women, who in their late thirties or later wants to conceive. Such women often either produce only a limited amount of oocytes and/or the quality is reduced to a limit where pregnancy becomes a difficulty.

One method that has attracted a lot of interest is a direct invasive method that aims to improve the quality of the oocyte. The energy consumption used to sustain fertilization is considerable and in some women's oocytes the cellular energy producer, the mitochondria, is not working optimally. A new method is now basically attempting to recharge the oocyte's energy producing capacity by injecting the woman's own mitochondria. Mitochondria contain their own DNA and are believed to undergo mutations more often than normal cellular DNA. In order to circumvent this problem the first attempt to use technique has employed a technique in which oogonial stem cells from a piece of ovarian tissue is produced from the patient herself. Only from oogonial stem cells, once established as a cell line, are the mitochondria purified and used to inject into the oocytes. Only preliminary clinical data have yet emerged and potential positive effect remains to be determined. It is now discussed whether the mitochondria actually needs to be derived from oogonial stem cells or may be derived from for instance granulosa cells, immature oocytes or preantral follicles from the same woman. Furthermore, mitochondria may be found in an activated form ready to produce energy and a more latent form in which energy production is less efficient, and it appears that only a small part of the oocytes mitochondria are active. Therefore, it may only necessary to inject relatively few activated mitochondria to enhance the energy production from the oocytes. The coming year's research will undoubtedly put light on these issues.

The lecture will in addition cover other aspects of performing oocyte performance enhancing measures to improve fertilizing capacity and the enable embryo production.

O-045 Non-invasive markers for embryo selection

H.N. Sallam[1]

[1]*Alexandria University Faculty of Medicine, Department of Obstetrics and Gynaecology, Alexandria, Egypt*

Abstract text

There exists a need for a reliable non-invasive method for embryo selection in women undergoing IVF to maximize the chances of a live birth and minimize the incidence of multiple pregnancies and its complications. Many methods have been suggested and practiced and the aim of this presentation is to evaluate these methods in the light of evidence. Proper evaluation requires constructing a receiver operating characteristic (ROC) curve followed by a randomized trial (RCT) in single embryo transfer cycles.

Since the beginning of IVF, embryos were selected on the basis of their morphology at the pronuclear stage (Scott et al., 2000), the cleavage stage (Giorgetti et al., 1995; van Royen et al., 1999; Hsu et al., 1999; Houghton et al., 2002) or the blastocyst stage (Gardner et al., 2000). Attempts at giving more subjectivity to morphological selection by calculating a graduated embryo score (Fisch et al., 2001) or by the computerized transformation of the embryo picture into a mathematical vector have not shown their superiority (Manna et al., 2004). Embryo selection by natural depletion in women with a large number of embryos has also been practiced and a meta-analyses of RCTs show that the transfer of embryos at the blastocyst stage is associated with a small but significantly higher live birth rate compared to cleavage stage transfers (Glujovsky et al., 2012).

A more recent approach is embryo selection on the basis of morpho-kinetics studied by time lapse photography (TLP) and the constructions of algorithms based on defined kinetic and morphologic markers. Despite the early optimism, a recent Cochrane review found insufficient evidence of differences in live birth or clinical pregnancy between TLP and conventional incubation (Armstrong et al., 2015) and a recent RCT concluded that embryo selection by TLP did not significantly improve clinical reproductive outcomes (Goodman et al., 2016). Embryo selection on the basis of oxygen consumption (OC) by embryos has also been tried, but a prospective RCT is still needed to confirm the validity of this method (Tejera et al., 2012).

Biochemical markers have also been studied in the spent culture medium in an attempt to select the embryo(s) with the best potential for implantation. These include pyruvate and glucose uptake as well as lactate production (Gott et al., 1990) and recently Gardner et al found that glucose uptake on day 4 of human embryonic development was significantly higher in embryos resulting in pregnancy (and in those resulting in female offspring) (Gardner et al., 2011). Similarly, Houghton et al studied the amino acids turn-over rate in the spent culture medium of embryos and found different patterns in embryos achieving pregnancy compared to those that did not (Houghton et al., 2002). Measurement of embryo metabolomics by spectroscopic analysis (Seli et al., 2010) as well as by nuclear magnetic resonance (Kirkegaard et al., 2014) has also been tried. However, a meta-analysis of 4 prospective randomized trials found no evidence that near infra-red (NIR) spectroscopy of spent embryo culture media improves live birth rates (Vergouw et al., 2014). Soluble human leukocytic antigen G (s-HLA-G) fragment was also studied and found to be a good predictor of embryo viability (Vercammen et al., 2008). However, prospective RCTs are still needed to confirm the validity of this method. Other biochemical markers include β-HCG, haptoglobin-α-1 fragment and platelet activating factor (PAF) (Xiao-Yan et al., 2013; Montskó et al., 2015; Roudebush et al., 2002). Finally, embryo selection by measurement of oxidative stress has been tried with promising results but prospective RCTs are still awaited (Wiener-Megnazi et al., 2011).

In summary, morphology assessment by an experienced embryologist remains the best available method for embryo selection until otherwise proved.

Monday 04 July 2016 **Hall 5 CB** **14:00–15:00**

O-046 The value of tele-monitoring in IVF/ICSI

J. Gerris[1]

[1]*University Hospital Ghent, Centre for Reproductive Medicine – Deptartment of Ob/Gyn, Gent, Belgium*

Abstract text

The need for serial vaginal sonograms to monitor ovarian stimulation for artificial reproductive technology (ART) treatments remains a cause for stress and sometimes a major practical challenge both for patients and health care providers. It hampers access to treatment for many couples seeking ART treatment or renders it strenuous from an organizational point of view. It creates a hidden cost when people have to travel frequently to have sonograms made or have to plan a hotel stay near the centre where oocyte retrieval and IVF embryology work take place. We have been exploring over the past couple of years the possibilities of a method (Self-Operated Endo-vaginal Tele-monitoring, SOET) allowing patients and/or their partners to make vaginal sonograms themselves at home or in fact anywhere and anytime if WiFi is available. Specific cloud-based communication software has been developed that can be installed on any notebook or tablet PC. If applicable, midwives, nurses or other health care providers such as general practitioners working independently from highly specialized services, can also perform these recordings. Current experience includes results from a published randomized trial (Hum. Reprod. 2014) comparing SOET with traditional monitoring as well as from a subsequent series of one hundred consecutive ART cycles where patients used SOET instead of traditional monitoring to monitor the stimulation phase. Clinical, laboratory and patient reported outcome data as well as health economic data show that after some initial teaching motivated patients are sufficiently prepared and competent to make and send adequate video recordings to the centre or to the physician following them up. The interpretation of these recordings does not lead to different

clinical decisions than when made on-site using high-end machines. On-site back-up remains always possible if there is a need to confirm unexpected results. This was the case is just 1% of patients. Laboratory and clinical results are similar to those obtained with traditional monitoring and patients are very satisfied with SOET. They can make sonograms discretely where and when it suits them best. Receipt of images and of responses is acknowledged by SMS. After measurement of the growing follicles, a structured response is sent to the patient, comprising dosing advice and next-step instructions. This facilitates the follow-up of ovarian stimulation, even if applicable initially to just a selected proportion of IVF patients. It can fit into the general tendency to make IVF more patient-centred and -friendly, to implement tele-medicine and increase patient empowerment and partner participation by supervised active participation to their treatment. It opens up access to treatment for patients who live far from IVF centres and widens the scope of patient recruitment for centers.

If combined with point of care determinations of estradiol to monitor patients at risk for OHSS, SOET may acquire a place in ART although the most recent Cochrane meta-analysis concludes that systematic E2 measurements do not increase pregnancy rates nor decrease the incidence of OHSS.

Impediments for implementation of this technology are disruption of the comfort zone of doctors, the novelty of the technology and financial considerations. SOET is not just a tool, but a disruptive change of practice where the patient and her partner are playing a central and active role in their treatment.

O-047 Optimising IVF outcome by monitoring serum progesterone levels during ovarian stimulation

C. Venetis[1]
[1]*University of New South Wales, UNSW Medicine, Sydney, Australia*

Abstract text
The prognostic role of progesterone elevation (PE) for the outcome of a fresh IVF cycle has been debated for more than 20 years. Following the publication of a meta-analysis of more than 60,000 cycles, there is now unequivocal evidence that in the presence of elevated progesterone on the day of hCG administration for final oocyte maturation the probability of pregnancy after a fresh embryo transfer is significantly reduced. This effect, believed to be exerted *via* the action of progesterone on the endometrium, is not negligible, since in certain cases it can be translated to a relative reduction of 30% or more in the effectiveness of an IVF cycle.

Not surprisingly, this has ignited a discussion among clinicians and clinical researchers on what is the most efficient way serum progesterone levels can be incorporated in routine monitoring in order to optimize IVF outcome.

Firstly, it has been shown that the cut-off of PE on the day of hCG might be not be the same for each clinic. This is highly dependent on the assay and the individual characteristics of the population treated in each setting. In order to identify the net effect of PE on the treated population of a specific IVF clinic, a rigorous methodological approach has to be applied with the removal of the potential confounding effect of a range of variables, including female age, the number of oocytes retrieved and the quality of the embryos transferred.

Some authors have also tried to identify a potentially better prognostic tool for IVF cycles that incorporates the serum concentration of progesterone. The measurement of progesterone on consecutive days during the late follicular phase and the calculation of the relevant area under the curve, as well as the ratio of progesterone-to-estradiol or progesterone-to-follicle have been proposed. However, there is no convincing evidence that these convey any benefit when compared to a single progesterone measurement on the day of hCG and, in certain cases, their physiological basis is questionable. The answer might actually be a more straightforward and physiologically sound approach which involves the incorporation of the serum progesterone concentration on the day of hCG in a prognostic model for live birth after IVF.

Two main strategies have been proposed in order to counteract the detrimental effect of elevated progesterone on pregnancy rates after a fresh embryo transfer. Prevention of the occurrence of PE and freezing-all embryos and deferring transfer in a frozen–thawed embryo transfer cycle.

Since PE on the day of hCG is known to be strongly associated with the magnitude of ovarian response, mild ovarian stimulation has been suggested as a method to prevent its occurrence. Identifying patients at high risk for PE is a key component of this strategy. Apart from known risk factors of high ovarian response, basal progesterone and previous history of PE have been shown to be strong predictors of PE on the day of hCG after ovarian stimulation for IVF.

Finally, in the presence of elevated progesterone on the day of hCG, elective cryopreservation of all embryos and subsequent transfer in a frozen–thawed embryo transfer cycle appears to be the most popular strategy, although high quality evidence originating from large RCTs is urgently warranted, especially for patients with a small number of oocytes retrieved.

INVITED SESSION

SESSION 13: CELLULAR INTERACTIONS IN OOCYTE PHYSIOLOGY

Monday 04 July 2016 **Hall 5 A** **14:00–15:00**

O-048 Dynamic imaging of the oocyte-granulosa dialogue

D. Albertini[1]
[1]*The Center for Human Reproduction, New York, NY, USA*

Abstract text
The ovarian follicle exploits the properties of a true cellular syncytium to maintain coordination of the processes of oogenesis and folliculogenesis. For over 30 years now, it has been appreciated that the syncytial properties of the follicle are dependent upon specialized intercellular junctions such as gap junctions mediating information exchange between granulosa cells and between granulosa cells and the oocyte. This presentation will review recent data on the role of specialized extensions from cumulus cells, known as transzonal projections (TZPs), in supporting the growth and maturation stages of oogenesis as revealed by the use of high resolution imaging modalities. TZPs are dynamic structures penetrating the zona and establishing specialized contacts with the oolemma in response to oocyte secreted factors during the growth stage of oogenesis and are negatively regulated by pulsatile FSH signals to establish the cumulus and mural cell lineages. The maintenance of a committed cumulus is required for the continued metabolic cooperation between somatic and germ cell compartments that includes provision of cholesterol synthesized in the cumulus and directly transferred to the oocyte *via* terminations of the oocyte that are both rich in mitochondria as well as vesicular exchange. The complexity of mechanisms available for intercellular molecular exchange at the cumulus-oocyte interface assures integration of the developing oocyte with that of its companion follicle and is likely at the heart of variations in oocyte and embryo quality observed with advanced maternal age.

O-049 RNA accumulation in competent oocytes

M.A. Sirard[1], A. Macaulay[1], R. Labrecque[1], E. Orozco-Lucero[1], D. Khan[1], C. Robert[1]
[1]*Université Laval, Deptartment of Animal Sciences, Quebec, QC, Canada*

Abstract text
The oocyte is invested with the responsibility of providing the infrastructure and the template for early embryonic development. The growth period must therefore prepare the oocyte for functions that are not required immediately but will be activated following the shutdown of transcription which occurs a few days prior to ovulation in most mammalian species. What can be stored in the form of proteins is already present in fully grown oocytes like cortical granules, most of the cytoskeleton and all organelles. In fact, the protein profile for the most abundant (~2000) proteins changes very slightly during that period but the mRNA profile and/or the de novo protein synthesis changes rapidly due to RNA accumulation and their specific recruitment. In larger mammals, unlike the mouse, the capacity of the oocyte to sustain embryonic development is not fully functional when the oocyte is fully grown but is acquired progressively as the follicles reaches dominance and it exhibits LH receptors. Therefore, the final accumulation of mRNA is critical during late folliculogenesis and specific follicular (granulosa cells) transcripts have now been associated with better developmental potential of the oocyte. In our bovine model, oocytes of different qualities can be generated by stimulating the development of dominant follicles with exogenous FSH and then depriving these follicles from FSH support for 1–2–3 or 4 days in the presence of low LH and high progesterone. This experiment increases oocyte quality as measured by blastocyst rates after IVF to an average of 75% in first 2 days followed by a decrease in quality at 4 days.

We have analyzed the RNA content by microarray and observed that transcripts associated with the control of mRNA processing are essential to support the embryonic program to follow. These mRNA can be followed through polyadenylation analysis, polysomal extraction and protein translation to identify those transcripts that are required during maturation, fertilization or early embryonic development. Although the source of these RNAs is believed to be principally from the oocyte nuclear transcription, recent evidences demonstrate that some RNA could be transmitted though trans-zonal projections. These RNAs would be synthesized in the cumulus, transported along the trans-zona projections and secreted as exosomes in the perivitellin space. This process was demonstrated using ultrastructure microscopy, immunohistochemistry, transfection analysis and genomic analysis. The oocytes show a rise in several transcripts in the last 2 days before ovulation and could be divided into two groups: the ones that may be used immediately and are present in the polysomes at metaphase II and the ones that have short poly-A tails and are present in higher quantity in early cleaving two-cells embryos, a sign of their implication in higher competence. The combination of several data sets now allow the identification of specific targets such as ATF1 that could be the result of final follicular signaling to improve oocyte quality before ovulation. In conclusion we believe that the follicle-cumulus-oocyte syncytium works as a single unit to ensure the proper accumulation of embryo-permissive mRNAs in the oocyte.

INVITED SESSION

SESSION 14: WHAT IS THE PROBLEM WITH ANONYMITY IN DONOR CONCEPTION?

Monday 04 July 2016 **Hall 3 AB** **14:00–15:00**

O-050 Anonymity in donor conception should not be allowed

P. Thorn [1]
[1]*Mörfelden, Germany*

Abstract text

In the context of donor conception, the term "anonymity" refers to the semen or egg donor/s being "nameless" for the intended parents and the child. Until the 1990s, anonymity as well as secrecy were common: It was feared that children may be confused about the "real" parent, bonding between the child and the social parent was assumed to be less secure if the child was aware of his/her conception, donors were not protected from legal paternity and medical professionals feared stigmatization if it became known that they carried out treatment socially unaccepted.

This has changed in the last two decades. In several countries, legislation has granted offspring the right to access the donor's identity and exempted the donor of any parental rights or responsibilities. Although there is no representative data, there is anecdotal evidence that an increasing number of parents share the donor conception with their child and significant others. Furthermore, more and more offspring are interested in securing information about their biological origins and indicate curiosity about half-siblings.

At the same time, the debate surrounding anonymous and identifiable donors remains controversial. Although sharing the conception with children even in countries with donor anonymity has become less exceptional, legislation itself in these countries remains unchallenged. Donors' identity remains shielded by legislation, as there are not only concerns that the number of donors may decline significantly if anonymity was abolished but also that family harmony may be strained if children knew their donor. In other countries, legislators send contradictory messages and add to ambiguities by granting offspring the right to access their biological origin but not protecting donors sufficiently from legal responsibilities. This suggests that some previous anxieties persist and that the stigma surrounding these (relatively) "new" family compositions continues.

In order to avoid frustration for offspring and provide them with equal rights as adoptees, it is vital to discontinue anonymity. Donor anonymity results in depriving offspring information about their biological heritage, which is taken for granted by many people in most cultures. Instead of minimizing the role of the donor, anonymity can have the adverse effect: Both parents and children may project unrealistic fantasies upon the donor and are unable to adjust them to reality. Current practice and anonymity also limits the information donors receive about the outcome of their donation and only little is known about their needs. However, there is an imbalance between the adult parties who can consent into an anonymous donation and the child who cannot. As long as there is the probability that children feel thwarted by anonymity, feel underprivileged in comparison to children in other family types and face the risk of an identity crisis, legislators have the duty to introduce legislation that avoids potential harm from these children.

However, legislating against anonymity is not sufficient. Infertility and donor conception are associated with deep-rooted stigmata which can only be tackled if a multi-level approach is applied: On the individual level, intended parents and donors should be recommended pre-treatment/pre-donation counselling in order to minimize anxieties and increase confidence; on the professional level, a framework for counselling imbedded in medical treatment and on-going multi-professional collaboration is needed; on the macro level legislative frameworks that protect the donor from responsibilities, that grant parents unambiguous legal maternity/paternity and offspring the right to access their biological origins as well as the possibility to contact half-siblings have to be introduced. If efforts are directed effectively at all three levels, the stigma will decrease, the dominant pattern of anonymity will change and donor anonymity will not be necessary anymore.

O-051 Anonymity in donor conception should be a parental choice

W.J. Dondorp[1]
[1]*University of Maastricht, Department of Health, Ethics, and Society HES, Faculty of Health, Medicine, and Life Sciences (FHML), Maastricht, Netherlands*

In this debate session I will defend that prospective parents should be allowed to choose between anonymous and open-identity gamete donation and that this approach best serves the interests of all parties concerned. I will argue that there are no good reasons for the mandatory anonymity that existed in the past. As there is no evidence that open-identity gamete donation entails a high risk of serious harm for the child, it is in line with the "welfare of the child" document of ESHRE's Task Force Ethics and Law (2007) to allow this as a parental choice. Many recipients of donor gametes find it important for their future child to have the opportunity to know the identity of the donor and perhaps also have contact with him or her. But similarly, there are no convincing arguments for disallowing the opposite. As there is no evidence that anonymity in donor conception entails a high risk of serious harm for the child, this should also be an option, available to recipients who have different views of what would best serve the interests of their child and their family. Either way, this should be respected as belonging to the sphere of parental responsibility. The tendency in several countries to move from mandatory anonymity to imposed non-anonymity is ethically problematic, as both positions limit reproductive freedom for no good reason. For some of those who are in need of donor gametes for reproduction open-identity donation is simply not an acceptable option. They may have difficulties accepting a potential role of the donor as a third person in the future life of their family, or have no intention to disclose the method of conception to their child (for instance because donor conception is not well accepted in their community). Imposed non-anonymity may mean that these people will see no other option but to go to countries with different legislation, or if that proves to costly, may have to refrain from having children altogether. This is a high price to pay, that would be justified if it could be shown that anonymous donation leads to serious harm for donor children. But that, I argue, is not the case.

SESSION 15: PARAMEDICAL 1 - NURSING

Monday 04 July 2016 **Room 101** **14:00–15:00**

O-052 Quality of life and predictive factors in a French cohort of infertile women undergoing assisted reproductive technology

J. Gonnot[1], M. Bourdon[1], V. Blanchet de Mouzon[1], C. Cervantes[1], V. Gayet[1], J. De Mouzon[2], P. Santulli[1], D. De Ziegler[1], C. Chapron[3]
[1]*Hopital Cochin Port Royal, Service Médecine de la Reproduction, Paris Cedex 14, France*

[2]Hopital Cochin Port Royal, INSERM, Paris Cedex 14, France
[3]Hopital Cochin Port Royal, Service de Gynécologie Obstétrique II et Médecine de la Reproduction, Paris Cedex 14, France

Study question: To evaluate quality of life (QOL) in a cohort of women undergoing assisted reproductive technology (ART) and to identify predictive factors of poor QOL.
Summary answer: In French women, the risk of poor QOL is significantly increased with shorter infertility duration.
What is known already: Many published studies reported that assisted reproductive technology (ART) could be stressful and affect QOL in infertile women. Boivin et al. (2011) developed the fertility quality of life (FertiQol) score. FertiQol items were designed to translate QoL into quantitative items that could collectively indicate the impact of fertility problems. To date, no study has been performed in a large French cohort of infertile women requiring ART.
Study design, size, duration: Retrospective observational cohort study conducted between 01/01/2014 and 31/06/2014 in a tertiary care university hospital. A total of 166 patients who underwent IVF or ICSI programs were analysed. QOL was assessed using FertiQol International evaluation before starting IVF treatment. The evaluation consists of two validated modules measuring QoL (the FertiQoL Core and the Optional FertiQoL Treatment module). We defined poor QOL as a Total FertiQol score below the 25th percentile.
Participants/materials, setting, methods: A total of 166 patients completed the self-administered FertiQol questionnaire. Women were allocated to two groups according to the situation of their total FertiQol score towards the 25th percentile: ≤25th (n = 40) or >25th percentile (n = 126). Statistical analysis was conducted using univariate methods and multivariate logistic regression models. Statistical significance was obtained for $p < 0.05$. In the logistic model, results were given as odds ratios (OR) with their 95% confidence interval (CI).
Main results and the role of chance: Median Total FertiQol score in our population was 65.44/100. The 25th percentile was 57.35/100. At univariate analysis, women with poor Qol (total FertiQol score ≤25th percentile) were significantly more often aged less than 38 years compared to the group of QoL higher than the 25th percentile (82.5 vs. 62.7%, $p = 0.02$). Similarly, an infertility duration of less than 5 years was more often observed (82.5 vs. 62.0%, $p = 0.02$). After multivariate logistic regression, only infertility duration of less than 5 years was associated with a Total FertiQol Score below the 25th percentile (OR = 3.89, 95% CI: 1.26–12.01, $p = 0.02$).
Limitations, reasons for caution: Young infertile women discover the difficulties of ART treatment, while older women, who have a long medical history of infertility, seemed to be more familiarized by care pathways, which could causes interferences between the answers.
Wider implications of the findings: Women with short duration of infertility were associated with worse QoL. These findings can be used to achieve a higher quality of care for patients, in order to increase their QoL. This may be added to the recent ESHRE guidelines on psychological counselling, according to women characteristics, published in 2015.
Trial registration number: Not applicable.

O-053 Fertility preservation brings hopefulness and wellbeing for young oncologic women

J. Assi[1], S. Juliana[1], B. Tatiana[2,3], E. Motta[3,4], P. Serafini[4,5], M. Chehin[3,6]
[1]Huntington Medicina Reprodutiva, Nurse, São Paulo, Brazil
[2]Huntington Medicina Reprodutiva, Scientific Department, São Paulo, Brazil
[3]Universidade Federal de São Paulo – Escola Paulista de Medicina UNIFESP-EPM, Departamento de Ginecologia – Disciplina de Ginecologia Endocrinológica, São Paulo, Brazil
[4]Huntington Medicina Reprodutiva, Clinical Head, São Paulo, Brazil
[5]Faculdade de Medicina da Universidade de São Paulo FM-USP, Departamento de Obstetrãcia e Ginecologia – Disciplina de Ginecologia, São Paulo, Brazil
[6]Huntington Medicina Reprodutiva, Clinical, São Paulo, Brazil

Study question: What are the feelings, worries, life's quality impact about fertility preservation in oncological patients?
Summary answer: Desire of motherhood is intrinsic to women, but cancers bring helplessness. Fertility-preservation brings hopefulness and safety; women would be disturbed if it wouldn't be performed.
What is known already: Infertility is a major consequence of cancer treatment. In young women the risk of ovarian failure after radiotherapy and/or chemotherapy is of concern, as it can reach up to 80% of cases. Thus, the worry about reproductive future of those patients deserves increased attention. There is no doubt about the psycho-emotional gains of fertility preservation after cancer diagnosis, as the impossibility of biological conception is one of reasons for anxiety and can affect even the cancer recovery. In addition, FP for cancer women can positively influence a patient's overall wellbeing by lessening anxiety due the chance fertility loss.
Study design, size, duration: This is a qualitative cross-sectional study based on a questionnaire applied to a selected group of women diagnosed of cancer, who underwent fertility-preservation at least 6 months before the study (November–December, 2015). Twenty-three eligible women were contacted by phone and the questionnaire was applied and completed in 16 women. Seven women were to follow-up. The structured questionnaire contained 16 questions, 14 multiple-choice and 2 opened questions.
Participants/materials, setting, methods: The questions enquired about actual cancer conditions, decision-making process of fertility-preservation, feelings at fertility-preservation moment, actual feelings, possibility of using the oocytes/embryos cryopreserved, importance and impact of fertility-preservation in their life. Participants could choice more than one option for the multiple-choice questions. We excluded one teenager and 15 women ageing 23–39 years were included in the study.
Main results and the role of chance: Among women interviewed, 10 became disease-free and 5 are under cancer treatment. At the moment of fertility-preservation, no patient had a child, and most of them (73%) declared wish of having children. When they were argued about feelings at the fertility-preservation time, the most frequent answers were hope (26.3%), safety (26.3%), relief (26.3%) and peacefulness (15.8%). One patient (5.3%) reported suffering. Regards the decision about fertility-preservation, time (38.8%) was the main challenging point, followed by financial costs (33.3%). At the interview, all women declared the importance of fertility-preservation; 73.4% stated that it is warrant the possibility of a biological pregnancy, due to risk of infertility after chemio-radiotherapy. Finally, women were argued "if they had not done the fertility-preservation, how would they feel and what would be the impact in their lives?" The answers stated emotional impairment, low quality of life, relationship problem and uncertainty about the maternity.
Limitations, reasons for caution: The number of women interviewed is a limitation. However, those are preliminary results and we are continuing the interviews when women had completed 6 months after fertility-preservation. Also, opened questions make interpretation difficult, but an appropriated analysis method will be used when a higher number of patients are included.
Wider implications of the findings: Fertility-preservation strategy for oncologic patients is a positive approach, as it increases the chance of biological child in the future. Beyond this, all women felt the fertility-preservation is a worth process and the safety of had done FP brings peacefully for the oncological treatment and higher quality of life.
Trial registration number: Not applicable.

O-054 The association between endometriosis patients' quality of life and the patient-centeredness of their care

S. Apers[1], E. Dancet[2], J. Aarts[3], K. Kluivers[3], T. D'Hooghe[2], W. Nelen[3]
[1]Leuven, Belgium
[2]KU Leuven, Leuven University Fertility Centre, Leuven, Belgium
[3]Radboud University Medical Center, Department of Obstetrics and Gynaecology, Nijmegen, Netherlands

Study question: Is quality of life associated with patient-centered care in women with endometriosis?
Summary answer: There was a trend towards a significant association between the quality of life of patients with endometriosis and the experienced patient-centeredness of their care.
What is known already: The physical symptoms of endometriosis can have a negative impact on women's quality of life. Qualitative studies suggest that endometriosis patients' quality of life is associated with the patient-centeredness of their health care. Quantitative studies showed a significant association between quality of life and patient-centered care in subfertile women but not yet in women with endometriosis.
Study design, size, duration: For this cross-sectional study, valid and reliable questionnaires were administered by postal mail in 2011. Non-responders received two reminders. In total, 109 out of 194 eligible patients responded (56%).

Participants/materials, setting, methods: Dutch speaking women having been diagnosed with endometriosis and treated by laparoscopy for pain and/or infertility in a Dutch tertiary fertility clinic between 2009 and 2010 were eligible. Quality of life was assessed with the Endometriosis Health Profile-30 (EHP-30) and patient-centeredness with the ENDOCARE-questionnaire (ECQ). For both measures scores were converted to a scale from 0 to 100. Higher scores reflected worse quality of life and less positive healthcare experiences. Linear regression analyses were conducted.
Main results and the role of chance: Participants had a mean age of 35 years. The majority self reported a diagnosis of moderate to severe endometriosis (79%) and experienced endometriosis-related symptoms during the past year (89%). The mean overall quality of life was 29/100 and the mean overall experience score for patient-centeredness was 38/100. Regression analyses found no significant associations between overall quality of life and any of the ten dimensions of patient-centered care after controlling for experiencing endometriosis-related symptoms during the past year. A trend towards a significant association between overall quality of life and the dimensions "respect for patients" values, preferences and expressed needs' (B = 0.19; p = 0.103) and "information, communication and education" (B = 0.26; p = 0.095) was observed. The "emotional well-being" dimension of quality of life was associated with the patient-centered care dimensions "information, communication and education" (B = 0.33; p = 0.046) and "respect for patients" values, preferences and expressed needs' (B = 0.29; p = 0.023). Additionally, the "social support" dimension of quality of life was also associated with the patient-centered care dimension "information, communication and education" (B = 0.42; p = 0.023).
Limitations, reasons for caution: The cross-sectional design of this study does not allow drawing conclusions on the direction of associations. The single-center setting resulted in a small sample size. This could, in turn, explain why no significant associations were found between overall quality of life and patient-centeredness.
Wider implications of the findings: Providing patient-centered care might lead to improved quality of life in women with endometriosis, especially if paying attention to the dimensions "respect for patients' values, preferences and expressed needs" and "information, communication and education." Large-scale longitudinal research is needed to investigate this further.
Trial registration number: NA.

O-055 Psychosocial vulnerability identified by screening in early pregnancy is not increased after fertility treatment.

M. Salomon[1], L. Eskildsen[2], I. Rose Joergensen[1], E. Carlsen[1], A. Loft[1], A. Nyboe Andersen[1]
[1]*Copenhagen University Hospital Rigshospitalet, Fertility Clinic, Copenhagen, Denmark*
[2]*Copenhagen University Hospital Rigshospitalet, Obstetric Clinic, Copenhagen, Denmark*

Study question: Is psychosocial vulnerability in early pregnancy increased after fertility treatment?
Summary answer: After early antenatal screening for psychosocial vulnerability similar risk prevalence was found among women who conceived with or without fertility treatment, but psychosocial-diagnosis differed.
What is known already: More than 10% of mothers develop postpartum depression (PPD), and additionally 5–10% show other mental reactions such as anxiety. In order to cope with psychosocial problems during pregnancy and postpartum, Danish pregnant women are classified using a risk score of 1–4, recommended by the National Board of Health. Women at risk, are offered additional care in an expanded antenatal care unit. According to Danish Law, if medical professionals before initiating fertility treatment suspect parenthood unsuitability, the patients should be referred to the State Administration in order to decide whether treatment can be offered or not.
Study design, size, duration: This cross-sectional study includes all pregnant women referred to the antenatal clinic, at Copenhagen University Hospital Rigshospitalet, through 2013–2015. At the antenatal clinic, a screening-program for psychosocial risk factors is carried out. The screening-program consists of a questionnaire. If the woman shows parameters of risk, follow-up by telephone-interview is made. Hereafter it is decided whether the patient should be referred to the Expanded Antenatal Care-Unit (EAC-Unit), a specialist-team of doctors, nurses, midwives, psychologists and social-workers.
Participants/materials, setting, methods: All patients (n = 18.038) referred to the antenatal clinic were classified according to methods of conception; i.e., conceived after fertility treatment (study group) or naturally conceived (control group). The prevalence of women referred to the EAC-Unit was calculated for the two groups and the psychosocial diagnoses were compared. The following diagnoses were recorded: depression, anxiety, eating disorders, other psychiatric diagnoses, various social problems, history of abuse, abuse in pregnancy, repeated miscarriages and previous stillbirth.
Main results and the role of chance: In total 1,877 (10.4%) of all the women referred to the antenatal clinic were pregnant after fertility treatments and of these 154 (8.2%) were referred to the EAC-Unit. In the control group of natural conceptions (n = 16.161; 89.6%) a similar proportion of pregnant women (1,519/16,161; 9.4%) were referred to the EAC-Unit. The following psychosocial diagnoses were recorded among the fertility patients versus the control group: (1) Depression and/or anxiety: 43/154 (27.9%) versus 470/1,519 (30.9%) (p = 0.44); (2) Eating disorders: 16/154 (10.4%) versus 154/1,519 (10.1%) (p = 0.92); (3) Other psychiatric diagnosis 10/154 (6.5%) versus 216/1,519 (14.2%) ($p \leq 0.05$); (4) Social problem 14/154 (9.1%) versus 257/1,519 (16.9%) ($p \leq 0.05$); (5) History of abuse 2/154 (1.3%) versus 46/1,519; (3.0%) (p = 0.22); (6) Abuse in pregnancy 0/154 (0%) versus 50/1,519 (3.3) ($p \leq 0.05$); (7) Repeated miscarriages 3/154 (1.9%) versus 20/1,519 (1.3%) (p = 0.54); (8) Previous stillbirth 9/154 (5.8%) versus 58/1,519 (3.8%) (p = 0.22); (9) Other problems/unclassified 57/154 (37.0%) versus 248/1,519 (16.3%) ($p < 0.01$).
Limitations, reasons for caution: Data were collected from a tertiary referral hospital, placed in the capital of Denmark, which includes highly specialized functions. The consequence for our investigation could be an increased prevalence of patients with psychosocial vulnerability, but this would influence the results in both groups.
Wider implications of the findings: Our results reflect the intention of the Danish law on ART that patients treated should be similar in terms of psychosocial characteristics compared to the general population. It is reassuring that the proportion of ART patients considered to need special psychosocial care did not differ from the background population.
Trial registration number: No trial number.

SESSION 16: PREIMPLANTATION GENETIC SCREENING AND MITOCHONDRIAL DNA

Monday 04 July 2016 **Hall 1** **15:15–16:30**

O-056 Day 7 blastocysts prove beneficial for preimplantation genetic screening cycles.

J.B. Whitney[1], N.L. Nugent[1], R.E. Anderson[1], M.C. Schiewe[1]
[1]*Ovagen Fertility, ART Laboratory, Newport Beach, CA, USA*

Study question: Are there benefits to culturing embryos 168 h post-insemination? Do day 7 blastocysts result in similar aneuploidy and implantation rates compared to day 5/6?
Summary answer: Culturing embryos to day 7 has proven beneficial to achieving viable euploid blastocysts. Day 7 growth is poor but euploidy is similar to day 5/6.
What is known already: Routine human blastocyst culture extends embryo development up to 6 days or 144 h post-insemination. *In vivo* embryo implantation is theorized to initiate sometime from 96 to 144 h post-insemination, but exact limits and timing are relatively unknown. Furthermore, it is hypothesized that *in vitro* cultured embryos may be delayed in their development compared to their *in vivo* counterparts. For many programs, embryos must display viability prior to transfer and/or cryopreservation, with subjective evaluations concluding on the sixth day of culture. With an embryos' ploidy status influencing implantation, it is unknown if prolonged embryo culture increases aneuploidy.
Study design, size, duration: A single center prospective observational cohort study analyzing 292 autologous oocyte cycles (average age: 37.3 ± 4.3) and 23 donor oocyte cycles yielded 1,565 fair-to-excellent quality blastocysts (i.e., BB to AA, respectively), between January 1, 2015 and December 31, 2015. These patients were enrolled in *in vitro* fertilization treatments involving blastocyst

biopsy/cryo-all cycles. All cycles included PGS with trophectoderm biopsy for aneuploidy determination. Only vitrified-warmed single euploid blastocyst transfers were performed. Differences were assessed by Chi-squared analysis.
Participants/materials, setting, methods: Patient embryos were cultured in Life Global media with LGPS under tri-gas incubation conditions, and biopsied at or beyond the full blastocyst stage. Embryos grown to day 7 failed to meet quality or expansion criteria to biopsy by day 6. All trophectoderm biopsy samples were analyzed using NextGen sequencing. These cycles resulted in 151 single embryo transfers; 87 using a day 5 blastocyst, 53 day 6 blastocysts and 11 day 7 blastocysts.
Main results and the role of chance: Day 7 blastocysts achieved a euploidy rate of 36% (n = 111) per biopsy with top quality day 7 blastocysts (i.e., AA, AB, BA) achieving 50% euploidy (n = 50). Although blastocyst formation on day 7 was poor and only accounted for 6.3% of all blastocyst development, the resulting transfer of euploid blastocysts (n = 11) achieved a 63.6% implantation, which was not statistically different than day 5 or day 6. Interestingly, there was an increased loss rate of 28.5% with the day 7 blastocysts. The ongoing pregnancy rate of 45.5% was lower ($p < 0.05$) than both the day 5 (75.9%) and day 6 (69.8%) embryos. There were no differences observed for implantation, embryonic/fetal loss or ongoing pregnancies between day 5 and day 6 blastocysts. Utilizing standard morphology grading, all top quality embryos maintained an average euploidy rate of 49.4%, showing no statistical difference between day 5, 6 or 7. Meanwhile, poor quality day 5 blastocysts achieved a statistically higher ($p < 0.05$) euploidy rate at 44.5% compared to poor quality day 6 (28.9%) and day 7 (24.6%) blastocysts.
Limitations, reasons for caution: The option to continue development past day 6 holds promise to attaining more viable embryos. It is of concern that extending embryo culture may increase possible detrimental effects. Yet, it is unknown if these day 7 blastocysts are at higher risk for any genetic, developmental or congenital risks.
Wider implications of the findings: An additional day of embryo growth allows extended possibilities for *in vitro* development. The success obtained questions the universal ideology that human embryos must blastulate by day 6 to be viable, and further questions if implantation failures are a result of an asynchrony between embryo and uterus.
Trial registration number: None.

O-057 Time-lapse analysis of preimplantation embryos affected by single chromosome abnormalities in PGS cycles

A. Colasante[1], V. Zazzaro[1], T. Riccio[1], A. Ruberti[1], E. Cursio[1], F. Scarselli[1], A. Lobascio[1], V. Casciani[1], A. Caragia[1], K. Litwicka[1], M. Minasi[1], A. Biricik[2], F. Spinella[2], F. Fiorentino[2], E. Greco[1]
[1]*European Hospital, Medicina della Riproduzione, Rome, Italy*
[2]*Genoma Group, Molecular Genetic Laboratory, Rome, Italy*

Study question: To analyze differences in morphokinetic development of preimplantation embryos affected by single chromosome aneuploidy in Preimplantation Genetic Screening (PGS) cycles.
Summary answer: A trend towards slower blastocyst formation time was found in embryos affected by monosomies involving the larger chromosomes (1–5) compared to smaller chromosomes (21–22).
What is known already: Standard morphology evaluation has been the most widespread approach in many laboratories worldwide to select the embryo with the higher implantation potential. Many aneuploid embryos were shown to be compatible with development until blastocyst stage and were proven to reach good morphology grades. After the introduction of time-lapse technology, is recently available a more deepen software analysis for the examination of embryo development which can take into account also the morphokinetic parameters. Several studies assessed the association between morphokinetics development and embryo aneuploidy, although a clear relationship is still unmarked.
Study design, size, duration: This retrospective study was performed from September 2012 to December 2015. The morphokinetic development of 2385 embryos obtained in 733 PGS cycles with trophectoderm biopsy and array Comparative Genomic Hybridization (aCGH), was analyzed. All embryos were individually cultured in a time-lapse incubator at 37°C, 6.0% CO_2, 5.0% O_2. Mean female age was 36.6 ± 4.07 years old. The morphokinetic data are expressed in hours ± standard deviation.
Participants/materials, setting, methods: Among single chromosome's aneuploidies, with both monosomies and trisomies represented almost equally, a comparison between two groups of affected embryos based on chromosome's size, was performed: embryos where the largest chromosomes (from 1 to 5) or the smallest chromosomes (21 and 22) are involved. The morphokinetic parameters observed were: IIPB extrusion, 2PN appearance, pronuclear fading, onset of 2- to 8-cell divisions, time between 3- and 4-cell stage, morulae (tM), blastulation (tB), expansion and hatching timing.
Main results and the role of chance: A total of 8816 oocytes were collected, 6412 MII were injected and 4719 fertilized (73.6%). On day-3, 4702 embryos were obtained (99.6%). On day 5–7, a total of 2546 blastocysts were obtained (54.1%); 2455 blastocysts were incubated with time-lapse technology. All of them were biopsied. The genetic result was conclusive for 2385 embryos (97.2%). A total of 70 embryos failed to amplify (2.8%); 927 embryos (38.9%) resulted euploid while 1458 embryos (61.1%) resulted aneuploid. Among these latter: 295 embryos (12.4%) were established monosomy; 224 embryos (9.4%) were trisomy diagnosed and 939 embryos (39.3%) had multiple chromosomal aneuplodies. Among monosomies, chromosomes from 1 to 5 or chromosomes 21 or 22 are involved in the same number of embryos (n = 50; 16.9%). Among trisomies, 30 embryos (13.4%) were identified concerning chromosomes from 1 to 5 and 45 embryos (20.1%) chromosomes 21 or 22. Only a trend toward slower development has been issued for morphokinetic analysis of embryos where monosomy involves larger chromosomes showing that the morulae and blastocyst stage are reached and fully expand slightly slower if compared to smaller chromosomes: tM_{1-5} = 97.0 ± 11.1, tM_{21-22} = 93.0 ± 9.1 (p = 0.057); tSB_{1-5} = 106.3 ± 10.8, tSB_{21-22} = 102.2 ± 10.2 (p = 0.062); tB_{1-5} = 114.5 ± 11.1, tB_{21-22} = 110.4 ± 9.9 (p = 0.056); tEB_{1-5} = 124.4 ± 12.5; tEB_{21-22} = 119.1 ± 11.7 (p = 0.058). No statistical differences were found for the remaining morphokinetic parameters.
Limitations, reasons for caution: Restrained number of embryos enrolled in this study represent a limit to the amplitude of such findings. Moreover there is still a large discordance in the literature regarding the usefulness of different morphokinetic parameters to predict blastocyst development and implantation potentials as well as the related ploidy status.
Wider implications of the findings: Morphokinetic parameters are increasingly applied as informative for embryo competence to implant. This biological methodology require newer efforts, as literature's never-ending evidences are controversial. This study is meant to put forward novel insights which may help to clarify those prognostic factors that can predict embryo viability and its ploidy status.
Trial registration number: Not available.

O-058 Evidence that differences between embryology laboratories can influence the rate of mitotic errors, leading to increased chromosomal mosaicism, with significant implications for IVF success rates

D. Wells[1], S. Alfarawati[2], S. Taylor[2], N. Kubikova[2], K. Spath[2], K. Turner[3], C. Hickman[4], E. Fragouli[2]
[1]*Reprogenetics UK, Oxford, UK*
[2]*Reprogenetics UK, Institute of Reproductive Sciences, Oxford, UK*
[3]*Oxford Fertility Unit, Institute of Reproductive Sciences, Oxford, UK*
[4]*Boston Place, IVF Laboratory, London, UK*

Study question: Do individual IVF clinics have different rates of chromosome abnormality in the embryos they produce, and if so, what might explain the differences observed?
Summary answer: Aneuploidy rates vary significantly between clinics. This is largely attributable to differing mitotic error rates, leading to chromosomal mosaicism, likely associated with suboptimal embryo culture.
What is known already: It is widely assumed that the incidence of aneuploidy in human preimplantation embryos is patient specific, principally influenced by female age, and little affected by variations in IVF laboratory procedures. What little debate there has been has tended to focus on the impact of alternative stimulation procedures on the risk of oocytes experiencing a meiotic error, becoming chromosomally abnormal, and ultimately producing an aneuploid embryo after fertilisation. To date, no convincing evidence has been presented indicating any effect on aneuploidy rate of differing embryo culture procedures, equipment or consumables, yet this remains an intriguing possibility worthy of further investigation.
Study design, size, duration: A total of 623 blastocyst stage embryos, derived from seven different IVF clinics, were biopsied and subjected to comprehensive chromosome screening. These analyses were part of routine preimplantation genetic screening (PGS) undertaken at a single genetic reference laboratory.

Participants/materials, setting, methods: Trophectoderm (TE) biopsy was followed by whole genome amplification and cytogenetic assessment. In order to provide the most rigorous evaluation, a well-validated next-generation sequencing (NGS) methodology was utilised. NGS provides highly accurate detection of aneuploidy affecting any chromosome. Additionally, it allows losses and gains of chromosomal fragments (segmental aneuploidy) to be detected. Finally, NGS has the greatest dynamic range of any chromosome screening method currently available, thus allowing sensitive detection of mosaic chromosome abnormalities.
Main results and the role of chance: Analysis of large numbers of blastocyst stage embryos confirmed that overall aneuploidy rates, seen in individual clinics, were similar once variation in maternal age had been accounted for. This confirms that the incidence of meiotic error in oocytes and sperm is relatively unaffected by differences in the protocols employed. The use of NGS provided an opportunity to examine the incidence of chromosomal mosaicism, caused by errors that occur in the mitotic divisions following fertilisation. The evaluation of appreciable numbers of embryos for mosaicism using comprehensive chromosome screening methods has not previously been possible, due to technical limitations and the high cost of such analyses. Importantly, the proportion of TE samples with evidence of mosaicism differed significantly ($p = 0.009$) between the clinics involved in the study, varying from 32% to over 60%. In particular, two clinics consistently produced high levels of mosaic embryos. The fact that mitotic errors producing mosaicism occur during embryo culture, suggests that variation in laboratory procedures could be responsible for the observed differences. Laboratory optimisation in order to reduce mosaicism is highly desirable, since most clinics opt to discard such embryos. The loss of potentially viable embryos due to induced mosaicism will inevitably impact IVF success rates.
Limitations, reasons for caution: Conclusions were drawn from data obtained from seven fertility clinics. Although comparison of results revealed that two of the seven clinics had significantly higher rates of chromosomal mosaicism, it is unclear whether such variation is commonplace or represents a relatively rare occurrence, found in this set of clinics by chance.
Wider implications of the findings: This study provides the first indication that differences between embryology laboratories affect chromosome abnormality rates. This finding was only possible due to application of new cytogenetic methods. Most clinics discard mosaic embryos and consequently laboratories that produce more mosaics will have fewer embryos available for transfer, negatively affecting pregnancy rates.
Trial registration number: Not applicable.

O-059 Quantification of mitochondrial DNA in preimplantation embryos: a tool to predict implantation potential of chromosomally normal embryos

F. Spinella[1], E. Cotroneo[1], S. Bono[1], A. Biricik[1], E. Greco[2], M.G. Minasi[2], A. Ruberti[2], F. Fiorentino[1]
[1]*"Genoma", Molecular Genetics Laboratory, Roma, Italy*
[2]*European Hospital Rome, Reproductive Medicine, Rome, Italy*

Study question: Can measurement of the mitochondrial DNA (mtDNA) content in preimplantation embryos improve the identification of the most likely euploid embryo resulting in a baby?
Summary answer: Low levels of MtDNA are related with increased potential of an embryo to successfully implant and result in a baby.
What is known already: MtDNA is a high copy-number, maternally inherited genome that codes for a small number of essential proteins involved in oxidative phosphorylation, metabolism and apoptosis. MtDNA molecules are very heterogeneous and allow cells to process energy very differently and the difference is able to differently regulate cell fate. Evidence form several mammalian species indicates that mtDNA content may cause a high level of developmental retardation and arrest of preimplantation embryos. However, there is limited data related to mtDNA content and its clinical relevance in the human embryo obtained during preimplantation genetic screening (PGS)/IVF.
Study design, size, duration: This study investigated the mtDNA, and nuclear DNA content in 96 blastocysts obtained from previously performed PGS cycles. These included 23 euploid embryos, 63 aneuploid, 10 mosaic and 5 degenerated embryos. The mtDNA copy number was correlated with blastocyst grading and clinical outcome (implantation, miscarriage, and live birth rate) after euploid embryos transfer.
Participants/materials, setting, methods: All embryos were cultured to blastocyst stage. After trophectoderm biopsy, and Whole Genome Amplification (WGA), mitochondrial and chromosomal DNA copy number variation were examined simultaneously with next generation sequencing (NGS). Analysis was accomplished with BlueFuse Multi software. mtDNA copy numbers was based on the observed ratios of sequence coverages between mtDNA and autosomal DNA.
Main results and the role of chance: The relative quantity of mtDNA was significantly lower in euploid embryos than those present in aneuploid embryos, and similar to those present in mosaic embryos. Among euploid blastocyst, the fully expanded (Grade 5 or 6) blastocysts had an mtDNA average value 1.6-fold lower than those with expansion grade 3. Additionally, mtDNA levels were elevated in embryos that degenerated, independent of chromosomal status ($P = 0.025$). Assessment of clinical outcomes after transfer of euploid embryos to the uterus revealed that blastocysts that successfully implanted and resulted in baby born, tended to contain the lower mtDNA quantities compared with those that failed to implant ($P = 0.007$) while those that resulted in biochemical pregnancy or early abortion showed an intermediate levels. mtDNA quantity threshold was established, above which implantation was never observed. Approximately 40% of the euploid blastocysts that did not implant or resulted in biochemical pregnancy had unusually high (above the threshold) mtDNA levels.
Limitations, reasons for caution: Due to the limited number of samples, further data and broad-based clinical application are required to better define the clinical relevance of mtDNA.
Wider implications of the findings: The results of this study suggest that increased mtDNA may be related to reduced viability and embryo degeneration. This data strongly suggests that mtDNA quantification has the potential to provide clinically relevant information additional to that provided by aneuploidy testing, representing a valuable biomarker of embryo viability.
Trial registration number: None.

O-060 Clinical implications of mitochondrial DNA quantification on pregnancy outcomes: a blinded prospective non-selection study

E. Fragouli[1], K. Ravichandran[2], S. Munne[2], J. Grifo[3], C. Mccaffrey[3], D. Wells[1]
[1]*Reprogenetics UK, Institute of Reproductive Sciences, Oxford, UK*
[2]*Reprogenetics – A Cooper Surgical Company, Reprogenetics, Livingston, NJ, USA*
[3]*NYU, NYU Langone Medical Center, New York, NY, USA*

Study question: Can quantification of mitochondrial DNA (mtDNA) in trophectoderm biopsy specimens provide information concerning embryo viability, potentially enhancing embryo selection and improving IVF treatment outcomes?
Summary answer: This study demonstrates that mtDNA levels are highly predictive of embryo potential. Euploid embryos of good morphology, but with high mtDNA levels fail to implant.
What is known already: Better methods of embryo selection are highly desirable in order to improve IVF treatment efficiency. Even the transfer of chromosomally normal embryos of high morphological grade cannot guarantee that a pregnancy will follow. Recently, the quantity of mtDNA in embryonic cells has been proposed as a new biomarker of viability – higher levels of mtDNA associated with reduced implantation potential. However, to date no prospective blinded studies have been undertaken to confirm this possibility. The current investigation involves the first evaluation of the predictive power of mtDNA quantification in a prospective, blinded, non-selection setting.
Study design, size, duration: mtDNA was quantified in 280 blastocysts, previously biopsied and shown to be chromosomally normal using preimplantation genetic screening (PGS). These were generated by 143 couples (average female age 37.2 years). All patients underwent IVF in a single clinic. The study took place in a blinded, non-selection manner – i.e., mtDNA quantity was not known at the time of single embryo transfer. The fate of the embryos transferred was subsequently compared to the mtDNA levels measured.
Participants/materials, setting, methods: Embryos were biopsied at the blastocyst stage. The trophectoderm samples obtained were subjected to whole genome amplification followed by comprehensive chromosome analysis using a next generation sequencing strategy (NGS). The same biopsy specimens were also tested using quantitative PCR, allowing highly accurate mtDNA quantification. After embryo transfer, the code used for blinding was broken and

analysis undertaken to reveal whether the amount of mtDNA had any association with blastocyst implantation.
Main results and the role of chance: mtDNA analysis of the 280 blastocysts revealed that 15 (5.4%) contained unusually high levels of mtDNA. At the time of writing, outcome data was available for 111 of the blastocysts, transferred after PGS results had been obtained but before mtDNA levels were known. All transfers involved a single chromosomally normal blastocyst of good morphology. Of these, 78 (70%) led to ongoing pregnancies, and all (100%) had mtDNA levels considered to be normal/low. The remaining 33 (30%) blastocysts failed to implant. Among these non-viable embryos there were 7 (21%) with unusually high levels of mtDNA. This meant that the ongoing pregnancy rate for morphologically good, euploid blastocysts, with normal/low levels of mtDNA was 76% (78/103). In contrast, the ongoing pregnancy rate for the same type of embryos, but with elevated mtDNA levels, was 0/7 (0%). This difference was highly statistically significant ($P < 0.0001$).
Limitations, reasons for caution: This study provides strong evidence that mtDNA quantification can serve as a valuable tool to improve the identification of viable blastocysts. However, to determine the true extent of any clinical benefits a randomised clinical trial will be necessary. Research is needed to improve understanding of the biology of mtDNA expansion.
Wider implications of the **findings:** This is the first study to evaluate the clinical impact of increased mtDNA in a prospective blinded manner. Results confirm that embryos with elevated mtDNA rarely implant, supporting its use as a viability biomarker. 76% of euploid embryos with normal/low mtDNA implanted vs. 70% for the cohort as a whole.
Trial registration number: Not applicable.

SELECTED ORAL COMMUNICATIONS

SESSION 17: BENCHMARKING ART

Monday 04 July 2016 **Hall 5 CB** **15:15–16:30**

O-061 How to measure success in ART: Using national registry data to inform patient, provider and policy decision making

G. Chambers[1], A. Macaldowie[1], K. Harris[1], A. Chughtai[2], M. Chapman[3]
[1]*University of New South Wales, National Perinatal Epidemiology and Statistics Unit, Kensington, NSW, Australia*
[2]*University of New South Wales, School of Public Health and Community Medicine, Kensington, NSW, Australia*
[3]*IVF Australia, Medical Consultant, Kogarah, NSW, Australia*

Study question: What are the most appropriate and relevant measures of ART success using population data?
Summary answer: Registry-based measurements of ART success vary widely and should reflect the perspective of the intended audience.
What is known already: There is no single measure of ART treatment success. "Dimensions" of success include efficacy, effectiveness, safety, and equity, while "perspectives" of success include that of the patient, providers, government and community. Traditional measures of success, such a live birth rate per cycle, are being challenged as new models of ART clinical practice emerge, particularly the shift to embryo banking and preferentially transferring frozen embryos. Furthermore, evolving models of care, increasing numbers of ART clinic providers worldwide and more informed patients, make the comparative reporting of ART success of increasing importance.
Study design, size, duration: A population-based study of ART treatments undertaken in 2009–2013 in Australia and New Zealand. During this period, 104,000 women undertook 340,000 fresh and frozen/thaw cycles resulting the 61,000 deliveries. A cohort of 39,698 women who had their first fresh ART cycle between 2009 and 2011 were followed through all fresh and thaw cycles to 2013 to calculate cumulative live birth rates based on a varying assumptions. Survival analysis was used to calculate age specific time to pregnancy.
Participants/materials, setting, methods: Information on ART cycles was sourced from the Australian and New Zealand Assisted Reproduction Database (ANZARD). ANZARD data are collected annually from all 80 fertility clinics in Australia and New Zealand as part of licencing agreements. ANZARD includes demographic characteristics of patients undergoing treatment, the types of ART procedures performed, and information on pregnancy and birth outcomes. ANZARD is a woman based data collection such that repeated cycles can be assigned to the same women.
Main results and the role of chance: The different dimensions (efficacy, effectiveness, safety, and equity) and perspectives (patient, health provider, funder, society) of measuring success in medicine are used as the foundation for demonstrating how ART success differs depending on how that data is portrayed. Detailed examples are demonstrated suing the ANZARD registry data.

Cycle-based success rates vary based on the selection of numerator and denominator, from 13.2% for Birth Emphasizing a Successful Singleton at Term (BESST) to 31% for clinical pregnancy per embryo transfer. The cumulative live birth rates per woman vary based on the definition of a cycle [a single cycle or a complete cycle (fresh plus frozen/thaw)], the age of the patient, and the assumptions made about women who discontinue treatment without achieving a pregnancy. The cumulative live birth rate varies by up to 30% points between conservative and optimistic assumptions about prognosis of women who discontinue treatment, and based on how a cycle is defined. Caution must therefore be taken when presenting these rates to patients.
Limitations, reasons for caution: This study used population-based data which is not reflective of an individual's ART success rates. Data was not available on length of infertility and BMI, and the definition of cause of infertility was not standardised. These factors are related to the likelihood of ART success and were not adjusted for.
Wider implications of the findings: The choice of measurement of ART success should reflect the intention of treatment and the target audience. If used appropriately, ART registry data is useful for informing patients about their likelihood of success over successive treatment cycles and time, for informing clinics about their performance, and for guiding public policy.
Trial registration number: NA.

O-062 The construction and the validation of an ART global score to quantitate an ART process

M. Benchaib[1,2,5], J. Lornage[1,2,3], C. Rapin[2], L. Mery[4], E. Labrune[1,2,5]
[1]*HFME – Laboratoire de Biologie de la Reproduction, Lab. de Biologie de la Reproduction, Bron Cedex, France*
[2]*INSERM U1208, SBRI, Bron Cedex, France*
[3]*Université Lyon I, Faculté de Médecine Lyon-Sud, Oullins Cedex, France*
[4]*CHU Hôpital Nord, Biologie de la Reproduction, Saint-Priest en Jarez, France*
[5]*Université Lyon 1, Faculté de Médecine Lyon-Est, Lyon Cedex, France*

Study question: Could we construct an objective ART Global Score to appreciate an ART process?
Summary answer: The construction and the validation of an ART Global Score were performed. This one was constructed with parameters presents in every database.
What is known already: In ART procedure it is very difficult to obtain an objective assessment of the procedure. The use of an ART database has become the norm, and the integration of a score calculated from the data in this database is then easy. However, the construction of an objective score is difficult. It must meet several requirements: be easy to calculate, built from a small number of variables, variables must be present in the database. Actually, none ART Global Score is available and has been validated.
Study design, size, duration: The ART Global Score was constructed using data from the MediFirst© database used in our center. The development of the score was conducted on a sample of 507 *In vitro* fertilization cycles carried out between January 2011 and July 2011. The validation of score was performed with 3801 cycles (from 2012 and 2013) obtained in our center (2741 cycles) and from another center (1060 cycles) in order to validate robustness of this one.
Participants/materials, setting, methods: Parameters were selected with univariate analysis (ROC curve, *t* test, …). Quantitative data were transformed to categorical variables (CHAID method classification). For each modality a weight was assigned. The weights were defined using logistic regressions and/or multiple linear regressions. The ART Global Score was the weight sum of each modality. The constraint was to obtain a linear relationship between ART Global Score and the pregnancy rate. The validation was performed with another set of ART cycles.

Main results and the role of chance: The ART Global Score is obtained from data from the woman, man and ART procedure. For Women, variables were age, BMI, initial LH and the rank of the puncture. For the man the selected variables are: BMI2222, sperm quality and sperm concentration after selection. And finally for the ART procedure: collected oocytes, Estradiol/oocyte, Gonadotropin/egg/day, 2 pronuclei oocytes on D1, fertilization rate, total embryos, embryos transferred, transfer stage and performing freezing. The ART Global Score could vary from 72 to 215. This ART Global Score was segmented into four classes depending on the pregnancy rates. There is a linear relationship between the ART Global Score and pregnancy rate ($r = 1.0$, $p < 0.001$). For an ART Global Score below than 90, the pregnancy rate was equal to 2.0%; for an ART Global Score between 91 and 115, the pregnancy rate was equal to 15.7%; for an ART Global Score between 116 and 155, the pregnancy rate was equal to 28.9%; and for an ART Global Score above 155, the pregnancy rate was equal to 43.7%. Similar results were obtained with the validating data; whatever the center and year, a linear relationship was obtained between ART Global Score and pregnancy rate.
Limitations, reasons for caution: This ART Global Score was constructed with an agonist ovarian stimulation, no antagonist stimulation was included. Some prognostic parameters were not included. AMH and sperm DNA fragmentation were not included as the measurement were not performed or not allowed for the majority of the cycles.
Wider implications of the findings: This ART Global Score could quantify objectively an ART process. Its scope is vast: clinical activity, research design, and quality indicator during accreditation process. The next step is the development of an algorithm to detect variables decreasing the ART Global Score, for a couple, in order to improve its management.
Trial registration number: None.

O-063 Performance heterogeneity of 41 IVF centers on cumulative live birth rate: measurement and practical implications for quality control and prognostic models

P. Arvis[1], I. Parneix[2], L. Fresneau[3], P. Lehert[4], C. Avril[5], F. Lesourd[6]
[1]Clinique la Sagesse, Rennes, France
[2]Polyclinique Jean Villar, Department of Assisted Reproductive Technology, Bruges, France
[3]Merck Serono SAS, an Affiliate of Merck KGa-Darmstadt-Germany, Lyon, France
[4]Faculty of Medicine, University of Melbourne, Melbourne, VIC, Australia
[5]Clinique Mathilde, Department of Assisted Reproductive Technology, Rouen, France
[6]Hôpital Paule de Viguier, Department of ART, Toulouse, France

Study question: Very few results are available concerning the comparison of Cumulative Live Birth Rate (CLBR) performance between IVF centers, and no validated methodology was proposed.
Summary answer: Our first investigation in France demonstrated a considerable relative variation of the mean CLBR rate of 52.3% and a maximum/minimum ratio of 2.34.
What is known already: Historical studies assessed the performance of centers essentially at cycle level. Strong between centers differences on CLBR were found, even after adjusting for patient characteristics (patient Mix). The ratio of maximum/minimum may exceed 3, and SD/mean coefficient of variation is near 50%. Explanatory causes are initial patient's selection, cancellation's rate, used ART and freezing techniques, number of embryos per transfer, and used statistics. As a higher number of cycles may compensate for lower LBR per cycle, center's performance was studied in terms of CLBR, but also on the total number of cycles required to achieve a live birth.
Study design, size, duration: We conducted a longitudinal observational national multicenter study on retrospective data in selecting couples starting IVF, and documenting all their successive fresh and frozen IVF cycles, during 3 years follow-up (Single Stage Cluster Sampling combined with within-center sequential recruitment). This study began in 2010 and was powered to provide a maximum error of 5% on CLBR, in planning a representative selection of 40 centers with a fixed recruitment of 100 couples per center.
Participants/materials, setting, methods: The performance Index (PI), ratio of LB on the total number of cycles, and CLBR constituted the two main measurements of performance. All the recruited patients were analysed on intent to treat basis. A mixed model was used in adjusting for women age, ovarian reserve and previous parity as fixed covariates, and center as random factor. The heterogeneity was tested as global (random intercept effect) and for subgroups (random effect of age, ovarian reserve).
Main results and the role of chance: Out of 58 selected IVF centers, 41 gave complete data and recruited 4081 couples, for a total of 8349 fresh and 2282 frozen IVF cycles. Our sample was characterized by a median age of 33 years (IQR = 7), mean BMI of 23.4 ± 4.7 and 18% smokers, 74.9% of childless couples, median duration of subfertility of 3 years (IQR = 3).

The unadjusted mean PI was 0.32 (range = 0.20; 0.49, IQ = 0.25, 0.37). By adjusting for Patient mix, we identified a decreasing quadratic effect of age, and a positive linear effect of previous LB parity and number of retrieved oocytes. By assuming the referent population as women aged 30 years, with 10 retrieved oocytes, the observed mean PI is 0.39 (0.37, 0.42). The standard deviation of the center effect SD = 0.05 [(0.03, 0.07), $p < 0.001$] provides a relative variation of 52.3%. The random effects of center on the number of oocytes and age were not significant.

The unadjusted mean CLBR was 0.48 (Range = 0.32; 0.64, IR = 0.41, 0.54), and some discordance was found among the centers between both values [R = 0.81, CI (0.76, 0.92)]. By adjusting for patient mix, the mean PI for the referent population is 0.59 corresponding to the above defined population of reference, with a relative variation of 39%.
Limitations, reasons for caution: Our model is sensitive to the center selection. In spite of random selection, centers refusing to participate may bias the results. Our first investigation is limited to France; results cannot be generalizable to other countries. In adjusting for patient Mix, some information was unavailable, in particular socio-cultural and environmental variables.
Wider implications of the findings: A strong heterogeneity of the performance among centers was found. Between-center collaboration may help: periodic data based on a mixed model constitutes a simple, accurate, and anonymous indication for each center. Moreover, adding center effect to patient mix provides a very accurate center-specific predictive model.
Trial registration number: It is not a clinical trial.

O-064 The impact of embryo transfer catheter retraction rate on fertility outcomes in intracytoplasmic sperm injection cycles: a randomized controlled trial

B. Devranoglu[1], Ö. Özdamar[2], G. Kaya[3], E. Doğer[3], S. Selçuk[1], M. Küçükbaş[1], Y. Çakıroğlu[3], T. Kutlu[1]
[1]Zeynep Kamil Maternity and Children's Hospital, Department of Obstetrics and Gynecology, Istanbul, Turkey
[2]Gölcük Military Hospital, Department of Obstetrics and Gynecology, Kocaeli, Turkey
[3]Kocaeli University, School of Medicine, Department of Obstetrics and Gynecology, Kocaeli, Turkey

Study question: Does retraction of embryo transfer (ET) catheter following a 30-s waiting period at the end of ET process affect pregnancy and clinical pregnancy rates in ICSI/ET cycles?
Summary answer: The retraction of ET-catheter following a 30-s waiting period inside the uterus has no positive effect on the rates in ICSI/ET cycles.
What is known already: Although many variables in ET such as catheter type, catheter loading technique, presence of blood on the catheter tip, have been studied as the determinants of a successful pregnancy, ET-catheter withdrawal rate has not been investigated.
Study design, size, duration: Prospective randomized controlled trial including 300 women aged <40 undergoing ICSI/ET cycles at our tertiary health care facility between October 2014 and March 2015. The patients were randomly enrolled to two groups as Group A and Group B. Following exclusion of 3 and 2 patients from the group A and B, respectively, the final statistical analyses included a total of 295 women.
Participants/materials, setting, methods: Group A included women in whom ET-catheter was retracted within the first 5-s; Group B consisted those in whom ET-catheter was retracted following a 30-s waiting-period at the end. As visualized by ultrasonography, women with and without fundal positioning of air bubble were evaluated as Group 1a and 1b, whereas those with a distance between catheter tip and fundal endometrial surface <15 and ≥15 mm were evaluated as Group 2a and 2b, respectively.
Main results and the role of chance: Demographic characteristics across all groups were comparable. Groups A and B did not significantly differ regarding pregnancy [32% ($n = 47$) and 32.4% ($n = 48$), respectively; $p = 0.933$] and clinical pregnancy [29.9% ($n = 44$) and 27.7% ($n = 41$), respectively; $p = 0.673$]

rates. In Group 1a (n = 207), pregnancy rate and clinical pregnancy rates were 33.8% (n = 70) and 28.4% (n = 25), respectively (p = 0.363), whereas in Group 1b (n = 88) were 30.4% (n = 63) and 25% (n = 22), respectively (p = 0.178). The distance between the catheter tip and fundal endometrial surface ≥15 mm (n = 144) was associated with significantly higher rates of pregnancy and clinical pregnancy than those with a distance <15 mm (n = 151) (26.5 versus 22.5%; p = 0.032 and 38.2 versus 35.4%; p = 0.014, respectively).

Limitations, reasons for caution: Lack of data regarding ongoing pregnancy, live birth and going home baby rates limit this study. Although air bubbles visualized at the time of ET are presumed to present the embryo position, it is only a surrogate of embryo itself.

Wider implications of the findings: In ICSI/ET, withdrawal of the ET catheter after a 30-s waiting inside the uterus or fundal migration of air bubble do not improve pregnancy or clinical pregnancy rates. Performing ETs with a distance of catheter tip to fundal endometrial surface ≥15 mm may be associated with better reproductive outcomes.

Trial registration number: N/A.

O-065 Is there a different effect of lifestyle intervention in subgroups of infertile obese women? Prespecified subgroup analyses of the LIFEstyle randomised controlled trial

Study question: Is there a different effect of a 6-month lifestyle intervention preceding fertility treatment on reproductive outcomes in subgroups of obese infertile women?

Summary answer: Lifestyle intervention increased natural conception rate in anovulatory compared to ovulatory women, whereas rate of vaginal births of healthy singletons did not differ in subgroups.

What is known already: Obese women are at an increased risk of infertility and are less likely to conceive after fertility treatment. We previously demonstrated in the LIFEstyle study, that a 6-month lifestyle intervention preceding fertility treatment in obese infertile women did not increase the rate of vaginal births of healthy singletons at term within 24 months follow-up as compared to immediate fertility treatment (Relative Risk RR 0.77, 95% Confidence Interval CI 0.60–0.99). Natural conceptions of an ongoing pregnancy occurred more frequently in women who received a 6-month lifestyle intervention preceding fertility treatment (RR 1.6, 95% CI 1.2–2.2).

Study design, size, duration: Data of a multicentre, randomised controlled trial were used. Between 2009 and 2012, 577 obese infertile women were randomly assigned to a 6-month lifestyle intervention followed by fertility treatment (intervention group) or to immediate fertility treatment (control group). Subgroups were prespecified in the study-protocol based on frequently used cut-off values in the literature: age (≥36 or <36 years), ovulation status (anovulatory or ovulatory) and body-mass index (BMI, ≥35 or <35 kg/m^2).

Participants/materials, setting, methods: The rate of vaginal births of healthy singletons at term and the rate of natural conceptions of an ongoing pregnancy in the subgroups were calculated. Adjusted odds ratios (aOR) with corrections for baseline variables and the accompanying 95% CIs were provided. Logistic regression models with randomisation group, subgroup and the interaction between randomisation group and subgroup were used. A significant interaction was defined as a p-value <0.1. Follow-up period was 24 months after randomisation.

Main results and the role of chance: Data of 564/577 randomised women who had complete follow-up in the LIFEstyle study were analysed. The rates, % and aORs of a vaginal birth of a healthy singleton at term (Table 1) and natural conception of an ongoing pregnancy (Table 2) in women in the intervention group compared to women in the control group according to the subgroups and the accompanying p-values for interaction were:

Table 1. Rates and aOR of vaginal birth of healthy singletons at term.

	Rate (%)		$OR_{adjusted}$ (95% CI)	$p_{interaction}$
	Intervention	Control		
≥36 years	1/34 (2.9)	5/29 (17.2)	0.11 (0.00–6.23)	0.12
<36 years	75/246 (30.5)	95/255 (37.3)	0.90 (0.60–1.34)	
Anovulatory	37/123 (30.1)	52/140 (37.1)	0.82 (0.46–1.46)	0.91
Ovulatory	39/157 (24.8)	48/144 (33.3)	0.84 (0.49–1.44)	
BMI ≥ 35.0	43/175 (24.6)	61/180 (33.9)	0.78 (0.47–1.28)	0.62
BMI < 35.0	33/104 (31.7)	39/103 (37.9)	0.92 (0.49–1.76)	

Table 2. Rates and aOR of natural conceptions of an ongoing pregnancy.

	Rate (%)		$OR_{adjusted}$ (95% CI)	$p_{interaction}$
	Intervention	Control		
≥36 years	5/34 (14.7)	1/29 (3.5)	3.12 (0.27–35.9)	0.56
<36 years	68/246 (27.6)	45/255 (17.6)	2.17 (1.37–3.42)	
Anovulatory	35/123 (28.6)	16/140 (11.4)	4.15 (2.04–8.44)	0.02
Ovulatory	38/157 (24.2)	30/144 (20.8)	1.33 (0.73–2.41)	
BMI ≥ 35.0	47/175 (26.9)	33/180 (18.3)	1.93 (1.12–3.34)	0.37
BMI < 35.0	26/104 (25.0)	13/103 (12.6)	3.20 (1.42–7.22)	

Limitations, reasons for caution: This was a subgroup analysis of a randomised controlled trial and sample size determination of the trial was based on the primary outcome of the study. The study was not powered on analyses of subgroups or interaction tests. In general, interaction tests are prone to be underpowered.

Wider implications of the findings: The effect of a preconceptional lifestyle intervention is the strongest in anovulatory women and therefore it should be offered as first-line treatment for anovulation in obese women. An individual patient data analysis could give more insight on the effectiveness of lifestyle intervention in other subgroups of obese infertile women.

Trial registration number: The LIFEstyle study was registered at the Dutch trial registry (NTR 1530).

SELECTED ORAL COMMUNICATIONS

SESSION 18: COMPLICATIONS AND CONSEQUENCES

Monday 04 July 2016 **Hall 5 A** **15:15–16:30**

O-066 Late pregnancy complications and outcomes in women with threatened miscarriage: a systematic review and meta-analysis

R. Pillai[1], J. Konje[2], D. Tincello[3], N. Potdar[4]

[1]*Leicester, UK*

[2]*Sidra Medical and Research Centre, Department of Obstetrics and Gynaecology, Doha, Qatar*

[3]*University of Leicester, Department of Health Sciences, Leicester, UK*

[4]*University Hospitals of Leicester NHS Trust, Women's Health CMG, Leicester, UK*

Study question: Are women with bleeding in early pregnancy at high risk of developing maternal and fetal complications that can contribute to term still-births?

Summary answer: Threatened miscarriage is associated with significantly increased risk of adverse maternal and fetal complications that can contribute to term still births.

What is known already: 16–25% of pregnancies suffer from early pregnancy bleeding and threatened miscarriage is diagnosed when along with the vaginal bleeding a viable pregnancy is noted on an ultrasound scan. Threatened miscarriage can be a reflection of placental development and dysfunction, which in turn explains the increased incidence of maternal and perinatal complications. A previously published systematic review and meta-analysis (Saraswat 2009) used a combination of both prospective and retrospective studies and has highlighted the need for more prospective studies in this field. Ever since more prospective studies have been published and therefore warrants an updated systematic review.
Study design, size, duration: This is a systematic review and meta-analysis of late pregnancy complications and outcomes in women with threatened miscarriage at less than 24 weeks of gestation (1946–2015). After thorough literature search and review, 11 prospective studies were found to be eligible for quantitative meta-analysis including 32,063 women.
Participants/materials, setting, methods: The electronic database search included Medline (1946 to December 2015), Embase (1980 to December 2015), Cochrane library, ClinicalTrials.gov and bibliographies of retrieved primary articles. Key MESH and Boolean terms were used for the search. Data extraction and collection was performed by two authors independently. Quality assessment of the individual studies was done using the Newcastle–Ottawa Scale and statistical analysis performed using the Cochrane systematic review manager 5.3 and Stata vs. 13.0.
Main results and the role of chance: The meta-analysis has shown that women with threatened miscarriage are at significantly increased risk of having preterm birth (OR 3.83; 95% CI 3.37–4.35); placental abruption (OR 4.29; 95% CI 2.72–6.75); placenta praevia (OR 4.9; 95% CI 2.34–10.29) and pregnancy induced hypertension (OR 5.79; 95% CI 4.56–7.34). They are also at an increased risk of still birth/intra uterine death (OR 1.97; 95% CI 1.21–3.19), pre-eclampsia (OR 2.6; 95% CI 2.01–3.36) and intra uterine growth retardation (OR 1.64; 95% CI 1.31–2.01). Threatened miscarriage also contributes to other complications like preterm pre-labour rupture of membranes (OR 2.62; 95% CI 2.1–3.28), low birth weight (OR 1.58; 95% CI 1.31–1.89), increased rate of caesarean section (OR 2.85; 95% CI 2.56–3.16), neonatal asphyxia (OR 1.78; 95% CI 1.1–2.89) and congenital anomalies/fetal malformations (OR 1.59; 95% CI 1.19–2.12).
Limitations, reasons for caution: The quality of some of the included studies is a limitation of this meta-analysis. Also potential confounding variables like maternal age, ethnicity, previous obstetric history, BMI are not accounted for, which could contribute to bias.
Wider implications of the findings: Threatened miscarriage can be associated with significant maternal and perinatal complications, therefore these women should be offered increased surveillance in the antenatal period. In light of the recent MMBRACE: UK perinatal mortality surveillance report 2015, there is a strong need to recognize and monitor factors contributing to still birth.
Trial registration number: Not applicable.

O-067 Risk factors for ectopic pregnancy in assisted conceptions: secondary analysis of human fertilization and embryology authority (HFEA) data

S. Bhattacharya[1], E. Bambara[2], S. Shanthakumaran[1], E.A. Raja[3]
[1]University of Aberdeen, Dugald Baird Centre for Research on Women's Health, Aberdeen, UK
[2]Universite Claude Bernard Lyon, Public Health, Lyon, France
[3]University of Aberdeen, Medical Statistics, Aberdeen, UK

Study question: What are the risk factors for ectopic pregnancy (EP) in a population receiving fertility treatment?
Summary answer: Tubal disease, low sperm motility, and increasing number of embryos transferred were associated with increased risk of EP.
What is known already: The prevalence of ectopic pregnancies has increased in recent times. It is thought that assisted reproductive technology may have contributed to this risk increase. Yet the reported risk of EP among the ART population varies between 0.8 and 8.6 versus 1% in the general population. This reported increase could be due to earlier diagnosis of pregnancy in the ART population.
Study design, size, duration: Case control study design was used to analyse HFEA data for first cycles only between 1998 and 2012. There were 99,528 pregnancies analysed of which 1,285 were ectopic. The risk factors assessed included age of women, year of procedure, primary or secondary infertility, duration of infertility, causes of infertility, type of ART procedure, fresh or frozen cycle and number of embryos transferred.
Participants/materials, setting, methods: All first cycles of IVF or DI conducted in the United Kingdom between 1998 and 2012 collected in the anonymised HFEA database were analysed. Univariate and multivariate logistic regression was conducted to calculate unadjusted and adjusted odds ratios with 95% confidence intervals for EP associated with each of the risk factors.
Main results and the role of chance: The incidence of ectopic pregnancy in this population was 1.31% (95% Confidence Intervals 1.30, 1.32). Tubal disease was strongly associated with the risk of EP in both univariate [1.63 (95% CI 1.37, 1.93)] and multivariate [1.89 (95% CI1.59, 2.25)] analyses. Low sperm motility [adjusted OR 1.90 (1.23–2.94)], was also associated with risk of EP. Risk of EP increased linearly with increasing number of embryos transferred – adjusted OR 1.18 (95% CI 1.02–1.38), 1.35 (1.21–1.50) and 1.02 (0.85–1.22) for two, three and four or more embryos transferred respectively.

On univariate analysis, increasing age of women was associated with reduced risk of EP, but this association was no longer significant on multivariate analysis. The odds of EP were not significantly increased with increasing year of procedure or duration of infertility. Secondary versus primary infertility was also not found to be a significant risk factor for EP in the adjusted model.

Analysis of a large population based database such as the HFEA database is likely to yield statistically significant results that may or may not be clinically significant. However, the strong associations seen with some of the risk factors in this analysis are also biologically plausible and thus unlikely due to chance.
Limitations, reasons for caution: Due to the anonymization of the HFEA database, multiple cycles belonging to the same woman cannot be identified. We accounted for this by analysing only the first cycles. There was also no information about any previous history of EP, the single most important risk factor for EP.
Wider implications of the findings: EP is a leading cause of maternal mortality and morbidity. Its association with ART procedures can further reduce chances of treatment success. Single embryo transfers may reduce the risk of ART associated EP.
Trial registration number: Not a trial.

O-068 Prevention of adhesions post (spontaneous) abortion (PAPA study); a randomized controlled trial evaluating application of hyaluronic acid (HA)

A. Hooker[1], R. Leeuw de[2], A. Thurkow[3], H. Brölmann[2], J. Huirne[2]
[1]Zaans Medical Center ZMC, Department of Obstetrics and Gynaecology, ZAANDAM, Netherlands
[2]VU University Medical Center, Department of Obstetrics and Gynaecology, Amsterdam, Netherlands
[3]Sint Lucas Andreas Hospital, Department of Obstetrics and Gynaecology, Amsterdam, Netherlands

Study question: Does intrauterine application of Hyalobarrier® Gel Endo (HA) in women undergoing a recurrent D&C, reduces the amount of intrauterine adhesions (IUAs).
Summary answer**:** Intrauterine application of HA following conventional D&C for miscarriage, in women with at least one previous D&C, significantly reduces the cumulative rate of IUAs.
What is known already: Approximately 15–20% of all clinically recognized pregnancies will end in a miscarriage; a pregnancy that fails to progress before 20–24 weeks of gestation. IUAs, defined as fibrous strings at opposing walls of the uterus or cervix may result in menstrual disorders and infertility while pregnancy is frequently complicated; because of the possible implications, prevention is important.
Study design, size, duration: From December 2012 through April 2015, we performed a multicenter, open-label, randomized controlled trail at one university and seven university-affiliated teaching hospitals. Women, undergoing a recurrent D&C were randomized preoperatively by a web based computer program and allocated to receive either Hyalobarrier ® Gel Endo (prevention group) or nothing (control group) post operatively. A hysteroscopic procedure was scheduled 8–12 weeks after the D&C-procedure to evaluate the uterine cavity.
Participants/materials, setting, methods: Women with at least one previous D&C in history, a group with an increased risk of clinically significant adhesion

formation, were eligible to participate if they were diagnosed with a miscarriage and planned for a surgical intervention (D&C). Women suspected of a molar pregnancy and with severe signs of infection were excluded.
Main results and the role of chance: 152 women were randomized; 78 women were assigned to the prevention group and 74 to the control group. The vast majority of women (98.7%) assigned to the prevention group, received the study intervention. The baseline characteristics among participants were similar. IUAs were observed in 10 of 77 women (13.0%) in the prevention group compared to 22 of 72 women (30.6%) in the control group (RR 0.43; 95% CI: 0.22–0.83, $p = 0.01$). The number needed to treat (NNT) to benefit is 6. Mean adhesion scores, based on the extent of uterine cavity involvement, type adhesion and menstrual pattern was significantly lower in the prevention group compared to control; respectively 2.80 versus 4.41 (MD − 1.61, 95% CI − 3.16 to − 0.06, $p = 0.04$). No complications or adverse events were reported related to the application of Hyalobarrier® Gel Endo.
Limitations, reasons for caution: We were not able to blind the surgeon performing the D&C procedure, we made sure that the hysteroscopic examiner was unaware of the assignment: the examiner may not have participated or contributed to the initial D&C procedure of the woman being examined.
Wider implications of the findings: There is an association between the presence and extent of IUAs and long-term reproductive complications but few studies addressing the link are available; prevention is important. The effect of prevention on reproductive outcome will emerge from ongoing work.
Trial registration number: The Netherlands Trial register (NTR 3120).

O-069 Effectiveness of treatment in the secondary prevention of obstetric complications in the antiphospholipid syndrome: systematic review and meta-analysis

R. Callec[1], O. Unlu[2], M. Olivier[1], W. Denis[3], Z. Stéphane[3]
[1]*University Maternity, CHRU de Nancy, Obstetric and Fetal Unit, Nancy, France*
[2]*Hospital for Special Surgery, Barbara Volcker Center for Women and Rheumatic Disease, New York, NY, USA*
[3]*CHRU de Nancy, Regional Competence Centre for Rare Vascular and Systemic Autoimmune Diseases, Vascular Medicine Division, INSERM, UMR_S 1116, Nancy, France*

Study question: Which treatments are the most effective for the secondary prevention of obstetric complications in pregnant women with history of obstetric antiphospholipid syndrome (APS)?
Summary answer: This meta-analysis shows a trend towards superiority of aspirin + low-molecular-weight heparin vs. aspirin + unfractionated heparin in preventing miscarriages, and no effect of antithrombotic treatments on placenta-mediated complications.
What is known already: Several recent meta-analyses (Ziakas et al., 2010; Mak et al., 2010) were performed to assess whether antithrombotic treatments reduce the risk of miscarriages and placenta-mediated complications in the secondary prevention of obstetric APS pregnant women. However, even though the current practice is the use of low-molecular-weight heparin (LMWH), data on substitution of unfractionated heparin to LMWH remain inconclusive. Furthermore, the impact of antithrombotic therapy on the risk of placenta-mediated complications is still controversial.
Study design, size, duration: We selected studies that included pregnant women with obstetric APS (at least two miscarriages and the presence of antiphospholipid antibodies), and describing exposure to different treatments [heparin including unfractionated heparin and LMWH, aspirin, IV immunoglobulin (IVIG)]. The primary endpoint was the incidence of early miscarriages (before 14 weeks of gestation). Secondary outcomes were obstetric complications related to antiphospholipid syndrome: late miscarriages, preeclampsia, intra uterine growth retardation (IUGR), and premature delivery.
Participants/materials, setting, methods: To ensure the quality of the methodology, the MOOSE/PRISMA criteria have been met at all stages of the development of this meta-analysis. We searched the Cochrane Library, EMBASE, MEDLINE and reference lists of eligible studies from inception to September 2015, without any restriction. We also interviewed the ClinicalTrials.gov database for unpublished articles and meeting abstracts. Two reviewers independently extracted study characteristics and outcome data. Estimates were pooled using random effects models and sensitivity analyses.
Main results and the role of chance: Of 2018 identified abstracts, 26 primary studies (7 cohorts, 1 case-control, 18 randomized control trials) met inclusion criteria, including 1269 APS patients. Compared to aspirin alone, heparin with aspirin allows a 50% reduction of early miscarriages in APS [4 studies, 695 patients, OR = 0.46 (CI 95%; 0.31–0.69)]. Furthermore, our meta-analysis shows a very strong trend to superiority of LMWH compared with unfractionated heparin [3 studies, 138 patients, OR = 0.46 (0.21–1.01)] in the prevention of miscarriages, however without reaching statistical significance. The results on the effectiveness of conventional antithrombotic treatments in the prevention of placenta-mediated complications (late miscarriages, preeclampsia, and IUGR) did not reach statistical significance. However, adding IVIG to LMWH and aspirin was associated with an 85% decreased risk of pre-eclampsia [2 studies, 139 patients, OR = 0.15 (0.03–0.88)]. Finally, among all treatments, the association of aspirin and LMWH in comparison with aspirin alone was associated with an 80% decreased risk of prematurity [2 studies, 173 patients, OR = 0.21 (0.07–0.61)].
Limitations, reasons for caution: Some primary studies are non-randomized cohort studies. This could have impacted the internal validity of some results. Furthermore this meta-analysis was performed on published data.
Wider implications of the findings: Further randomized trials or an individual patient-level meta-analysis are needed to confirm these results and identify which treatments are effective in the secondary prevention obstetric APS manifestations especially those placenta-mediated.
Trial registration number: None.

O-070 Recurrent pregnancy loss is not associated with an increased breast cancer risk

C. Lambalk[1], E. Kolman[1], A.W. van den Belt-Dusebout[2], M. Spaan[2], I.M. Krul[2], E. Groeneveld[1], M. Hauptmann[2], F.E. Van Leeuwen[2]
[1]*Free University Hospital, Reproductive Medicine, Amsterdam, Netherlands*
[2]*Dutch Cancer Institute, Department of Epidemiology, Amsterdam, Netherlands*

Study question: Are women with recurrent pregnancy loss (RPL) (two or more miscarriages) at a higher risk to develop breast cancer over time?
Summary answer: Women with RPL are neither at a higher risk nor at a lower risk to develop breast cancer over time.
What is known already: Some studies suggest that RPL might be due to increased instead of decreased levels of angiogenic factors with consequently superfertility but because of allowance of implantation of also poor quality embryos the result is more clinical miscarriages. As breast cancer progression is also associated with increased angiogenesis, we wondered if RPL might be associated with an increased risk of breast cancer.
Study design, size, duration: The nationwide Dutch OMEGA cohort comprised 13,715 women who received *in vitro* fertilization between 1983 and 1995 and completed a questionnaire between 1997 and 2000. In total, 831 women refused linkage with disease registries and 4,318 women were excluded (diethylstilbestrol, nulliparous without miscarriages) leaving 8,340 women in our analysis. Breast cancer incidence was updated until January 2014 through linkage with the Netherlands Cancer Registry. Follow-up started at questionnaire completion. Mean follow-up time was 15.2 years.
Participants/materials, setting, methods: Women were classified according to their number of miscarriages as follows; zero miscarriages (5,871; 70.4%), one miscarriage (1,799; 21.6%) and RPL (670; 8.0%). In total, 298 breast cancer cases were identified. Breast cancer risks were estimated using a Cox regression model. Sensitivity analyses were done excluding all nulliparous women with miscarriages and within miscarriage groups.
Main results and the role of chance: Within the group without miscarriages 219 women had breast cancer, 55 women with one miscarriage, and 24 women with RPL had breast cancer. Hazard ratios (HR) were calculated for one miscarriage [0.92, 95% confidence interval (CI) 0.68–1.27] and RPL (1.06, 95% CI 0.68–0.164). When restricting to only parous women HR for one miscarriage and RPL remained similar. Within the one miscarriage (1.38, 95% CI 0.76–2.50) and RPL (2.72, 95% CI 0.93–7.99) group parous women had higher HRs for breast cancer risk, although not significant. When comparing all different groups (nulliparous women with one miscarriage, nulliparous women with RPL, parous women with zero miscarriages and parous women with RPL) with each other taking parous women with one miscarriage as reference group there were no significant findings. HRs for nulliparous women with one miscarriage

were 0.64 (95% CI 0.38–1.07), for nulliparous with RPL 0.43 (95% CI 0.16–1.15) and for parous women without miscarriages 0.88 (95% CI 0.63–1.23).
Limitations, reasons for caution: Information about miscarriages was obtained from the questionnaires and therefore may have been prone to recall bias. However, this is not very likely, because we expect recalling the miscarriages not to be dependent on having breast cancer in the future.
Wider implications of the findings: Since our results refute any relation between occurrence of breast cancer and previous RPL we cannot assume simple links between angiogenic features of breast cancer development and that of RPL and possible superfertility. We found a non significant lower breast cancer risk in nulliparous women with miscarriages.
Trial registration number: Not applicable.

SELECTED ORAL COMMUNICATIONS

SESSION 19: LOSS AND DISTRESS IN INFERTILITY. TREATMENT AND BEYOND

Monday 04 July 2016 **Hall 3 AB** **15:15–16:30**

O-071 He said, she said: gender differences in causal explanations for infertility/fertility problems

E. Koert[1], C. Harrison[1], M. Khan[1], L. Bunting[2], J. Boivin[1]
[1]*Cardiff University, Cardiff Fertility Studies Research Group, School of Psychology, Cardiff, UK*
[2]*Cardiff University, Brain, Neurosciences and Mental Health Research Institute NMHRI, Cardiff, UK*

Study question: Do men and women have different causal explanations for their fertility problems?
Summary answer**:** Men and women blame chance and medical problems for infertility. Men also blame their lifestyle (sexual practices) and women their reproductive choices (birth control, abortion).
What is known already: It is commonly believed that women take the blame for a couple's fertility problems in order to protect their partner's self-esteem or sense of masculinity. But research tells a different story. Some studies show women are more likely than men to blame their fertility problems on their own past behaviours. Other studies show the opposite – with men more likely to blame their fertility problems on their own past behaviours and women to blame destiny or fate.
Study design, size, duration: Mixed method design. A cross-sectional sample completed the causal attribution questions of the International Fertility Decision-Making Study (IFDMS, translated into 12 languages) over a 9-month period online, through a social research panel or in fertility clinics. Inclusion criteria were that respondents were between age 18 and 50, partnered, and trying to conceive for 6+ months.
Participants/materials, setting, methods: 10,045 respondents (1,690 men, 8355 women) from 79 countries participated. Respondents were 31.8 years and trying to conceive for 2.8 years. Participants rated on 5-point Likert-scales to what extent they perceived their fertility problems to be due to something they/their partner did or to other factors and to describe their reasons for making this attribution. 29.7% (337 men, 2651 women) provided 3,900 text responses to these questions. Textual data was analysed using thematic analysis.
Main results and the role of chance: In quantitative ratings, men and women most commonly attributed their fertility problems to chance or bad luck and medical conditions. Men were significantly more likely than women to attribute their fertility problems to something their partner had done, their or their partner's lifestyle, or their partner's age. Women were significantly more likely to cite chance or bad luck, medical or emotional conditions, God's will, or their age as causes of their fertility problems. Thematic analysis of qualitative results found that women tended to blame their fertility problems on their reproductive choices (most commonly abortion or birth control use), to failure to change lifestyle behaviors (e.g., weight, smoking), and to their partner's lack of readiness for parenthood (e.g., ambivalence about starting a family, lack of desire to be a parent). Women expressed regret and helplessness about these causes, which they perceived led to delayed childbearing and subsequent fertility difficulties. In contrast, men believed their lifestyle behaviours (e.g., smoking, specific sexual practices) and their partner's previous abortions were the cause of their fertility problems, and did not express feelings of regret or helplessness.
Limitations, reasons for caution: Respondents were self-selected and results principally reflect views of highly educated women with prior exposure to fertility health services.
Wider implications of the findings: Education campaigns should address misconceptions about the impact of abortion and birth control on future fertility. Future research should address that men's readiness for parenthood significantly influences the decision to start a family. Lifestyle behaviour change interventions should target feelings of ambivalence along with ways to reduce future regret.
Trial registration number: N/A.

O-072 Endometriosis is associated with depression and anxiety still at premenopausal age – a population based cohort analysis

T. Piltonen[1], S. VuontisjÃ¤rvi[1], S. Karjula[1], T. Nordström[2], J. Tapanainen[1,3], L. Morin-Papunen[1], J. Miettunen[2]
[1]*Oulu University Hospital and University of Oulu, Department of Obstetrics and Gynaecology, Medical Research Center, PEDEGO Research Unit, Oulu, Finland*
[2]*University of Oulu, Center for Life Course Health Research, Oulu, Finland*
[3]*Helsinki University Hospital, Department of Obstetrics and Gynaecology, Helsinki, Finland*

Study question: Is endometriosis associated with long lasting psychological consequences with increased mental distress (depression and anxiety) in early adulthood and in premenopause?
Summary answer: Endometriosis associates with higher rate of depression/anxiety symptoms and diagnosed depression at ages 31 and 46 compared with controls.
What is known already: Women with endometriosis have been shown to present with an increased prevalence of depression and anxiety. Infertility and chronic pain symptoms associated with endometriosis are considered the most important explanatory factors and the symptoms may prevail for years. However, there are only few longitudinal studies on age-related mental distress in these women and population based analysis are lacking.
Study design, size, duration: The study population was a prospective follow-up of a large national birth cohort including 12,231 subjects (5889 women). A postal questionnaire screening previously diagnosed endometriosis was collected at age 46. The symptoms for mental distress and depression diagnosis were screened both ages 31 (n = 4523) and 46 (n = 3706). The questionnaire identified 258 (7.7%) women with endometriosis and 3090 controls. We also analyzed the use of medication for depression and anxiety.
Participants/materials, setting, methods: Both 31 and 46-year questionnaire included Hopkins Symptom Check-list 25 (HSCL-25), a screening tool for depression/anxiety symptoms. The women were also asked whether they had been diagnosed or treated for depression. Furthermore, the study group was also screened for their current medication. The associations were calculated using Pearson Chi-square and Mann–Whitney U test when appropriate. The results were adjusted for BMI, smoking, hormonal contraceptive use, infertility and socioeconomic status (SES) with binary logistic regression model.
Main results and the role of chance: HSCL-25 revealed that women with endometriosis had more symptoms for mental distress both at age 31 [median (interquartile range): 1.32 (0.36) vs. 1.28 (0.32), p = 0.032, respectively] and 46 [1.32 (0.48), 1.26 (0.36), p = 0.018]. The HSCL-25 anxiety score was higher in women with endometriosis compared with controls up till perimenopause [31 years, 1.30 (0.4) vs. 1.22 (0.3), p = 0.013; 46 years, 1.30 (0.4) vs. 1.20 (0.3), p = 0.006]. Higher proportion of women with endometriosis had anxiety score in the upper quartile (31 years, 43.2 vs. 33.9% p = 0.003; 46 years, 41.2 vs. 31.8% p = 0.002) compared with controls. A similar trend was observed in the HSCL-25 depression score [31 years, 1.33 (0.4) vs. 1.27 (0.46), p = 0.065; 46 years, 1.33 (0.53) vs. 1.27 (0.46), p = 0.05].

History of endometriosis was associated with higher lifetime incidence of depression diagnosis compared with controls (31 years, 9.7 vs. 4.1%, $p < 0.001$; 46 years, 21.6 vs. 13.1%, $p < 0.001$). Furthermore, the prevalence of women having depression diagnosis both at age 31 and 46 was higher among women with endometriosis (6.3 vs. 2.4%, p = 0.001).

However, there was no difference between the study groups regarding the current use of anxiety (31 years, 2.3 vs. 1.9%, p = 0.816; 46 years, 12.4

vs. 10.7%, $p = 0.403$) or antidepressant medication (31 years, 1.6 vs. 1.2%, $p = 0.767$; 46 years 10.5 vs. 9.4%, $p = 0.580$).

The adjustments for smoking, SES, BMI, hormonal contraceptive usage and history infertility did not affect the results.

Limitations, reasons for caution: The diagnoses of endometriosis were self-reported. However, 37.7% of cases were available for validation using hospital patient records. The hospital register data confirmed endometriosis diagnosis for 76.3% of self-reported cases and of them 90.1% were diagnosed with laparoscopy.

Wider implications of the findings: This unique population based data demonstrates increased mental distress in women with endometriosis until premenopausal age implying the disease having long lasting consequence on women's mental well being. In clinical practice the women should be screened for mental distress beyond fertile age and offered with appropriate care.

Trial registration number: –.

O-073 Psychological morbidity of women who experience miscarriage: impact of a specific counselling training for residents using simulation

G. Legendre[1], M. Gicquel[1], P.E. Bouet[1], C. Morinière[1], P. Descamps[1]
[1]*CHU d'Angers, Obstetrics and Gynecology, Angers, France*

Study question: Does a specific training for residents in Gynecology and Obstetrics using simulation in the announcement of a miscarriage may reduce women's distress and psychological morbidity?

Summary answer: Training using simulation for residents in the announcement of a miscarriage improves the wellbeing and diminishes the psychological morbidity of patients after a pregnancy loss.

What is known already: Structured simulations are used for critical part of health professions education at every level. Breaking the bad new of a miscarriage is a challenging situation for doctor. Indeed, an early miscarriage is usually associated with a psychological distress. Women can express different feelings such as grief, guilt, post-traumatic stress, anxiety or depression. The announcement of a pregnancy loss and the information given during the consultation may have a major role on the psychological outcomes of the patients. The majority of patients underscore the need for a more considerate care of the healthcare team in the management of early miscarriage.

Study design, size, duration: A "before and after" prospective study was conducted in a French teaching hospital. All women who experienced an announcement of an early pregnancy loss in our gynecological department emergencies from May 2014 to May 2015 were included. At all, 72 patients were included, 45 before and 27 after the training.

Participants/materials, setting, methods: At half-time of the training course, all the six residents who were in charge of emergency cases over the study period attended the training which consisted in an "*in situ*" simulation of early miscarriage announcement. An auto-questionnaire was sent to all patients 8 weeks after the emergency consultation. This questionnaire included specific questions in order to assess the feelings at the end of the consultation and to assess the perinatal bereavement using a validated scale.

Main results and the role of chance: The mean age of the patients was 31 years. The mean term at miscarriage was 8 weeks gestation. The feeling of the patients experiencing a miscarriage was improved after a specific counselling training using simulation. Thus, the lack of availability and the indifference of doctors regarding the pregnancy loss are significantly less experienced by patients after training ($p = 0.03$ and $p = 0.04$ respectively). The information given during the consultation also appear to be more complete, with significantly fewer patients consulting another doctor after the consultation for answering their questions ($p = 0.04$). Concerning the perinatal grief scale, women before training experienced more intense grief scores after a miscarriage than in the post-training group (57.3 vs. 39, $p = 0.02$).

Limitations, reasons for caution: Our study, despite its prospective design, may suffer of a lack of power due to the small sample size. Another limit is the generalizability of the results due to the monocentric design of the study. Further studies are needed to confirm our data's.

Wider implications of the findings: A training for the residents in the announcement of a miscarriage seems to be associated with a better psychological morbidity on women. All gynecologists (seniors and juniors) should be able to receive training in the announcement of bad news in order to reduce the psychological implications of a miscarriage.

Trial registration number: None.

O-074 A meta-analysis of maternal psychosocial effects of twins and multiple births following assisted conception or natural conception/ART singleton births

O. van den Akker[1], G. Postavary[2], S. Purewal[3]
[1]*Middlesex University, London, UK*
[2]*Birkbeck, Centre for Sustainable Working Life, London, UK*
[3]*University of Wolverhampton, Institute of Psychology, Wolverhampton, UK*

Study question: Is maternal psychological health adversely affected by twins and multiple births, by assisted conception or both?

Summary answer: Mothers of ART multiples are significantly more likely to experience depression and stress compared to mothers of ART singletons, but not naturally conceived (NC) multiples.

What is known already: Research on adverse maternal psychosocial consequences of twins and multiple births following assisted reproductive technology (ART) is conflicting and no definitive evidence for the effects of ART and of multiple births on maternal psychological health exist.

Study design, size, duration: Meta-analytic data were analysed using random effects models.

Participants/materials, setting, methods: A bibliographic search was undertaken using PubMed, PsycINFO, CINAHL, ScienceDirect, and hand searches of reference lists up to September 2014. Where insufficient data was available, authors were contacted, which resulted in the inclusion of further unpublished data using PRISMA The review of abstracts and papers was informed following PRISMA and MOOSE guidelines. The quality criteria checklist included the recommendations of Cochrane Collaboration.

Main results and the role of chance: Eight papers (data from 2993 mothers) were included in the meta-analysis. Mothers of ART multiples were significantly more likely to experience depression (standardised mean difference $d = 0.198$, 95% CI 0.050–0.0345, $z = 2.623$, $p = 0.009$; heterogeneity $I^2 = 36.47\%$, $p = 0.146$), and were significantly more likely to experience stress (standardised mean difference $d = 0.177$, 95% CI 0.049– 0.305, $p = 0.007$; heterogeneity $I^2 \leq 0.01\%$, $p = 0.535$) than mothers of ART singletons. Meta-analysis of psychological distress (combined stress and depression) in mothers of ART multiples were no different from mothers of NC multiples (standardised mean difference $d = 0.371$, 95% CI 0.153–0.895 $p = 0.165$; $I^2 = 86.962\%$, $p = 0.001$). Similarly, when depression was analysed separately, no differences between mothers of ART multiples and mothers of NC multiples were found ($d = 0.152$, 95% CI 0.179–0.483: $z = 0.901$: $p = 0.368$; $I^2 = 36.918\%$, $p = 0.208$).

Limitations, reasons for **caution:** This systematic review and meta-analysis has confirmed that mothers of ART multiple births are significantly more likely to experience depression and stress compared to mothers of ART singletons, but the impact of the role of ART and multiple births is not yet resolved.

Wider implications of the findings: Clinicians should be aware of the likelihood of stress and depression in mothers of multiples and in women undergoing ART, and use these data to deter multiple embryo transfers and encourage eSET as the effects were demonstrated well into the first few years post-partum.

Trial registration number: NA.

O-075 Psychosocial adjustment after failed fertility treatment: a meta-analytical and qualitative review

S. Gameiro[1], A. Finnigan[2]
[1]*Cardiff University, School of Psychology, Cardiff, Wales, UK*
[2]*Cardiff University, School of Medicine, Cardiff, Wales, UK*

Study question: How do patients adjust after failed fertility treatment?

Summary answer: Failed treatment results in worse mental-health and well-being. Adjustment depends on patients' ability to accept childlessness, make meaning of their situation and pursue new goals.

What is known already: One-third of fertility patients do not achieve parenthood with treatment. It is unclear if these patients adjust worse than those who do. Quantitative research shows mixed results but these can be explained by conceptual and methodological heterogeneity. Furthermore, quantitative studies have not identified the risk factors nor the psychosocial mechanisms at play during this period. Therefore there is no clear indication for the provision of psychosocial support after failed treatment and no knowledge about the therapeutic mechanisms it should target. However, several qualitative studies focused on patients' experiences during this period and these can inform about their support needs.

Study design, size, duration: Meta-analytical and systematic qualitative review of articles focusing on adjustment after failed treatment published since 1978 in 5 electronic databases.

Quantitative studies had to include group mean comparisons on mental-health (anxiety, depression, psychopathology, stress, etc.) or wellbeing (general-wellbeing, life satisfaction, quality-of-life, etc.) between patients who did failed fertility treatment and a control group (successful treatment, children after treatment).

Qualitative studies had to focus on psychosocial adjustment or experiences or feelings after failed fertility treatment.

Participants/materials, setting, methods: Screening, data extraction and critical appraisal procedures were done independently by the authors using predefined protocols.

Two meta-analyses were performed on mental-health and wellbeing with a random effect model. Primary outcome was Hedge's *g* (0.20, 0.50, 0.80 indicate small, medium, large effect-sizes).

A 3-stage thematic analysis of results reported in primary qualitative papers was implemented following guidelines for qualitative meta-synthesis (Thomas and Harden, 2008). First-order descriptive and second-order interpretative themes were extracted.

Main results and the role of chance: The search returned 5979 non-duplicate records, 119 were retained based on title and abstract and 9 quantitative (2085 patients from 8 countries) and 9 qualitative (267 patients from 6 countries) were included. Quality ratings indicate none low, seven moderate (78%) and two (22%) high-quality quantitative studies, and none low, eight moderate (73%) and three (27%) high-quality qualitative studies.

Six (67%) of the quantitative studies reported on mental-health and 7 (78%) on wellbeing. The meta-analysis showed that the failed group had worse mental-health [$g = -0.450$, $P = 0.002$, 95% CI (−0.734 to −0.267]; $I^2 = 85\%$, $P < 0.001$] and wellbeing [$g = -0.319$, $P < 0.001$, 95% CI (−0.439 to −0.198), $I^2 = 45\%$, $P = 0.001$] than the control group.

The qualitative review resulted in a total of 33 first-order themes that were grouped into 6 second-order themes: childlessness experience – individual, childlessness experience – relational and social, childlessness acceptance, pursuit of new life goals, meaning making, and fertility care perceptions and needs. These themes captured how patients' individual and relational experience and their care perceptions and needs changed over time and how this change was associated with how successful they were in engaging with three main psychological tasks: accepting childlessness, making meaning of their past and current situation and pursuing new fulfilling life goals.

Limitations, reasons for caution: This was a sound quant+qualitative meta-synthesis. However, research in this topic is emergent and few studies were included, mostly being descriptive and suffering from methodological limitations. Only 5 (28%) were of high-quality. The qualitative synthesis was based on published papers that included some level of interpretation of the data collected.

Wider implications of the findings: Results provide compelling evidence for the provision of psychosocial support after failed fertility treatment. Such support needs to target psychological mechanisms that are usually involved in coping with stressful life-events and loss, namely accepting the loss, making meaning of the past/present situation and building new life-goals for the future.

SESSION 20: OVARIAN TISSUE CULTURE, CRYOPRESERVATION AND GRAFTING

Monday 04 July 2016 **Hall 3 DE** **15:15–16:30**

O-076 Improvement of ovarian tissue survival after cryopreservation with anti-apoptotic drugs supplementation of transport and freezing media

L. Henry[1], M. Fransolet[2], S. Labied[1], S. Blacher[2], M.C. Masereel[1], J.M. Foidart[2], A. Noel[2], M. Nisolle[1], C. Munaut[2]
[1]CHU du Sart-Tilman site Hôpital de la Citadelle, Gynecology-Obstetric, Liege, Belgium
[2]University of Liege, LBTD, Liege, Belgium

Study question: Does ovarian tissue supplementation with anti-apoptotic drugs during transport and cryopreservation improves ovarian tissue survival?

Summary answer: Addition of S1P or Z-VAD-FMK to transport and freezing media prior to ovarian tissue cryopreservation improves primordial follicular quality and the global tissue survival.

What is known already: Ovarian transplantation is avascular, resulting on tissue ischemia after grafting associated with reperfusion injury. This represents the main origin of follicular loss. In addition, freezing procedure induces tissue damage: fibrosis and alteration of the viability of both stromal and follicular cells within the ovarian samples. Apoptosis plays important role in cryo-injuries, mainly by the activation of caspases and Fas systems. Indeed, caspase activation was observed in frozen-thawed tissue with preserved architecture.

Study design, size, duration: Sheep ovaries were transported, prepared and frozen in solutions containing vehicle or anti-apoptotic drugs [Z-VAD-FMK or sphingosine-1-phosphate (S1P)]. After thawing, the ovarian cortex was cultured during 2 or 6 days. Six ovarian fragments were analyzed in the each 4 groups: Z-VAD-FMK, Z-VAD-FMK control, S1P and S1P control. These 4 groups were investigated at 4 timings: fresh, frozen-thawed, 2 days and 6 days culture.

Participants/materials, setting, methods: Ovaries of 4 ewes, 4 and 5 months old, were collected after euthanasia. The anti-apoptotic drugs included 10 µM Z-VAD-FMK diluted in DMSO and 10 µM S1P diluted in 0.3M NaOH. In the control groups, the anti-apoptotic drugs were replaced with the appropriate vehicles DMSO or NaOH. Follicular density, morphology and tissue proliferation analyses were performed on paraffin histological sections.

Main results and the role of chance: Only primordial follicles were analyzed due to a very low number of primary and secondary follicles. Transitional follicles were considered as primordial.

To limit the effect of the heterogeneous distribution of the follicular pool within the ovarian cortex, 12 sections per ovarian piece, which covered the entire fragment, were analyzed as previously described by our team. After the outcomes were logarithmically transformed, a linear mixed model was fit to the data to test differences between the treatments and the timings. In this model, the ovarian fragment was introduced as a random factor. To correct for multiple comparisons and to avoid type I errors, the level of statistical significance was set at $p = 0.01$.

After 2 days of culture, S1P improved the quality of primordial follicles; higher densities of morphologically normal ($p = 0.0005$) and proliferative primordial follicles were found compared to control ($p = 0.0087$). Z-VAD-FMK displayed similar effects by preserving global primordial follicular density, but after 6 days of culture ($p < 0.0001$ for global density, $p = 0.0035$ for morphologically normal follicles and $p = 0.0055$ for proliferative follicles). Z-VAD-FMK also improved global cell proliferation after 2 and 6 days of culture, compared to control ($p < 0.0001$ for both).

Limitations, reasons for caution: This study was performed only on sheep ovarian tissue. The beneficial effects of Z-VAD-FMK and S1P in culture over the span of 2–6 days does not necessarily equate into evidence that this approach would allow better engraftment and/or maintenance of primordial follicle health after transplantation.

Wider implications of the findings: Our study demonstrates the beneficial effect of Z-VAD-FMK, and to a lesser extent S1P, on primordial follicles preservation after cryopreservation. These results must be confirmed in human ovarian cortex and after transplantation. Therefore, this model at present only provides a surrogate marker to encourage additional work in this area.

Trial registration number: None.

O-077 Attempts to improve human ovarian tissue grafting with novel matrices for tissue fusion and regeneration

B. Fisch[1], D. Stav[2], Y. Taieb[2], A. Ben-Haroush[2], M. Kirshner[3], A.J. Younis[2], R. Orvieto[4], R. Gabbay-Benziv[2], R. Abir[5]

Study question: Can novel substances for tissue repair [small intestinal submucosa (SIS) and recombinant human collagen bioengineered in plant lines (Collage™)] improve outcomes of human ovarian grafting?
Summary answer: Collage promoted reduction in atretic follicles and in tissue apoptosis. It also increased follicular survival after grafting, while SIS supplementation did not benefit implantation.
What is known already: So far, 60 live births have been reported after grafting frozen–thawed human ovarian tissue to women. However, slow ovarian neovascularization after implantation leads to follicular loss. Therefore, methods to enhance revascularization are needed. Immunodeficient mice engrafted with ovarian tissue can serve as useful hosts for examining graft survival. *Host* treatment with melatonin with *graft* incubation with hyaluronan-rich biological glue+vascular endothelial growth factor A+ vitamin E (the "improvement protocol") promoted better human ovarian implantation in immunodeficient mice. SIS (Cook Biotechnology) enhanced wound healing and tissue remodeling also of rabbit ovaries, and Collage (Collplant) seems a promising new material for tissue repair.
Study design, size, duration: Frozen-thawed human ovarian samples were transplanted into 128 mice. Thawed tissue served as ungrafted control. Tissue was transplanted into the following groups: (1) untreated (grafted control); (2) with SIS or Collage alone; (3) with SIS or Collage+ "improvement protocol" *graft* treatment; (4) with SIS or Collage+ "improvement protocol" *host* treatment; (5) with SIS or Collage+"improvement protocol"; (6) with "improvement protocol" alone. The mice were euthanized 3 weeks after surgery, and the transplants were removed and fixed.
Participants/materials, setting, methods: Ovarian tissue was donated by nine women/girls (age 9–23 years) who underwent ovarian fertility cryopreservation in a tertiary medical center. Informed consent was obtained from the patients or parents of minors. Immunodeficient mice were engrafted with tissue covered with SIS or Collage with/without combinations of the "improvement protocol." Graft survival was assessed by follicle counts, apoptosis assay, immunohistochemical studies of Ki67 (follicular proliferation) and of platelet endothelial cell adhesion molecule (PECAM) (neovascularization) expression.
Main results and the role of chance: Collage and SIS fused well with the grafted ovarian tissue and neovascularization (PECAM staining) was identified in both Collage and SIS. Tissue apoptosis levels were significantly higher with Collage+the "improvement protocol" with/without *host* treatment (p = 0.03, 0.0015, respectively) than with Collage alone or the "improvement protocol" alone. Tissue apoptosis levels were significantly higher in all groups grafted with SIS with/without combinations of the "improvement protocol" than with the "improvement protocol" alone (p = 0.0025–0.0003). Follicular numbers were higher in ungrafted controls, but differences were statistically significant only compared to groups transplanted with SIS alone (p = 0.003) and SIS+ "improvement protocol" *host* treatment (p = 0.02). In grafted samples, recovered follicle number was highest in samples transplanted with Collage alone (NS) than in other groups. The number of atretic follicles was significantly high in most groups grafted with Collage combinations "improvement protocol" compared to Collage alone (p = 0.0002) or the "improvement protocol" alone (p = 0.03). The number of atretic follicles was significantly higher in most groups grafted with SIS with/without the "improvement protocol" than with the "improvement protocol" alone (p = 0.01 to <0.0001). Ki67 staining was identified in all morphologically normal grafted/ungrafted follicles.
Role of chance: There is an uneven ovarian follicular distribution, and we might have initially inadvertently transplanted slices with few follicles.
Limitations, reasons for caution: The availability of human ovaries for research is limited, and we could not allocate ovarian tissue from each patient in parallel to all groups. Moreover, although ovarian tissue from young girls contains numerous follicles their ovaries are small.
Wider implications of the findings: Results with Collage alone were at least as promising as those with the "improvement protocol" alone**.** Collage is non-allergic, non immunogenic and without potential risks of animal derived pathogens. Therefore, its use for grafting ovarian tissue may be easily applied for autotransplantation in cancer survivors without foreseeable risks.
Trial registration number: This not a clinical trial and a trial registration number is not required.

O-078 *In vitro* culture of human ovarian cortical strips in gas permeable dishes improves quality, viability and progression of follicles

R. Talevi[1], S. Sudhakaran[1], G. Russo[1], V. Barbato[1], S. Braun[1], A. Merolla[1], R. Ferraro[2], G. Catapano[3], R. Gualtieri[1]

[1]*Università degli studi di Napoli Federico II, Dipartimento di Biologia, Napoli, Italy*
[2]*Iatropolis, Centro Genesis, Caserta, Italy*
[3]*Department of Environmental and Chemical Engineering, University of Calabria, Cosenza, Italy*

Study question: Does an increased oxygen perfusion through the use of gas permeable dishes affect the quality, viability and progression of follicles in cultured human ovarian cortical strips?
Summary answer: An increased oxygen supply beneath human ovarian cortical strips during *in vitro* culture better preserves the quality, viability and progression of primordial toward secondary follicles.
What is known already: Ovarian tissue culture is a broadly focussed topic in fertility preservation and follicle *in vitro* growth. Conventional cultures fail to support ovarian cortical tissue at the long term, mainly due to the fact that basic physical requirements like oxygen tension and other mechanical stimuli are neglected. In this view, occurrence of central necrosis due to inefficient oxygen and nutrient perfusion is a major hurdle in establishing long term ovarian cortical cultures.
Study design, size, duration: Ten 1 mm × 1 mm × 0.5 mm strips/dish (from the same ovary) were cultured for 9 days in α MEM with 0.1% BSA, 3mM glutamine, 50 µg/ml ascorbic acid, 1% ITS and 1% pen/strep in 5 ml in conventional (CD) and gas permeable (PD) 6 cm dishes in 5% CO^2 in air. Grading and staging of follicles was assessed through histology, and viability through live-dead far red at the confocal microscope.
Participants/materials, setting, methods: Ovarian cortical biopsies collected from three consenting patients (24, 27 and 30 years old) were transported in Leibovitz L15 at 4°C to the lab within 2 h, dissected into strips with a tissue chopper and cultured in CD and PD. Fresh and cultured strips at 6 and 9 days were fixed in Bouin for histological analysis or labelled with live-dead far red and Hoechst 33342 for assessment of viability at the confocal microscope.
Main results and the role of chance: Overall data was collected from 1784 follicles. Fresh tissue at day 0 had a high quality (grade: 1, 47.2; 2, 45.3; 3, 7.5%) and most follicles were at the primordial stage (primordial, 85.5; primary, 14; secondary, 0.5%). At day 6 strips cultured in PD had a higher quality, progression to the secondary stage and viability (grade: 1, 30; 2, 18, 3, 52%; primordial 38; primary, 57; secondary, 5%; viability, 58%) compared to CD (grade: 1, 0; 2, 14; 3, 86%; 1, $P < 0.001$; 2, NS; 3, $P < 0.001$; primordial 31; primary, 69; secondary, 0%, $P < 0.001$; viability, 35%, $P < 0.01$). Data at day 9 confirmed that PD was able to support a higher follicle quality and viability (grade: 1, 30; 2, 21, 3, 49%; viability, 70%) compared to CD (grade: 1, 0; 2, 16, 3, 84%; 1, $P < 0.001$; 2, NS; 3, $P < 0.001$; viability, 47%, $P < 0.01$). Although there was a trend of PD to support a higher progression to the secondary stages, it was not statistically significant (PD: primordial 43; primary, 55; secondary, 2%; CD: primordial 34.5; primary, 64; secondary, 1.5%).
Limitations, reasons for caution: As this is a preliminary study, findings should be confirmed on a higher number of patients.
Wider implications of the findings: Oxygen perfusion dynamics represents a key factor that can control both long term survival and progression of follicles cultured *in situ*. These findings, translated into the design of a continuous flow-bioreactor system that more closely mimics the dynamic ovarian environment *in vivo*, could be applied clinically.
Trial registration number: None.

O-079 Do viable human preantral follicles recover after enzymatic isolation and vitrification?

K. Peeters[1], E. Van Eekelen[1], I. Goovaerts[1], K. Clasen[1], P. Janssens[1], L. Delbeke[1], D. De Neubourg[1], U. Punjabi[1]

[1]*Universitair Ziekenhuis Antwerpen, Centrum Reproductieve Geneeskunde, Edegem, Belgium*

Study question: How is the survival of preantral follicles after enzymatic isolation and subsequent vitrification linked to follicle diameter and morphology?
Summary answer: Enzymatically isolated preantral follicles of intact morphology can be vitrified in a closed system, while small follicles tend to have a lower survival rate.
What is known already: The technique of cryopreservation of ovarian tissue is well established in human fertility preservation, however, reintroduction of cancer cells during reimplantation is a major concern. Isolation of preantral follicles may overcome this problem either at the time of ovarian tissue prelevation

or after thawing. Vitrification of preantral follicles is well established in animal models but as far as we know has never been investigated in humans.
Study design, size, duration: Experimental study in an academic research unit using frozen- thawed ovarian tissue donated for research purposes. Preantral follicles were enzymatically isolated and stained with Neutral Red (N.R.) during isolation. After determining diameter and morphology, viable (N.R. positive) follicles were vitrified. After warming, the follicles were stained again with N.R. Follicles were grouped according to diameter and morphology and survival was compared between groups.
Participants/materials, setting, methods: Cortical ovarian tissue fragments of three former cancer patients, frozen between 2001 and 2003 using a slow freezing protocol, were thawed and digested in Liberase DH and DNase. Neutral Red was added as a viability stain. Isolated viable follicles were vitrified using Vit Kit Freeze and up to 8 follicles were loaded per HSV straw.
Main results and the role of chance: One hundred and fourteen isolated N.R. positive follicles were vitrified of which 101 (88.6%) were recovered after warming. Follicles were classified as being small (<50 µm, 31.6%), medium (50–70 µm, 47.4%) or large (>70 µm, 21.0%). Larger follicles had a higher recovery rate (95.8%) as opposed to 85.2% for medium sized follicles and 88.9% for small ones although these differences were not significant.

Overall, 61.4% of follicles survived vitrification. There was a tendency for a better viability after warming for medium and large follicles (69.6 and 65.2% respectively) compared to 46.9% for small follicles ($p > 0.05$). According to morphology, follicles were classified as being intact (intact basal membrane, close contact between granulosa cells and oocyte), fair (intact basal membrane and loosening of the contact between granulosa cells and oocyte) or compromised (damaged basal membrane). Intact follicles survived significantly better (90.9%) than fair (54.3%) and compromised (9.5%) follicles ($p < 0.005$).

Although potential damage by the use of cryopreserved ovarian tissue, isolation techniques and subsequent vitrification could occur, we still observed a good recovery rate of viable follicles.

Limitations, reasons for caution: Viability was assessed by one parameter only (N.R.) and no culture after thawing was performed to check for developmental competence.

Wider implications of the findings: Isolated human follicles can successfully be vitrified and stored for later use, even after having been cryopreserved for more than a decade. Further research into follicular development and matrix-carrier technology will broaden the horizon of fertility preservation.
Trial registration number: None.

O-080 Are there factors which predict the success of ovarian tissue grafting in oncofertility patients?

K. Stern[1], G. Rozen[1], D. Gook[1], F. Agresta[1], D. Braat[2], L. Hale[1]
[1]*Royal Women's Hospital and Melbourne IVF, Reproductive Services, Melbourne, VIC, Australia*
[2]*Radboud UMC, Obstetrics and Gynaecology, Nijmegen, Netherlands Antilles*

Study question: For oncofertiltiy patients having ovarian tissue grafting what factors, either in the graft tissue or the maternal environment, are associated with longevity of ovarian function or fertility/pregnancy?
Summary answer: Age of patient at time of tissue excision and follicular density were most strongly correlated with graft survival and potential fertility.
What is known already: Ovarian tissue cryopreservation with subsequent grafting is increasingly recognised as a realistic option for fertility preservation in female patients with cancer or other serious disease requiring gonadotoxic therapy. It is the only option for prepubertal girls. However, development of good quality embryos and achievement of pregnancy is still disappointingly elusive, perhaps at least partly due to accelerated atresia of follicles in the grafted tissue. Technical modifications may improve graft function and pregnancy rates and many factors, related to tissue handling, preparation of the environment, and stimulation protocols, are being investigated.
Study design, size, duration: We performed 28 ovarian tissue grafts in 19 patents, average age 28 years (range 18–37) at time of excision and 37 years (range 25 to 45) at time of grafting. Follow up after grafting has been performed for 1–8 years. Nine patients have requested fertility assistance with IVF and a modified low-dose stimulation protocol was employed.
Participants/materials, setting, methods: Young women who had developed premature ovarian failure were assessed for suitability for grafting and all tissue was assessed to exclude tumour. Graft sites included ovarian bed, pelvic side wall and anterior abdominal wall with 7 grafts performed in all three locations, 16 in two locations and five in one location. Monitoring was performed for endocrine and biophysical evidence of restoration of ovarian activity and follicular development, and subsequent fertility assistance was performed with IVF.
Main results and the role of chance: Restoration of ovarian function was achieved in 17/19 patients. Surprisingly, chemotherapy did not correlate with graft activity or duration of function. Graft function commenced on average 4 months (range 1–9 months) after surgery and duration of function of 1–55 months (ongoing) has been demonstrated. Younger age at tissue excision ($r = –0.69$, $p = 0.4$) and follicle number ($r = 0.61$, $p = 0.5$) were most strongly correlated with graft survival. Three births and a further three biochemical pregnancies have been achieved from a total of 21 embryos transferred, with 7 frozen oocytes and 8 frozen embryos currently in storage. However no oocytes were retrieved in 26% of treatment cycles. The twin delivery from abdominal grafting in a patient who had previously had bilateral oophorectomy unequivocally excludes the possibility of a spontaneous pregnancy.
Limitations, reasons for caution: The small number of patients (although one of the largest series reported), incomplete data regarding follicular density and total volume grafted, and our inability to accurately gauge the extent of follicular atresia all hampered our ability to more rigorously investigate predictors of success of graft function.
Wider implications of the findings: A previous report (Schmidt et al., 2010) in a smaller study did not demonstrate a clear relationship between follicle number/volume and graft function. However increasing attention to methods cryopreservation and *in vitro* models of graft function will allow more comprehensive understanding of graft follicle dynamics and hopefully better fertility outcomes.
Trial registration number: Institutional Review Approval.

SESSION 21: POOR RESPONDERS: NEW HOPE?

Monday 04 July 2016 **Room 101** **15:15–16:30**

O-081 The impact of total follicle-stimulating hormone (FSH) dose on outcomes in ESHRE Bologna poor ovarian responders. A *post-hoc* analysis of the ESPART randomized controlled trial

J. Hubbard[1], W. Chin[2], P. Humaidan[3]
[1]*EMD Serono, Global Clinical Development Center, Billerica, MA, USA*
[2]*EMD Serono, Global Biostatistics and Epidemiology, Billerica, MA, USA*
[3]*Aarhus University, Faculty of Health, Skive, Denmark*

Study question: Does FSH dose influence outcomes for poor ovarian responders (PORs) undergoing controlled ovarian stimulation with recombinant-human FSH (r-hFSH) or r-hFSH plus recombinant-human luteinizing hormone (r-hLH)?
Summary answer: In the ESPART study, PORs receiving a total FSH dose of 3000 to < 5000 IU had better outcomes than those receiving < 3000 or ≥5000 IU doses.
What is known already: A large retrospective database analysis by Baker et al. (2015) in IVF patients, suggested that live birth rates significantly decreased with increasing FSH dose, except in women ≥35 years with 1–5 oocytes retrieved. The ESPART randomized controlled trial investigated assisted reproductive technologies (ART) outcomes following controlled ovarian stimulation with r-hFSH or r-hFSH+r-hLH in PORs who met ≥2 of the following criteria (aligned with the Bologna criteria): >40 to <41 years; previous ART cycle with ≤3 oocytes retrieved with conventional stimulation; AMH level 0.12–1.3 ng/mL. A total of 939 patients were randomized and no difference in outcomes was observed between treatments.
Study design, size, duration: This was a *post-hoc* analysis of the ESPART study, not including patients with cycle cancellations. Number of oocytes retrieved, ongoing pregnancy rate (OPR), and live birth rate (LBR) over a single ART cycle were determined for patients grouped according to the total FSH dose received with both treatments. The dose groups investigated were: <3000 IU, 3000 to <4000 IU, 4000 to <5000 IU and ≥5000 IU, and data were summarized descriptively. Individual patient-level data were also investigated.

Participants/materials, setting, methods: The modified intention-to-treat population from the ESPART study, excluding patients with cycle cancellations, (r-hFSH+r-hLH, *n* = 427; r-hFSH, *n* = 445) was analysed. The mean [standard deviation (SD)] age of patients was 38.3 (3.0) years and the mean (SD) number of oocytes retrieved was 3.3 (2.71) and 3.6 (2.82) in patients receiving r-hFSH+r-hLH and r-hFSH, respectively. With r-hFSH+r-hLH, there were 51/462 (11.0%) and 49/462 (10.6%) ongoing pregnancies and live births, respectively; with r-hFSH, 59/477 (12.4%) and 56/477 (11.7%), respectively.
Main results and the role of chance: The total mean FSH dose was similar in both arms**.** The highest number of oocytes retrieved, OPR and LBR was observed with total FSH doses of 3000 to < 5000 IU, and results were similar for both treatment arms. When FSH dose <3000 or ≥5000 IU was used, the number of oocytes retrieved was lower, but similar in both treatment arms. There was a different trend in OPR and LBR at FSH <3000 and ≥5000 IU with or without LH supplementation to FSH (**Table**).

FSH dose	<3000 IU	3000 to <4000 IU	4000 to <5000 IU	≥5000 IU
Age (years), mean (SD)	37.9 (3.2) (*N* = 115)	38.3 (3.0) (*N* = 381)	38.5 (2.8) (*N* = 268)	38.2 (2.9) (*N* = 175)
AMH (ng/mL), mean (SD)	0.52 (0.39) (*N* = 114)	0.69 (0.53) (*N* = 379)	0.61 (0.51) (*N* = 266)	0.40 (0.33) (*N* = 174)
Number of oocytes retrieved, mean (SD)				
r-hFSH	3.3 (2.38) (*N* = 34)	4.4 (3.15) (*N* = 183)	3.7 (2.31) (*N* = 141)	2.9 (2.30) (*N* = 87)
r-hFSH+r-hLH	3.3 (2.29) (*N* = 61)	4.2 (2.97) (*N* = 179)	3.5 (2.32) (*N* = 111)	2.7 (2.15) (*N* = 76)
Ongoing pregnancy, *n*/*N* (%)				
r-hFSH	2/34 (5.9)	29/183 (15.8)	17/141 (12.1)	10/87 (11.5)
r-hFSH+r-hLH	7/61 (11.5)	27/179 (15.1)	15/111 (13.5)	3/76 (3.9)
Live birth, *n*/*N* (%)				
r-hFSH	2/34 (5.9)	28/183 (15.3)	16/141 (11.3)	9/87 (10.3)
r-hFSH+r-hLH	7/61 (11.5)	26/179 (14.5)	14/111 (12.6)	3/76 (3.9)

Limitations, reasons for caution: This was a *post-hoc* analysis, and the results should, therefore, be treated as exploratory. The inclusion criteria were aligned with the Bologna criteria, but not identical to them. Therefore, these results may not be applicable to the wider POR population.
Wider implications of the findings**:** This suggests PORs have maximal responses with 3000 to <5000 IU FSH. Outcomes for PORs not responding to these doses are unlikely to improve at higher doses, while lower doses seem insufficient for maximal response. The different pregnancy and live-birth outcomes observed at <3000 and ≥5000 IU with/without LH supplementation warrants further investigation.
Trial registration number: ClinicalTrials.gov identifier: NCT02047227; EudraCT Number: 2013-003817-16.

O-082 A randomised double blind placebo controlled study of recombinant human growth hormone (r-HGH) on live birth rates in women who are poor responders

R.J. Norman[1], H. Alvino[2], R. Hart[3], L. Rombauts[4], F. the LIGHT Investigators[5]
[1]*Robinson Research Institute, University of Adelaide, Fertility, Adelaide, SA, Australia*
[2]*Robinson Research Institute, University of Adelaide, Obstetrics and Gynaecology, Adelaide, SA, Australia*
[3]*University of Western Australia, Obstetrics and Gynaecology, Perth, WA, Australia*
[4]*Monash IVF, Obstetrics and Gynaecology, Melbourne, VIC, Australia*
[5]*Fertility Society of Australia, Obstetrics and Gynaecology, Adelaide, SA, Australia*

Study question: The primary objective of the study is the live birth rate in poor IVF responders.
Summary answer: This study showed no difference in the live birth rate between the r-HGH or placebo controlled group.
What is known already: Human Growth Hormone (HGH) is important for ovarian steroidogenesis and follicular development. Research to date indicates a trend to an improved live birth rate using HGH as an adjunct in an IVF cycle. However these studies have been underpowered, have significant clinical heterogeneity and the safety outcomes are uncertain.
Study design, size, duration: The study required an enrolment of 390 women to be recruited from 9 fertility centres in Australia and 1 centre in New Zealand. Allocation concealment was ensured by using prenumbered study drug kits allocated to participants on day 1 of their IVF cycle. The group allocation relating to this number was blinded by clinicians and participants until study completion. It was expected this study would be completed in 2 years.
Participants/materials, setting, methods: One hundred and thirty six participants, defined as well women who had a previous IVF/ICSI cycle with >250 IU FSH and <5 oocytes collected, an FSH level <15 IU were recruited to the study. Recombinant FSH stimulation >250 IU, started on day 2/3, study drug commenced on the same day as r-HGH injections All cycles required the use of an antagonist. Cycle management was according to each centres standard protocol.
Main results and the role of chance: One hundred and thirty one participants were randomized, 66 to the r-HGH group and 65 to placebo. 116 had oocyte retrieval, 97 had embryo transfer. 25 participants reported a positive pregnancy test, 16 delivered a live birth. This included 3 sets of twins, all in the r-HGH group. The overall live birth rate per patient randomized = 12.3%. Four serious adverse events, all congenital abnormalities, occurred, 3 in the r-HGH group and 1 in the placebo group. No serious adverse events occurred in the women.

	r-hGH	**Placebo**
Clinical pregnancy (%)	9.1	9.2
No. of oocytes collected (mean)	5.38 (SD 3.43)	4.96 (SD 3.47)
Embryo quality (median)	2.00 (1.00, 3.67)	2.14 (1.00, 4.00)
Days of FSH stimulation (median)	8 (2, 13)	8 (2, 15)
Days of a study drug (median)	8 (7, 14)	9 (0, 15)
No. of embryos transferred (mean)	1.0 (0, 2.0)	1.0 (0, 2.0)

Limitations, reasons for caution: Recruitment proved very difficult and the study was terminated after 4 years due to slow recruitment. The original numbers for enrolment were not reached; hence our study remained underpowered to answer our question. These results are based on an intention to treat analysis.

Wider implications of the findings: This study highlights the difficulty in answering important questions to provide the evidence to enable the best clinical treatment**.** The literature to date is diverse and divisive. Much of the literature does not address the most important clinical outcome our patients require, that of delivering a live healthy infant.
Trial registration number: ACTRN12609001060235 Australian New Zealand Clinical Trial Registry.

O-083 A prospective randomized controlled study depicting favourable IVF outcomes of pretreatment with transdermal-testosterone in poor-responders undergoing ART cycles

M. Singh[1], R. Singh[2], A. Jindal[2], P.C. Jindal[2]
[1]*Singh Monica, Infertility, Bhopal, India*
[2]*BTTB Centre, Infertility, Bhopal, India*

Study question: To evaluate the effect of transdermal testosterone preceding ovarian stimulation, in improving IVF outcome in women with poor ovarian response undergoing IVF-ICSI cycles?
Summary answer: Pretreatment with Transdermal testosterone may improve ovarian response to gonadotrophins in low-responder IVF patients.
What is known already: The poor response to ovarian stimulation among women undergoing IVF is of great concern in reproductive medicine. The reported incidence of poor response varies from 10 to 30%. Certain modalities have been tested to improve the response to gonadotrophin stimulation and thus reproductive outcomes. In daily practice, the most commonly used agents before or during ovarian stimulation are transdermal testosterone, dehydroepiandrosterone (DHEA), aromatase inhibitors, recombinant LH and recombinant human chorionic gonadotrophin (HCG). The results from previous many trials that aim to increase intra ovarian androgen concentrations in poor responders have shown conflicting results.
Study design, size, duration: Prospective randomized controlled trial to investigate the effectiveness of treatment with transdermal testosterone gel before controlled ovarian stimulation in 214 low responders patients between 2010 and 2015.

Our objective was to determine if administration of exogenous testosterone prior to gonadotropin stimulation leads to better IVF-ICSI outcome in known poor responders.

There were no differences in patients' characteristics between the two groups.

Patients were randomized into TTG pretreatment group and control group.
Participants/materials, setting, methods: A total of 214 poor responders (2010–2015) were included, defined as those who failed to produce <3 follicles with the result that <3 oocytes were retrieved despite the use of a high gonadotropin dose, in a previous failed IVF cycle. Patients were randomized into TTG pretreatment group and control group. For TTG pretreatment group, 12.5 mg TTG was applied daily for 21 days in the cycle preceding IVF cycle. GnRH antagonist protocol was used in both groups.
Main results and the role of chance: Total dose and days of FSH used were significantly fewer in the TTG pretreatment group than in the control group. The numbers of oocytes retrieved, mature oocytes, fertilized oocytes, and good-quality embryos were significantly higher in the TTG pretreatment group. Embryo implantation rate and clinical pregnancy rate per cycle initiated also were significantly higher in the women pretreated with TTG.

The primary outcome measured was the number of mature oocytes retrieved. Secondary outcomes included total amount and days of FSH administered, numbers of fertilized oocytes and good-quality embryos, implantation rate, clinical pregnancy rate per cycle, and live birth rate per cycle. Embryo implantation rate (13%) was significantly higher in the TTG pretreatment group than in the control group (06%). The clinical pregnancy rates were also significantly higher in the TTG pretreatment group than in the control group (29 and 14% respectively).
Limitations, reasons for caution: Studies to date have focused on older patients or women with reduced ovarian reserve and "resurrecting" these ovaries may be an impossible task. Considering the relatively long duration of folliculogenesis compared with exposure to androgens used, possibly different doses and duration of androgen treatment may ultimately be required.
Wider implications of the findings: TTG pretreatment might be beneficial in improving both response to COS and IVF outcome in poor responders undergoing IVF/ICSI. Our study demonstrated that TTG pretreatment can increase the numbers of oocytes retrieved, fertilized oocytes, better embryos and pregnancy rate as well as reduce the amount of FSH required during IVF/ICSI cycles.
Trial registration number: BTTBC/2010/13.

O-084 Dehydroepiandrosterone administration does not increase pregnancy rates in poor responders: a meta-analysis

E. Kolibianakis[1], J. Bosdou[1], C. Venetis[2], T. Tarlatzi[1], L. Zepiridis[1], K. Chatzimeletiou[1], B. Tarlatzis[1]
[1]Medical School, Aristotle University of Thessaloniki, Unit for Human Reproduction, First Department of Obstetrics and Gynecology, Thessaloniki, Greece
[2]University of New South Wales, Department of Women's and Children's Health, St George Hospital, School of Women's and Children's Health, Kogarah, NSW, Australia

Study question: Does dehydroepiandrosterone (DHEA) administration improve the probability of pregnancy in poor responders undergoing ovarian stimulation for *in vitro* fertilization (IVF)?
Summary answer: DHEA administration in poor responders undergoing ovarian stimulation for IVF is not associated with an increase in the probability of pregnancy.
What is known already: DHEA administration in poor responders undergoing ovarian stimulation for IVF has been hypothesised to increase the intra-ovarian androgen concentration and the sensitivity of developing follicles to follicle stimulating hormone. A recently published Cochrane meta-analysis suggests that treatment with DHEA is associated with an improved probability of pregnancy in poor responders. However, this conclusion was based on synthesis of data from studies that did not recruit exclusively poor responders and thus it is of questionable value.
Study design, size, duration: A literature search was performed in MEDLINE, CENTRAL and Web of Science until January 2016, aiming to identify randomised controlled trials (RCTs) evaluating DHEA administration exclusively in poor responders undergoing IVF. Seven eligible RCTs evaluating a total of 576 patients were meta-analysed.
Participants/materials, setting, methods: The main outcome measure was achievement of pregnancy, expressed as either clinical pregnancy or as live birth. Secondary outcome measures included duration of stimulation, total units of gonadotrophins required, number of cumulus-oocyte complexes (COCs) retrieved, number of 2-pronuclei oocytes and number of embryos transferred.
Main results and the role of chance: Administration of DHEA for a period of 6–12 weeks prior to ovarian stimulation did not improve significantly the probability of clinical pregnancy (RR: 1.10; 95% CI: 0.81–1.50) or live birth (RR: 1.18; 95% CI: 0.36–3.88) as compared to no DHEA treatment. Although DHEA administration was associated with a significant decrease in the total units of gonadotropin required (WMD: −783.9 IU, 95% CI: −1065.6 to −502.3), no significant differences were observed in the duration of stimulation (WMD: −1.25 days, 95% CI: −2.53 to +0.03), in the number of COCs retrieved (WMD: +0.66 COCs, 95% CI: −1.88 to +3.19), in the number of 2-pronuclei oocytes (WMD: +1.13 2pn, 95% CI: −0.32 to +2.58) and in the number of embryos transferred (WMD: +0.53 embryos, 95% CI: −0.24 to +1.30), respectively.
Limitations, reasons for caution: The definition of poor ovarian response, the protocols used for DHEA administration and for ovarian stimulation varied among studies. Despite the fact that statistical heterogeneity was managed by using random effects models, where appropriate, the limited number of the studies analysed precluded an insightful evaluation of clinical heterogeneity.
Wider implications of the findings: The current meta-analysis, based on synthesis of data from RCTs including exclusively poor responders, does not suggest that DHEA improves the probability of pregnancy in this category of patients. This information is important for appropriately counselling poor responders without offering them unrealistic expectations regarding their prognosis.
Trial registration number: –.

O-085 Elevated progesterone on the day of triggering final oocyte maturation significantly predicts its reoccurrence in a subsequent IVF cycle

C. Venetis[1], E. Kolibianakis[2], J. Bosdou[2], G. Lainas[3], I. Sfontouris[3], B. Tarlatzis[2], T. Lainas[3]
[1]University of New South Wales, School of Women's and Children's Health, Sydney, NSW, Australia
[2]Aristotle University of Thessaloniki, First Department of Obstetrics/Gynecology, Thessaloniki, Greece
[3]Eugonia, ART Clinic, Athens, Greece

Study question: Does progesterone elevation (PE) on the day of triggering final oocyte maturation during an IVF cycle increase the risk of PE in subsequent cycles?
Summary answer: History of PE on the day of triggering final oocyte maturation is a significant predictor of its reoccurrence in a subsequent IVF cycle.
What is known already: Progesterone elevation on the day of triggering final oocyte maturation is associated with the magnitude of the ovarian response to stimulation. Whether patients with previous occurrences of PE on the day of hCG are at a higher risk for PE in subsequent cycles as compared to patients with no PE in a previous cycle is not currently known.
Study design, size, duration: This is a retrospective analysis of a cohort of fresh IVF/ICSI cycles (N = 1,702) performed in a single IVF center during the period 2001–2015.
Participants/materials, setting, methods: Patients in which ovarian stimulation was performed with FSH and GnRH antagonists and with basal follicle FSH <14.0 mIU/mL and estradiol (E2) ≤80 pg/mL prior to initiation of stimulation were examined. Cycles from patients that had contributed ≥2 cycles (n = 197) in the study sample were analyzed by generalized estimating equation (GEE) analysis to calculate odds ratio (OR) with 95% confidence intervals (CI) for the prediction of PE occurrence and also to adjust for the intensity of ovarian stimulation.
Main results and the role of chance: Overall, 168 patients contributed 2 cycles, 25 patients contributed 3 cycles and 4 patients contributed 4 cycles. In 230 cycles (with a previous cycle in the study sample), 15 exhibited progesterone elevation (6.5%, 95% CI: 4.0–10.5) while in 22 cycles there was history of PE in a prior cycle (9.6%, 95% CI: 6.4–14.1). In six out of these 22 cycles, PE reoccurred, while this was the case only in 9 out of the 208 cycles without a history of PE.

A GEE regression analysis indicated that PE on the day of hCG in a previous cycle was associated with an increased risk of PE in a subsequent cycle (OR: 8.4, 95% CI: 2.8–24.9). The adjusted risk of PE was 4.3% (95% CI: 1.5–7.0) and 27.3% (95% CI 10.3–44.3) for cycles without and with history of PE, respectively. A full model adjusting for the intensity of ovarian stimulation showed that history of PE was still a significant predictor (OR: 6.26, 95% CI: 1.81–21.62).
Limitations, reasons for caution: This is a retrospective analysis and although the effect of the most important confounders was controlled for in the multivariable analysis, the presence of residual bias cannot be excluded.
Wider implications of the findings: The findings of this study might help clinicians identify patients at high risk for PE and either opt for an approach that will reduce the probability of PE (e.g., milder stimulation) or counsel them

about the increased probability of freezing all embryos and deferring embryo transfer.

Trial registration number: Not applicable.

O-086 Extensive sequencing of the embryo: implications and complications

T. Voet[1]

[1]*Leuven University Hospital Campus Gasthuisberg, Department of Human Genetics, Leuven, Belgium*

Single-cell genomics enables investigating the extent and nature of genomic and transcriptomic heterogeneity which occurs in both normal development and disease, and provides new tools for clinical application. We have developed various *in vitro* and *in silico* methods that allow analysing a solitary cell at high resolution via microarray and next-generation sequencing platforms. Most recently, we developed methods to sequence both DNA and RNA of the same single cell, enabling genotype-phenotype correlations on the single-cell level (Macaulay et al., 2015; Angermueller et al., 2016), as well as methods for concurrent DNA copy number typing and haplotyping of single cells (Zamani Esteki et al., 2015). Data on the application of these methods for understanding the biology of cellular heterogeneity during the first cell divisions of life will be presented (Bolton et al., 2016; Goolam et al., 2016; Destouni et al., in press), including also unpublished data on human preimplantation embryos. Finally, novel single-cell genome-wide analysis methods that are now clinically applied for human embryo selection for the purpose of preimplantation genetic diagnosis (Zamani Esteki et al., 2015) and a visionary on the future will be introduced.

O-088 Timing in reproduction in mammals by photoperiod

F.J.P. Ebling[1]

[1]*University of Nottingham Queens Medical Centre, School of Life Sciences, Nottingham, UK*

Seasonal reproduction is the norm amongst mammals indigenous to temperate and polar regions, such that offspring are born in the optimal season for their mothers to support pregnancy and lactation, and for their own survival. Almost all species use the annual change in photoperiod as the primary cue to regulate the seasonal changes in neuroendocrine function that underlie such reproductive rhythms. In the last decade huge advances have been made in understanding the mechanisms whereby this happens, revealing neuroendocrine pathways that may help us understand hypothalamic control of energy metabolism and reproduction in humans. Annual changes in daylength are primarily detected by melanopsin-containing retinal ganglion cells. This information is integrated by the suprachiasmatic nucleus of the hypothalamus, and regulates the nocturnal duration of melatonin secretion. Although the pivotal role of the changing pattern of melatonin secretion in seasonal reproduction has long been known in mammals, recent evidence indicates that the pars tuberalis (pituitary stalk) is a key site of action of melatonin. The short duration of nocturnal melatonin secretion in long days promotes thyroid stimulating hormone (βTSH) secretion from the *pars tuberalis*, which acts in paracrine fashion on hypothalamic tanycytes whose end feet project to the pituitary stalk. βTSH promotes expression of deiodinase 2 gene in tanycytes, which catalyses the local conversion of inactive thyroid hormone (thyroxine: T_4) into the active form of thyroid hormone: T_3 (tri-iodothyronine). Conversely, in short days, the long nocturnal duration of melatonin reduces the βTSH signal from the *pars tuberalis,* and deiodinase 2 gene expression decreases in tanycytes, whereas deiodinase 3 (DIO3) gene expression increases. DIO3 deiodinates T_4 and T_3 to generate inactive compounds, so across all seasonal mammals studied to date there is a clear photoperiod-regulated change in local availability of T_3 in the hypothalamus. The increase in local hypothalamic T_3 concentrations in long days and the consequent decrease in short days are functionally important for activity of the hypothalamic–pituitary–gonadal axis. Our experiments in the Siberian hamster have revealed that placement of microimplants releasing T_3 into the hypothalamus blocks short-day induced testicular regression. Correspondingly, placement of such implants into animals previously exposed to short days with regressed testes will induce gonadal recrudescence. Thus, the high T_3 concentrations in long days promote reproductive activity, but the reduction of T_3 in short days results in the inactivation of the reproductive axis. These seasonal changes ultimately reflect changes in kisspeptin activation of gonadotrophin-releasing hormone neurons, but these neuroendocrine changes are not simply a direct consequence of high hypothalamic thyroid hormone concentrations. In seasonal species like sheep that become reproductively active under short days, the activation of the reproductive axis is associated with a decrease in hypothalamic T_3 concentrations, and an increase in T_3 in the hypothalamus is necessary to terminate the breeding season. As T_3 is critical for initial development of the brain in the fetus, it has been hypothesized that T_3 exerts long-term control of hypothalamic function by the recapitulation of mechanisms important in initial development. Tanycytes are a stem cell niche supporting hypothalamic neurogenesis in the adult brain, and play a key role in the transport and regulation of thyroid hormone availability and other developmentally important signals such as retinoic acid in the hypothalamus. According to this view, the hypothalamus as a plastic region of the brain, capable of being reprogrammed, so we should appreciate that seasonal species provide valuable model systems to elucidate the mechanisms underlying adult brain plasticity. Such plasticity is not only core to seasonal cycles of reproductive activity, but also to seasonal cycles of appetite, energy expenditure and fat metabolism, with which reproductive cycles are intimately associated.

O-089 Influences of environmental conditions on the reproductive system and fertility in humans

A. Lerchl[1]

[1]*Jacobs University Bremen, Life Sciences and Chemistry, Bremen, Germany*

Most environmental factors fluctuate with considerable amplitude, such as temperature, photoperiod, tide, humidity and precipitation. Since all of them are a consequence of astronomical cycles of the earth, and the moon, respectively, they occur *cum granum sale* with high reliability and precision. Secondary to these changes, the presence of organisms at various times of the day and the year fluctuates with high precision and predictability as well. Therefore it is highly advantageous for a species' survival to adapt to such physical and biological environmental fluctuations with high reliability. In contrast to passively reacting to those changes, anticipating them is favorable, and therefore reliable biological clocks have evolved with frequencies of approximately

24 h (circadian), 12.5 h (circatidal), 28 days (circalunar), and 1 year (circannual). These rhythms persist without any environmental entraining rhythm ("zeitgeber"), and some of them are present even in unicellular organisms. In many mammalian species the time of reproduction is strictly regulated by the environmental factor photoperiod *via* the hormone melatonin and limited to a distinct period of the year, thus ensuring that the offspring find optimal conditions for survival after birth. Due to the different gestational length, rodents reproduce mainly in late spring and summer (long-day breeder), while ruminants are sexually active in late autumn or winter (short-day breeder). While humans are generally believed to reproduce throughout the year without a strict seasonality, there are nevertheless marked seasonal birth rate fluctuations which depend on geographical and secular influences. Because humans lack melatonin receptors in the *pars tuberalis* which is the site of action of the hormone in seasonal breeders, these fluctuations are considered to be potential epiphenomena of other factors, e.g., behavioral changes. This assumption is corroborated by observations showing a marked shift by 6 months in seasonal birth rates in many countries in the 1960s to 1980s. The explanation for this effect may be that environmental cues are more and more shielded from humans due to central heating and artificial illumination. Less easily explained are seasonal patterns of secondary sex ratios in humans and their influences by environmental temperatures before conception. Although these data are in good accordance with studies in rodents and other species, and although the effect as such makes sense in evolutionary terms, the mechanisms which are responsible for this effect are enigmatic. For the production of sperm, circadian rhythms may play a decisive role because a number of so-called clock genes have been found to be expressed at highly variable levels. It is argued that not only the maturation of sperm and oocytes depend on intact circadian clock genes, but also that the synthesis of steroids in the Leydig cells, and the granulosa cells, respectively, are severely hampered if the circadian gene expression machinery is not working properly. This kind of research is certainly promising in an area where a large proportion of infertility is diagnosed as idiopathic. In recent years, some attention has been attracted by studies allegedly showing detrimental effects of exposure to artificial radiofrequency electromagnetic fields (RF-EMF, such as those originating from mobile phones) on sperm production. While a possible mechanism for such effects has not been identified yet and is quite unlikely to exist for biophysical reasons, many experimental studies performed so far chronically suffer from inadequate exposure conditions. In contrast, carefully designed multi-generation studies in mice have not indicated any negative effect of RF-EMF exposure on both sexes. Likewise, the numbers of offspring up to the fourth generation were not affected.

INVITED SESSION

SESSION 24: CONSEQUENCES OF AN EXTRA X-CHROMOSOME – LESSONS FROM MOUSE MODELS AND CONSEQUENCES FOR CHILDREN

Monday 04 July 2016 **Hall 3 AB** **17:00–18:00**

O-090 Molecular mechanisms of the supernumerary X chromosome in the XXY* mouse model

J. Wistuba[1]
[1]*Centre for Reproductive Medicine and Andrology, Muenster, Germany*

Study question: Can general molecular mechanisms and the genetic impact of the supernumerary X-chromosome be adequately examined in 41,XX^{Y}* male mice?
Summary answer: Data obtained in 41,XX^{Y}* mice suggest their usefulness for the examination of the effects of a supernumerary X-chromosome in a male environment.
What is known already: Klinefelter syndrome (KS, 47,XX^{Y}) provokes infertility, hypogonadism, gynecomastia, disturbed bone metabolism, diabetes, cardiovascular and cognitive problems. Although morbidity and mortality are increased, the disorder is underdiagnosed, likely because of heterogeneous phenotype and variable severity. Generally, loss of germ cells and hypogonadism are observed. Although X-inactivation is normal in KS men, genes escaping from silencing ("escapees") seem to provoke genetic and epigenetic changes resulting in affected DNA methylation and differentially expressed X-chromosomal and autosomal genes. However, clinical studies are limited. Thus, the availability of mouse models resembling human KS is of advantage.
Study design, size, duration: During the last 10 years we characterized 41,XX^{Y}* mice in several studies for inactivation of X-chromosomal genes, the dynamics of germ cell loss, testicular vascularization, and the function of the somatic Leydig and Sertoli cells as well as memory recognition over the entire postnatal life from newborn to adult animals. Male and female littermates of 41,XX^{Y}* mice served as controls.
Material/settings/methods: Male 41,XX^{Y}* and male and female control mice for experimental use were obtained from our B6Ei.Lt-Y* mouse colony. Group sizes varied between three animals per group and time point up to >40, dependent on the analyses. Expression of genes was examined by qPCR, protein abundances by immunohistochemistry, for endocrine measurements radioimmuno assays were employed, vascularization was assessed by ultrasound imaging and cognition by behavioural phenotyping.
Main results and the role of chance: In mice only few genes escape from X-inactivation making the analysis feasible compared to the more complex situation in patients. However, these few most relevant escapee genes which mice and men share, i.e., *Utx*, *Kdm5c*, *Eif2s3x* and *Ddx3x* are also inducing a phenotype very similar to human KS. Analyzing the expression of these genes in 41,XX^{Y}* male mice, we found tissue- and gene- but also development-specific expression profiles rendering genotype-phenotype relations more complex than thought so far. Physiologically, data from mouse models elucidated that the disturbed metabolism and the cognitive deficits have a genetic background and are not only metabolic consequences of the disorder. In addition, experimental exploration using the animals revealed germ cell loss to start already during the intrauterine life period and to be accompanied by fading expression of spermatogonial markers like Lin28 and Pgp9.5 in the early postnatal phase. However, the steroidogenic Leydig cells seem to function normally although being hyperactivated, i.e., not to be causative for hypogonadism, a finding which was later confirmed in patients. The latter finding pointed to a possible problem of testicular blood supply, confirmed recently by reporting the testicular vascularization in 41, XX^{Y}* mice to be disturbed.
Limitations, reasons for caution: Whilst human KS results in a heterogeneous phenotype; in the models it is homogeneous. A substantial proportion of KS patients exhibit XY/XX^{Y} mosaicism, not observed in the mice. Studies addressing the germ cell loss must consider different rodent and primate spermatogonial systems as well as developmental differences.
Wider implications of the findings: Experimental exploration of KS has identified genetic and epigenetic effects in KS which appear rather complex. Mouse models can be used to define genotype-phenotype correlates. This might become especially important in terms of so far overlooked features of the syndrome, e.g., the hampered circulation and cardiovascular problems.
Study funding: Deutsche Forschungsgemeinschaft; grants no. WI 2723/2-1, -4-1.

O-091 Treatment options for infertility in Klinefelter patients

H. Tournaye[1]
[1]*UZ Brussel, Center for Reproductive Medicine, Jette, Brussels, Belgium*

At the onset of puberty, Klinefelter men face testicular stem cell loss by slowing-down their self-renewal and by intensified apoptosis. While in the adult Klinefelter testicular tubules show a Sertoli-cell-only pattern with sclerosis and fibrosis, occasional tubules showing active spermatogenesis may be observed in about half of them. In case, spermatozoa can be surgically harvested for ICSI. While in many case-series chromosomally normal offspring has been reported, at present it remains unclear how successful this strategy can be overall since these reports tend to overestimate the actual outcome in a biased way. There is also great controversy in regards to whether pubertal adolescent Klinefelter boys should have TESE offered to preserve future fertility. The controversy is even greater for fertility preservation in pre-pubertal Klinefelter boys. At present, there is no data demonstrating any benefit of early fertility preservation in adolescents compared to the adult patients. No data at all exist on the benefit of testicular tissue banking at pre-pubertal age. Testicular tissue freezing in pre-pubertal 47,XX^{Y} boys requires further validation in a research framework. Not only do we need to scrutinize the potential benefits vs. drawbacks, but because of progressing fibrosis of the testes, the need for *in vitro* maturation strategies should be investigated too.

O-092 Effect of the timing of oocyte insemination or injection on the fertilization and embryo utilization rates in assisted reproduction

B. Desmet[1], S. Santos-Ribeiro[1], N. De Munck[1], W. Meul[1], H. Van de Velde[1], G. Verheyen[1]
[1]*UZ Brussel, Centre for Reproductive Medicine, Jette, Brussels, Belgium*

Study question: Does the time interval between ovulation triggering and oocyte insemination or injection affect the fertilization and utilization rates in conventional IVF and ICSI cycles?
Summary answer: There is no clinically relevant impact of oocyte insemination or injection timing after ovulation triggering on fertilization and embryo utilization rates.
What is known already: Oocyte retrievals are commonly scheduled 36 h after ovulation triggering. Previous studies have shown that MII oocyte nuclear and cytoplasmic maturation seems to be optimal 38 h to 39 h after ovulation triggering, which corresponds with 2 to 3 h post-retrieval. Time intervals above 40 h may lead to *in vitro* oocyte aging and an increased risk of ultrastructural defects. However, it may be difficult from a practical point of view to respect this short timeframe, especially in ART centres with heavy workloads. Time intervals lower than 38 h and higher than 39 h are common practice in busy IVF laboratories.
Study design, size, duration: A single-centre retrospective cohort analysis of 1696 IVF and 14,553 ICSI cycles from 2008 until 2015 was performed. The time between ovulation triggering and oocyte insemination/injection were grouped in one of the 7 following regular 1 h-interval categories: <36, 36, 37, 38, 39, 40 and ≥41 h. Our main outcome measures were the fertilization and utilization rates (embryos adequate for transfer or cryopreservation) per inseminated cumulus-oocyte complex for IVF or per MII for ICSI.
Participants/materials, setting, methods: Only cycles using fresh autologous gametes were included. We excluded managed natural cycles, cycles with combined conventional IVF/ICSI, PGD cycles and IVM cycles. In total, we analyzed 16,866 inseminated (IVF) and 104,593 injected (ICSI) oocytes. We performed mixed-effects multilevel multivariable regression analysis, accounting for the clustering of oocytes by cycle and patient and also the following potential confounders: female age, pre-preparation sperm concentration and post-preparation sperm motility.
Main results and the role of chance: In the IVF group, no significant differences in the adjusted fertilization (range 57.4–62.9%) and utilization rates (range 30.4–34.8%) were observed between the time intervals. In the ICSI group, the pairwise comparison showed that, compared to all other timeframes, the adjusted fertilization rate was slightly but significantly lower for the <36 h interval (71.0 versus 78.3, 77.6, 78.0, 78.9, 79.3 and 79.9% for each 36 to > 41 h 1 h-regular interval, respectively). However, the adjusted utilization rates after ICSI did not vary significantly between all the time intervals assessed (41.1, 44.3, 43.1, 45.5, 44.8, 43.9 and 43.8%, respectively).
Limitations, reasons for caution: This was a retrospective study with its inherent limitations. Furthermore, these results should not be extrapolated to other cycle outcomes, such as pregnancy rates.
Wider implications of the findings: These results offer reassurance to centres which find themselves frequently forced to re-schedule oocyte insemination/injection timing owing to an extenuating workload. Although we found a slight decrease in fertilization after ICSI performed <36 h after triggering, this difference seemed clinically irrelevant since it had no expression on the utilization rates.
Trial registration number: None.

O-093 Cumulus growth pattern of *in vitro* matured cumulus-oocyte-complexes (COC) of transsexual persons obtained during cryopreservation of ovarian tissue correlates with the maturation status.

S. Lierman[1], K. Tilleman[1], C. De Roo[1], S. Weyers[2], G. T'Sjoen[3], P. De Sutter[1]
[1]*University Hospital Ghent, Department for Reproductive Medicine, Ghent, Belgium*
[2]*University Hospital Ghent, Department of Gynaecology, Ghent, Belgium*
[3]*University Hospital Ghent, Department of Endocrinology, Ghent, Belgium*

Study question: Is the morphology growth pattern of COCs from female-to-male transsexual persons during *in vitro* maturation (IVM) an indicator for oocyte meiotic competence?
Summary answer: Cumulus expansion was a significant positive indicator and the cumulus–oocyte interaction a significant negative indicator for maturity of the *in vitro* matured oocyte.
What is known already: Baboon oocytes collected from small antral follicles during ovary dissection in the luteal phase were *in-vitro* matured and produced viable embryos (Woodruff et al., 2011). The meiotic competence of these oocytes was positively correlated with the number of surrounding cumulus cells (CC). In PCOS patients, immature oocytes collected from non-stimulated cycles showed that the amount, the morphology of the CC and its connection to the oocyte played an important role in predicting the final quality of the COCs (Liu et al., 2010).
Study design, size, duration: Cumulus mass (CM); cumulus expansion (CE) and contact between CC and the oocyte (CO) were scored according to Smitz (2004), the size of the expansion was measured and calculated on day 0, 1, and 2. After 48 h IVM, oocytes were denudated and the maturation status was assessed.
Participants/materials, setting, methods: A total of 123 COCs were collected at the moment of cryopreservation of ovarian tissue from 4 female-to-male transgender persons with a mean age of 20.1 ± 2.7 years. IVM was performed for 48 h using a commercial IVM media (Origio). To assess the independent effect of each parameter, logistic linear regression analysis (SPSS v23) was performed to predict which variable was statistically associated with maturity ($P < 0.05$).
Main results and the role of chance: On day 0, 65.0% (80/123) of the COC were fully enclosed by their CC (CO), 87.8% (108/123) showed tight dense CC mass (CE) and 56.1% (69/123) had 10 or more layers of CC (CM). Generally, 43.1% (53/123) of the COCs were fully enclosed with tight dense cells of 10 or more layers of CC. Mean size of day 0 COCs was 366.5 ± 263.7 µm.

On day 1, 63.4% (78/123) of the COCs were still fully enclosed (CO). For the expansion status (CE), 35.8% (44/123) of the COCs showed already moderate expansion of their CC and 9.8% (12/123) showed fully expanded CC. After 24 h *in-vitro* culture, 5.7% (6/123) were already naked oocytes. Mean size of day 1 COCs was 473.9 ± 263.7 µm.

On day 2, 33.3% (41/123) of the COCs showed moderate expansion, 13.8% (17/123) showed fully expanded CC. After 48 h *in-vitro* culture, 22.0% (27/123) were naked oocytes.

Finally, 20.3% (25/123) of the IVM COCs reached MII stage. Statistical analysis showed that the CE on day 2 was a positive indicator for MII ($P = 0.021$) and that de CO was a negatively associated with MII ($P = 0.007$).
Limitations, reasons for caution: This study is limited in the number of COCs and patients used to conclude that morphological parameters can be clinically applied as statistical prognostic tool in the oocyte maturation outcome in IVM programs for transgender persons.
Wider implications of the findings: The morphological growth pattern during maturation can help us to study the maturation competence of these COCs that are obtained during the ovarian tissue cryopreservation. Expansion of the cohort would make it possible to design a prognostic model for clinical use in fertility preservation programs for transgender persons.
Trial registration number: This research is conducted with the approval of the local ethics committee 2015/0124 – B670201523543).

O-094 The difference in size between male and female pronuclei immediately before pronuclear membrane break down (PNMBD) identifies embryos that have potential for successful live birth

K. Hatano[1], J. Otsuki[1], T. Iwasaki[1], Y. Katada[1], H. Sato[1], Y. Tsutsumi[1], Y. Tsuji[1], K. Furuhashi[1], Y. Matsumoto[1], S. Kokeguchi[1], M. Shiotani[1]
[1]*Hanabusa Women's Clinic, Reproductive Medicine, Kobe, Hyogo, Japan*

Study question: Can the difference in size between male and female pronuclei (PN) be one of the indicators to tell normal embryos?
Summary answer: Yes, the birth of healthy babies derives from zygotes having similar sized male and female pronuclei, when this measurement is achieved immediately before PNMBD.

What is known already: The size of a male pronucleus is known to be larger than a female pronucleus, however, observation of the size is generally made about 16–20 h after fertilization, although the PN continues to grow until PNMBD.
Study design, size, duration: Retrospective cohort study involving 71 frozen–thawed single blastocyst transfers observed by time lapse system (Embryo Scope) from June 2013 to December 2014.
Participants/materials, setting, methods: Time lapse recordings were performed and the areas of male and female pronuclei were retrospectively analyzed by measuring vertical and horizontal diameter of pronuclei. The measurements were taken 4 h before the PNMBD, which is equivalent to 16–20 h after insemination or ICSI, and right before the PNMBD. The difference in square measurements between the 2PNs in embryos resulting in clinical pregnancy and live born babies were compared to those of embryos from failed pregnancies.
Main results and the role of chance: 71 frozen-thawed blastocysts were transferred after observation with a time-lapse system. The hCG, gestational sack (GC), fetus heart beat (FHB) positive rates were 74.2% (52/71), 63.4% (45/71) and 57.7% (41/71) respectively. Among the 41 cycles with positive FHB, 36 cases were delivered without any chromosomal abnormality, 4 cases miscarried and one case lost contact. The average difference in area (±SD) between 2 pronuclei 4 h before and immediately before PNMBD among patients resulting in the birth of healthy babies were 39.9 μm^2 (±37.8) and 11.6 μm^2 (±15.5) respectively, whereas the average difference in those resulting in unsuccessful birth were 62.8 μm^2 (±43.0) and 62.8 μm^2 (±53.3) respectively. Statistically significant differences were obtained between patients with successful and unsuccessful births both 4 h before ($p = 0.012$) and immediately before ($p < 0.001$) the PNMBD. In addition, the average difference among patients with successful birth was significantly smaller when the measurement was achieved immediately before PNMBD than 4 h before PNMBD ($p < 0.001$). This difference was not detected among patients with unsuccessful birth.
Limitations, reasons for caution: The analysis of PNs is restricted to 2D in this study. 3D analysis will show more precise data when 3D analysis becomes possible. The birth of babies derived from natural conception, which occurs during frozen–thawed HRT cycles, cannot be eliminated in this study, although the occurrence is very small.
Wider implications of the findings: As the size of pronuclei immediately before PNMBD was similar in embryos resulted in the birth of healthy babies, a large difference in size between the 2PN may indicate the presence of aneuploidy, which could be a useful tool in deselecting embryos.
Trial registration number: Not applicable.

O-095 The relation between cell size and developmental stage in human day 2/day 3 embryos is a predictor for blastocyst formation on day 5

V. Muyshond[1], S. De Gheselle[1], I. De Croo[1], K. Tilleman[1], B. Heindryckx[1], P. De Sutter[1], E. Van Den Abbeel[1]
[1]University Hospital Ghent, Department for Reproductive Medicine, Ghent Fertility and Stem Cell Team G-FAST, Ghent, Belgium

Study question: Does cell size and developmental stage synchronicity in day 2 (D2)/day 3 (D3) embryos has an impact on blastocyst formation on day 5 (D5)?
Summary answer: The percentage of NSS embryos in a cohort of D2 and (or) D3 embryos was 53.5%. Their further developmental potential *in vitro* is reduced.
What is known already: Cleavage-stage embryos that have a correct relation between cell size and embryo developmental stage are called stage specific (SS) embryos while embryos identified with an incorrect relation between cell size and embryo developmental stage are called not stage specific (NSS) embryos. In human preimplantation embryology *in vitro*, little is known about the incidence of SS and NSS embryos and on the developmental consequences of a correct or incorrect relation between cell size and embryo developmental stage.
Study design, size, duration: This study is a retrospective analysis from 25 June 2015 until 31 December 2015. We performed 396 oocyte collection cycles, 4190 oocyte-cumulus cell complexes were retrieved and 3088 MII oocytes were injected by ICSI. After ICSI, 2034 fertilized oocytes (2PN oocytes) were obtained and 1817 were cultured and evaluated until D5 of the oocyte collection cycle (OCC).
Participants/materials, setting, methods: The correlation between cell size and embryo developmental stage was analyzed on D2 and D3. Four embryo categories were identified: Group 1: SS embryos on D2 and D3; group 2: SS embryos on D2 but that developed to NSS embryos on D3; group 3: NSS embryos on D2 but that developed to SS embryos on D3; group 4: NSS embryos on D2 and D3. Statistical analysis was performed by Fisher's exact-test ($p < 0.05$).
Main results and the role of chance: The relation between cell size and developmental stage could be quantified on D2 in 1756 embryos and on D3 in 1629 embryos. On day 2, 1184 (67.4%) embryos were SS embryos and 572 (32.6%) embryos were NSS embryos In the D2 SS embryos 68.8% developed further to SS embryos on D3 (group 1) and 31.2% developed further to NSS embryos (group 2). In the D2 NSS embryos 26.9% of the embryos developed further to SS embryos on D3 (group 3) and 73.1% developed further to NSS embryos (group 4). Interestingly, the distribution of NSS embryos versus SS embryos was significantly different between asynchronously dividing embryos (3-, 5-, 6-, 7-cell embryos) and synchronously dividing embryos (2-, 4- and 8-cell embryos). Significantly more NSS embryos were found in asynchronously dividing embryos as compared to synchronously dividing embryos ($p < 0.05$). Furthermore, In group 1, the blastocyst formation rate was 60.4% (457/757) as compared to 39.5% (136/344) in group 2, 48.6% (69/142) in group 3 and 33.4% (129/386) in group 4 ($p < 0.00001$).
Limitations, reasons for caution: This was a retrospective analysis and the scoring of the relation between cell size and embryo developmental stage was done by several embryologists. The implantation potential of NSS versus SS embryos was not analyzed.
Wider implications of the findings: The correct correlation between cell size and D2/D3 embryo developmental stage is a good predictor for their developmental potential *in vitro*. The findings of this study might contribute in further improving the selection of the embryo with the highest developmental potential.
Trial registration number: NA.

INVITED SESSION

SESSION 26: DO IVF PATIENTS DESERVE STANDARD TREATMENTS?

Tuesday 05 July 2016 **Hall 1** **08:30–09:30**

O-096 Are all patients the same? Adapting protocols methodologies to individual cases

E. Bosch[1]
[1]Instituto Valenciano de Infertilidad, Human Reproduction, Valencia, Spain

Since the first successful *In vitro* Fertilization (IVF) treatment was reported almost 4 decades ago, the number of procedures performed every year increase exponentially across the world. The reasons behind this growth are the improvement on its efficiency, and the widening of the type of patients treated. As a consequence, different phenotypes of patients undergo a procedure that in essence is constant in its laboratory aspects, but that can have an equally wide number of different clinical approaches.

Because IVF is a relatively recent medical technique, issues about its adaption to patients' phenotype are controversial. While many other fields of medical practice acknowledge without doubts that individualization of the clinical approach is crucial for the success of the procedure, IVF practitioners still debate if the clinical strategies should be uniform and homogeneous for all types of patients, or should be customized to each patient phenotype.

There is no discussion about the differences among patients undergoing IVF. It is also well established that these differences have a significant impact on the chances of success, such as age, ovarian reserve, body mass index or presence of ovarian dis-functions. However, it is much less clear if considering these features at the time of indicating a particular clinical strategy has a real impact on the probability of success. Very often, the choice between a standardized or an individualized approach, is depending on who ultimately carries with the cost of the procedure. In environments in which the treatment is reimbursed, standardization is the rule, while when the patient pays the procedure out of pocket, the trend is to individualize the treatment.

Those advocating for a standardized practice, claim to inter-cycle variability and to the tremendous influence of Evidence Based Medicine (EBM) to support their position. EBM focuses on the generalization of the results, the

aggregation of data, and the evaluation of the efficacy in average patients. Randomized controlled trials (RCT) have become the keystone for EBM. On the top of that, this type of approach usually involves lower costs per procedure, as less monitorization and time consuming is needed.

On the other hand, defenders of an individualized practice are based on Patient Centered Medicine (PCM). PCM proposes to look back to the individual patient, and tries to provide the best health care to each of them under the conditions of clinical practice, taking into account their preferences as well as their economical resources. While the RCT is the basis for EBM, careful individual observations are the foundation for patient-oriented research.

IVF practice is full of examples of PCM: From the use of different doses and types of gonadotropins to the diverse options of pituitary suppression. Moreover, several co-treatments have been also purposed, according to certain patients' conditions. Unfortunately, most of these strategies are applied in a trial and error basis, far away of what should be proper clinical research. Although some great advances have been done in terms of patients' qualification, especially regarding ovarian reserve evaluation, our field is still lacking of studies on genetic predisposition to treatment response, when compared to others. Furthermore, well-designed RCT in specific subpopulations are scarce, and most of the studies are *post-hoc* sub-analysis. Protocols that have shown to be effective only in ideal patients are often applied to patients with very different characteristics, providing unsurprisingly poorer outcomes.

In summary, despite its clear and crucial benefits, the way to personalized medicine and customized therapy in Reproductive Medicine is still very large, with several barriers to overpass. The integration between clinical research and medical care should define the way to optimize the benefits of IVF for future patients.

O-097 Adopting the same laboratory strategies to all patients. Does it make sense?

J. Hreinsson[1]
[1]*Falun, Sweden*

Assisted reproduction is a technologically oriented field where new methods and advanced treatment modalities are developed continuously. This lecture is intended to be a review of the techniques available to the embryologist today and will offer some guidance and examine evidence for or against various methods to aid in practical decision making in the IVF-laboratory.

Arguments for adopting an individualized approach are that patients vary in terms of age, ovarian reserve, indications for treatment, and quite simply in biological fertility potential. Therefore patients will require various applications of the technological arsenal at our disposal. Simultaneously it is necessary to operate selectively since cost-efficiency, risk/benefit ratios and general minimalist principles dictate that we must not do more than is required to ensure a successful procedure.

To evaluate any method, the underlying biological principles must be taken into account. It is not enough to rely on clinical studies to answer questions regarding new technological developments. Technical difficulties must be overcome, not used as a reason to abandon new methods. This focus on biology leads us to think in a different way regarding the evaluated techniques, focusing on innovation and development: We know that oocytes and embryos are to a large degree susceptible to aneuploidy which may be a reason for miscarriage. It is therefore logical that genetic screening should improve treatment outcome in IVF.

We know that observing a cleaving embryo for less than a minute per culture day gives limited information regarding cleavage progression. Since information on cell divisions will improve embryo selection, then time-lapse imaging should improve success rates.

Knowing that vitrification must occur in all cases of cryopreservation of human embryos, then slow-cooling for 2 h preceding vitrification must have a detrimental effect compared with direct vitrification.

Methods such as assisted hatching, IMSI and chemically induced activation of oocyes will also be discussed and evidence for and against these will be presented.

This way of considering technological advances in assisted reproduction makes it clear that specialization and individualization of treatment modalities must be the best way to further improve our field and ensure optimal treatment for our patients. Simultaneously, it is important to realize that patients may request more than is motivated and professional decision making based on scientific evidence is important to ensure optimal treatment decisions. Competition pressure must not drive clinics beyond professional and academic standards.

INVITED SESSION

SESSION 27: EPIGENETIC REMODELLING IN EMBRYOS: VIEW ON EXPRESSION BY MAGNIFYING GLASS

Tuesday 05 July 2016 **Hall 5 CB** **08:30–09:30**

O-098 Epigenetic landscape in pre-implantation embryo development

G. Kelsey[1], K. Stewart[2], L. Veselovska[2], C. Hanna[2], S. Smallwood[2], H. Saadeh[2], S. Clark[2]
[1]*Babraham Institute, Cambridge, UK*
[2]*Babraham Institute, Epigenetics Programme, Cambridge, UK*

Epigenetic mechanisms are fundamental for the orderly regulation of gene expression throughout the life-course, providing a critical memory of earlier decisions. They can ensure resilience against environmental change, but also allow adaptation. Nowhere is this more important than in the gamete and the early embryo. We are seeking to understand what governs how DNA methylation and other epigenetic marks are patterned during gametogenesis and embryogenesis. Using mouse as a model, we have shown that transcription is the major determinant of the DNA methylation landscape in the oocyte. To understand the mechanistic connection between transcription and *de novo* methylation, we have profiled histone modifications in growing oocytes and identify chromatin states permissive for and resistant to DNA methylation characterised by reciprocal enrichment of H3K4me2/me3 and H3K36me3. This finding is reinforced by the consequences on the DNA methylation landscape of genetically ablating specific H3K4 demethylases and methyltransferases. Key to such studies is the development of methods for genome-wide profiling of epigenetic marks in low numbers of cells, including at the single-cell level, which could have application widely in epigenetic studies, particularly for rare cell types and for investigating cell-to-cell heterogeneity in epigenetic marks at critical developmental transitions.

O-099 Molecular and structural insights into bovine embryonic genome activation

E. Wolf[1]
[1]*Gene Center, LMU Munich, Molecular Animal Breeding and Biotechnology, Munich, Germany*

Maternal-to-embryonic transition is the period when maternal RNAs and proteins stored in the oocyte are gradually degraded and transcription of the embryonic genome is activated. The onset of embryonic transcription is obscured by the presence of maternal transcripts and could only be determined for genes which are not expressed in oocytes. Using RNA sequencing of bovine germinal vesicle and metaphase II oocytes, and of 4-cell, 8-cell, 16-cell and blastocyst stage embryos, we established the most comprehensive transcriptome data set of bovine oocyte maturation and early development. The embryos investigated were produced by *in vitro* fertilization of German Simmental (*Bos taurus taurus*) oocytes with sperm from a single bull of the genetically distant Brahman (*Bos taurus indicus*) breed to obtain a large number of single nucleotide polymorphisms (SNPs) for identification of the parental origin of transcripts. Further, RNA-Seq libraries were produced without polyA+ selection enabling the identification of intronic sequences in transcripts, which can be found in de novo synthetized transcripts due to incomplete co-transcriptional splicing and can thus be used to discriminate them from spliced maternal transcripts stored in the oocyte.

In all developmental stages investigated, transcripts from 12.4 to 13.7×10^3 different genes were detected. Our differential gene expression analyses revealed only few transcripts to be differentially abundant between the GV and MII oocyte and between MII oocyte and four-cell stage. According to the main embryonic genome activation we found a marked increase in the number of differentially expressed genes between four- and eight-cell stage and even more between the later stages. The proportion of transcripts with decreased abundance gradually increased during embryonic development from 17% between four-cell embryo and MII oocyte to about 55% between 8- and 16-cell embryos, which could be due to the degradation of maternal transcripts.

EGA was analyzed by (i) detection of embryonic transcripts which are not present in oocytes; (ii) detection of transcripts from the paternal allele; and (iii) detection of primary transcripts with intronic sequences. Using these approaches we were able to map the onset of embryonic transcription for almost 7,400 genes. A functional classification of the 414 genes found to be activated in bovine embryos at the four-cell stage or before revealed the gene ontology (GO) terms "RNA processing," "Translation" and "Transport," indicating the first transcriptional activity before major EGA. Our RNA-Seq study was able to detect the onset of embryonic expression for 4,489 specific genes at the eight-cell stage. GO classification of the eight-cell activated genes revealed the functional categories "Transcription, DNA-dependent," "Purine nucleotide metabolic process," "Protein ubiquitination," "Translational initiation" and most prominently "RNA metabolic process" to be significantly overrepresented. In addition, the GO classification of genes activated in later developmental stages revealed new roles and functions as compared to the earlier stages.

In summary, RNA-Seq analyses provided new insights into embryonic genome activation, allelic expression of genes, and transcriptional networks governing early development of embryos. RNA-Seq data provide a fundamental basis for embryo biosystems research, including germ cell potential and genetic, epigenetic and environmental disturbances of early development. In addition, studies based on structured illumination microscopy revealed major changes in higher order chromatin organization associated with major EGA.

INVITED SESSION

SESSION 28: ASRM EXCHANGE SESSION - SPECIAL CONSIDERATIONS FOR ART IN PATIENTS WITH SEX CHROMOSOME ANEUPLOIDY: KLINEFELTER SYNDROME AND TURNER SYNDROME

Tuesday 05 July 2016 **Hall 5 A** **08:30–09:30**

O-100 Klinefelter syndrome

R. Sokol[1]
[1]*Ventura, CA, USA*

Klinefelter Syndrome (KS) is the most common chromosomal disorder in men, and the most common cause of primary testicular failure and azoospermia. Prevalence is estimated to be between 1:500 and 1:1000. However the actual prevalence is probably greater owing to the historically frequent failure to identify and diagnose these patients. The expansion of noninvasive prenatal testing should lead to an increase in the number of diagnosed KS patients. In addition to the classic phenotype of the patient with seminiferous tubule dysgenesis and androgen deficiency, the spectrum of KS includes a number of equally important medical disorders: motor, cognitive and behavioral dysfunction; tumors; vascular disease; and endocrine, metabolic, and autoimmune diseases. Earlier diagnosis of KS may lead to earlier treatment of all aspects of the syndrome, including possible fertility optimization and preservation. The testicular function of KS patients progressively declines with age. Prepubertal KS boys have levels of testosterone comparable to non-KS boys until puberty when T levels begin to rise, only in turn to decrease by age 15 years in the majority of KS boys. Similarly, testicular histology is mostly normal in infancy, with progressive loss of spermatogonial stem cells at the onset of puberty, with progressive fibrosis and hyalinization of the seminiferous tubules and Leydig cell hyperplasia by adulthood. Because few KS men have sperm present in the semen, these men were considered incapable of fathering a child until ICSI and ART revolutionized their treatment. Success rates of sperm recovery by TESE in adult XXY men have been reported to be between 20 and 70%, with live birth rates of up to 50%. Genetic counseling of the KS patient in the ART setting is essential. Recently, because of the potential for earlier diagnosis of KS, focus has shifted to timing of initiation of testosterone therapy, cryopreservation of semen samples from KS boys in early puberty, pre-pubertal testicular biopsy and cryopreservation, and hope for subsequent *in vitro* maturation for use in future ART procedures. The latter proposed approaches are still in the research setting and require further validation and careful attention to ethical considerations.

O-101 Turner syndrome

R. Reindollar[1,2,3]
[1]*American Society for Reproductive Medicine, Dartmouth Medical School Department of Obstetrics and Gynecology, Lebanon, PA, USA*
[2]*American Society for Reproductive Medicine, UAB School of Medicine and Dartmouth Medical School, Departments of Obstetrics and Gynecology, Birmingham, AL, USA*
[3]*American Society for Reproductive Medicine, UAB School of Medicine and Dartmouth Medical School, Departments of Obstetrics and Gynecology, Lebanon, NH, USA*

Abstract text

Turner syndrome (TS) occurs at a rate of 1 in 2,500 female infants. A 45,X karyotype is very lethal: 99% of concepti are estimated not to survive first and second trimester and 15% of spontaneous abortions are associated with this monosomy. Historically, TS was the most common cause of delayed female puberty and found even as nonmosaic 45,X in women with adult onset ovarian insufficiency. Karyotypic-phenotypic relationships are not as easily made as clinically thought but recent findings suggest that those individuals identified prenatally have fewer findings than those ascertained in childhood or adolescence. In addition to pheontypic findings, this lecture will discuss the known genetic and ovarian etiologies for follicular and oocyte loss. It will present data on when that loss occurs as well as the proportion of women with Turner syndrome who have degrees of ovarian function before the premature insufficiency. While it was previously estimated that 5% of TS women will have menstrual function, 1% may become pregnant. Data regarding prior pregnancies and those requiring IVF with their own oocytes are presented. In addition, the option of freezing oocytes in young TS women who are still menstruating is discussed. For many years, however, the non Obstetrics and Gynecology literature reported the occurrence of aortic dissection and rupture for TS women in the nonpregnant state; an occurrence 500–2,000 times more frequent than for the general population and at a usual age between 20 and 40 years rather than the average age of 63 for the general population for which men outnumber women. Risk factors for aortic dilation, dissection and rupture are presented including congenital heart disease (especially bicuspid aortic valves and coarctation), known dilation and hypertension. TS women have the same histopathology of their vessels, cystic medial necrosis, as do those patients with Marfan syndrome. With a know predisposition for aortic dissection and rupture in the nonpregnant state, it was predicted that the increased blood volume, pulse pressure, and stroke volume would increase this risk during pregnancy. The data demonstrating this reality are presented. In addition to increasing the risk of death during pregnancy by an estimated 100-fold over all cause mortality, data are accumulating that overall morbidity is also increased, especially for hypertensive disorders of pregnancy. The question looming is whether the risk of maternal mortality is sufficiently high such that TS is an absolute contraindication to pregnancy? Further complicating this important question is the lack of registry data to understand the true prevalence of this occurrence and the fact that there has yet been a TS phenotype for which death has not occurred. For example, TS patients without overt risk factors have had dissection and rupture. In addition, TS women who have had spontaneous menses up through their 30s have had rupture as have those with a prior spontaneous pregnancy. A call to action for collecting these data by registry and potential future surgical options are presented.

INVITED SESSION

Tuesday 05 July 2016 **Room 101** **08:30–09:30**

O-102 Fertility preservation for transgender prior to transition surgery

K. Tilleman[1], C. De Roo[1], S. Lierman[1], G. T'Sjoen[2], P. De Sutter[1]
[1]*Ghent University Hospital, Department of Reproductive Medicine, Ghent, Belgium*
[2]*University Hospital Ghent, Department of Endocrinology and Center for Sexology and Gender Problems, Ghent, Belgium*

Abstract text

Hormonal and surgical treatments for transgender people have a devastating effect on the possibility for these patients to reproduce. Additionally, transgender people tend to start sex reassignment treatment at a young age, when reproductive wishes are not yet clearly defined nor fulfilled. The most recent Standards of Care of the World Professional Association for Transgender Health recommend clearly informing patients regarding their future reproductive options prior to initiation of treatment. Transgender patients are therefore a growing patient population visiting our fertility centers for advise on how to fulfill their future child wish or seeking fertility preservation treatments. Where genital reconstructive surgery definitely results in sterility, hormone therapy on the other hand also has an important, but partially reversible impact on fertility. The current fertility preservation options for trans men are embryo cryopreservation, oocyte cryopreservation and ovarian tissue cryopreservation. For trans women, sperm cryopreservation, surgical sperm extraction and testicular tissue cryopreservation are possible. Although certain fertility preservation techniques could be applicable in a standardized manner based on clear biological criteria, the technique that eventually will be performed should be the preferred choice of the patient after extended explanation of all possible options. I will discuss the possible options that are available for transgender people now or may be possible in the future based on a recent review of our group by De Roo et al. (2016) (*Int. Rev. Psychiatry*). Although, theoretically, both trans women and trans men are capable of using fertility preservation treatments, there is still an important psychological burden for trans women to masturbate in order to produce sperm, of for trans men to undergo repeated endovaginal ultrasound monitoring to eventually collect oocytes for subsequent vitrification. At Ghent University Hospital, the use of *in vitro* maturation of oocytes collected at the time of transition surgery upon cryopreservation of ovarian tissue is being explored as a future promising realistic fertility preservation technique for trans men. Preservation and freezing of ovarian tissue is often chosen as fertility preservation technique by young trans man: no additional controlled ovarian stimulation by vaginal ultrasound is needed and oophorectomy is standard, at least in Belgium, during sex reassignment surgery. During the manipulation of the ovarian tissue, cumulus-oocyte complexes can be collected and *in vitro* matured up to the MII stage. These oocytes display a normal spindle structure and chromosome alignment showing that supraphysiological doses of testosterone do not have an effect on recovered and *in vitro* matured oocytes in trans men. Do these oocytes exhibit normal fertilization and embryo development is a question we are in the process of answering. If this would be the case, this technique could definitely maximize fertility preservation option for trans men and give them a real option for fulfilling their future child wish with their own gametes. In summary, with this presentation I will discuss the theoretical part on fertility preservation in transgender people, share with you our experiences with this specific group of patients and show recent results from our research in transgender fertility preservation.

O-103 Are nurses and midwives competent enough to perform ultrasound monitoring in ovarian stimulation?

J. Schoonenberg-Pomper[1]
[1]*Radboud University Medical Center, Gynaecology and Obstetrics, Division of Reproductive Medicine, Nijmegen, Netherlands*

Abstract text

Over the past decades the number of clinical tasks in fertility clinics, which are performed by nurses or midwifes have increased. In fertility care one of the tasks, which nurses and midwifes are starting to perform, is ultrasound monitoring during ovarian stimulation.

One could question whether nurses are competent enough to perform this task. In 2009, the ASRM wrote a position paper supporting nurses to perform ultrasound monitoring during ovarian stimulation. This paper pleads that nurses performing ultrasound monitoring need a bachelor degree, theoretical training and training on the job. Furthermore, the clinics allowing the nurses to perform this task need specific guidelines on ultrasound monitoring and need make sure that a physician is available for supervision, if needed, while the nurses perform their scans. A recent study did show that midwifes have a high inter- and intra-reliability while performing ultrasound scanning during ovarian stimulation.

One could question whether asking nurses or midwifes to perform ultrasound monitoring during ovarian stimulation will affect the safety and effectiveness of fertility care. There is no study that compares the pregnancy rates and risks of fertility treatments depending on whether a physicians or a nurse/midwife performs the ultrasound monitoring during ovarian stimulation. Nevertheless, clinics in which nurse and/or midwifes have started to perform the ultrasounds monitoring do not see a decline in pregnancy rates. Research from other medical fields showed that effectiveness and safety outcomes are not affected by nurses/midwifes performing an ultrasound (e.g., ultrasound scanning during a peripheral intravenous (IV) catheter placement). Professionals often focus on effectiveness or more specifically pregnancy rates or live birth rates or safety when talking about improving the quality of fertility care. However, one in three compliant couples will not go home with a baby.

One could question whether asking nurses or midwifes to perform ultrasound monitoring during ovarian stimulation will affect other dimension of quality of fertility care than its safety and effectiveness. According to the "Institute of Medicine" quality of care depends on timeliness, efficiency, equity, and patient-centeredness besides effectiveness and safety. Regarding timeliness and efficiency, allowing nurses and midwifes to perform more clinical tasks can resolve the documented waiting lists for treatment in clinics, in which physicians are understaffed.

In addition, research from other medical fields indicated that giving more clinical tasks to nurses or midwifes can improve the patients-centeredness of care. Research showed that patients do not only want the highest chance of pregnancy but they want their care to be patient-centered. The patient-centeredness of care is defined by ten dimensions; provision of information, competence of clinic and staff, coordination and integration, accessibility, continuity and transition, physical comfort, attitude of and relationship with staff, communication, patient involvement and privacy and emotional support. The fact that allocating more tasks to nurses or midwifes can improve patient satisfaction with patient-centered care can be explained by the attention given to communication, education and emotional support in nursing and midwifery education and by the fact that nurses and midwifes take out more time for their patients.

Finally, research from other medical fields also showed that nurse and midwifes are more willingly to work within the boundaries of guideline, which might in turn result in improving the quality of care.

In conclusion, trained nurses and midwife can perform ultrasound monitoring during ovarian stimulation. It seems that this could improve several dimension of quality of care while maintaining pregnancy rates. This should, however, be confirmed by high quality randomized controlled trials.

SELECTED ORAL COMMUNICATIONS

SESSION 30: IVF LABORATORY QUALITY AND STRATEGIES

Tuesday 05 July 2016 **Hall 1** **10:00–11:30**

O-104 Evaluation of the effects produced by volatile organic compounds (VOCs) over human embryo development

V. Vásquez[1], D. Beltrán[1], J. Remohí[1], J.M. De Los Santos[1], A. Galán[1], S. Perez[1], A. Mercader[1], M.J. De Los Santos[1]
[1]*Instituto Universitario IVI Valencia, IVF Laboratory, Valencia, Spain*

Study question: Can specific concentrations of common IVF ambient air VOCs produce adverse effects over the human embryo *in vitro* development?

Summary answer: Embryos cultured along with IVF ambient air- related concentrations of VOCs, such as benzene and limonene, have worst embryo score and reduced embryo survival rates.

What is known already: Previous studies have found a correlation within the presence of harmful VOCs and adverse effects on fertility (low implantation or pregnancy rates); however, there are few studies correlating the presence of VOCs inside the IVF and specific adverse effects over *in vitro* embryo development. At the same time, facilities manage occupational limit values (OLV) inside the IVF laboratories to daily cover exposed workers without adverse health effects, but specific quality standards and specific threshold levels, at which most of the common pollutants in the IVF`s ambient air can cause harm to cultured human embryos, have not been determined.

Study design, size, duration: Prospective cross sectional study with 400 human embryos, to perform a comparative analysis within 25 control (C) embryos and groups of 75 embryos randomly cultured from day 3 (D3) up to

day 6 (D6) of development, and exposed to 5 VOCs (recognized as harmful ambient air pollutants). Each compound has 3 experimental groups (EG), related to the atmospheric VOCs concentrations determined in routinely IVF`s environmental characterizations: exterior (E), laboratory (L) and double laboratory (D).

Participants/materials, setting, methods: Each developmental toxicity test (DT) exposes D3 embryos, with 6- 10 cells and less of 25% of fragmentation, by contaminating CCM™ blastocyst culture medium with 3 doses of Benzene, Limonene, Styrene, 1,1,2,2-Tetrachloroethane and Hexachloro-1,3-butadiene; doses are under 1% of the OLV. After thawing, 25 embryos are exposed to each dose up to D6 of development and embryo grading is performed. Biopsy of trophectoderm (TE) is done for future chromosomic and methylation analysis.

Main results and the role of chance: Up to now, 102 out of the 400 embryos have been thawed and cultured; 93 have been exposed to VOCs. First DT: we exposed 75 embryos to Benzene (B): BE = 268×10^{-5} ppm, BL = 256×10^{-5} ppm, BD = 512×10^{-5} ppm. 62 out of 75 (82.7%) developed to blastocyst stage, of which 77.4% ($n = 48$) reached expanded to hatched status. Inner cell mass (ICM) and TE good quality scores (A-A, A-B, B-A, B-B) were only registered on 23/48 developed embryos (47.9%). Morphologically there were A-A score embryos only in dose groups BE and BD ($n = 4$ in each); however other good scores were registered in all groups: BE = 6, BL = 2, and BD = 6. Second DT: so far, we have exposed 18/75 embryos to Limonene (L): LE = 87.5×10^{-5} ppm, LL = 113.6×10^{-5} ppm, LD = 226×10^{-5} ppm. 17 out of the 18 (94.4%) reached blastocyst stage; 72.2% ($n = 13$) reached expanded or initiating hatching status. ICM and TE good quality have been seen in 7/17 embryos (41.2%). A-A scores have not been observed but other good scores were seen in the three groups: LE = 3, LL = 3, LD = 1. In the control group ($n = 9$), 100% of embryos reached different blastocyst stages; 55.5% ($n = 5$) had good scores but none of them have scored A-A either.

Limitations, reasons for caution: Results are being obtained by direct contamination of the culture medium with VOCs, which does not represent exact laboratory conditions. Relationship of blastocyst stage with early scores will be analyzed to follow individual pattern of development, and ploidy status should be obtained as well, to correlate with the morphology.

Wider implications of the findings: Associating specific morphologic, chromosomal and molecular results, produced over the embryos by the most common ambient air VOCs inside the IVF, an official database can be established, along with health regulatory institutions, with accurate OLVs for human embryo culture.

Trial registration number: N/A.

O-105 Worse by the hour: *in vitro* aging of oocytes lowers the chance of achieving a pregnancy but does not affect live birth rates.

A. Pujol Masana[1], A. Obradors[1], D. Garcia[2], V. Vernaeve[1], R. Vassena[1]
[1]*Clinica Eugin, Clínica Eugin, Barcelona, Spain*
[2]*Fundacio EUGIN, Fundacio EUGIN, Barcelona, Spain*

Study question: Does the aging of *in vitro* of oocytes between ovum pick up (OPU) and ICSI affect reproductive outcomes after fresh embryo transfer?

Summary answer: Biochemical and clinical pregnancy rates are lowered by *in vitro* oocyte ageing, however, live birth rates after fresh embryo transfer (ET) are not.

What is known already: Appropriate oocyte cytoplasmatic and nuclear maturation are of paramount importance in order to ensure an optimal embryonic developmental competence. While nuclear maturation is usually attained by the time an oocyte reaches OPU, cytoplasmic maturation cannot be readily assessed and might be incomplete. On the other hand, excessive *in vitro* aging of human oocytes affects their ultrastructural characteristics and, in mice, induces alterations in expression and epigenetic modifications of chromatin and histone patterns. Defining an optimal moment to inseminate after OPU might have a positive effect on embryo development and reproductive outcomes.

Study design, size, duration: Retrospective study including 1,478 ICSI cycles between December 2012 and September 2015. All ET were fresh. *In vitro* ageing times studied: OPU–denudation (DN); DN-ICSI and OPU-ICSI. A radiofrequency based system was used to record exact times. The effect of total and partial time intervals between procedures, from OPU to ICSI, on fertilization rate and on biochemical, clinical, ongoing pregnancy and live birth rates were analyzed.

Participants/materials, setting, methods: Differences in biochemical, clinical, ongoing, and live birth rates were tested by Mann–Whitney *U* test. The likelihood of positive clinical outcomes was further modeled by logistic regression, adjusting for woman's age and body mass index (BMI), day of ET, number of transferred embryos and mean embryo quality, sperm origin (partner/donor) and status (fresh/frozen), and number of mature oocytes obtained at OPU. Effect of time on fertilization rate was modeled by probit regression.

Main results and the role of chance: The mean woman age was 38.4 (SD 4.6). Overall biochemical, clinical, ongoing pregnancy rates, and live birth rate were: 38.3, 29.8, 21.7 and 20.0%, respectively. Mean times in hours for OPU-DN, DN-ICSI and OPU-ICSI were: 1.0 ± 0.4, 4.7 ± 2.9 and 5.7 ± 2.9, respectively, and were not different for pregnant and non pregnant patients. However, the multivariate analyses showed that on average (anti-log transformed), each 60-min increase in the OR-ICSI time reduced the likelihood of biochemical pregnancy by 7.8% (95%CI 1.2–14.9%) and of clinical pregnancy by 7.9% (95%CI 1.1–15.2%). No effect of time was observed for ongoing pregnancy or live birth. Similar effects were observed for the DN-ICSI times (OR 0.74, 96%CI 0.59, 0.92, $p = 0.008$ for biochemical and OR 0.77, 96%CI 0.61, 0.98, $p = 0.032$ for clinical pregnancy), whereas OPU-DN time did not show to have a significant effect on PR. Increasing OPU-ICSI time reduced the fertilization rate ($B = 0.28$, $p < 0.01$). Again, this effect was mainly due to an increase in DN-ICSI time while OPU-DN had no statistically significant effect.

Limitations, reasons for caution: The main limitation of this study is its retrospective nature. The lack of relationship between *in vitro* ageing and live birth rates might be due to uncontrolled variables. These results should not be extended to other ART protocols such as *in vitro* maturation of oocytes or classical IVF fertilization.

Wider implications of the findings: This study indicates that *in vitro* ageing of oocytes significantly affects the chance to become pregnant. Effect on live birth rates, although not evident in this study, cannot be excluded. Limiting *in vitro* ageing in the IVF lab might improve reproductive results for most patients.

Trial registration number: NA.

O-106 The role of intracytoplasmic sperm injection (ICSI) for non-male factor infertility in women aged 40 and over

A. Gilman[1], S. Tannus[1], G. Younes[1], W.Y. Son[1], M. Dahan[1]
[1]*MUHC Reproductive Centre, Obstetrics and Gynecology, Montreal, QC, Canada*

Study question: Does intracytoplasmic sperm injection (ICSI) improve pregnancy and live birth rates when compared to conventional *in vitro* fertilization (IVF) in women aged 40 and over?

Summary answer: There is no improvement in pregnancy and live birth rates with ICSI vs. conventional IVF in women aged 40 and over with non-male factor infertility.

What is known already: ICSI is an effective treatment for male factor infertility but it is increasingly being used for patients without male factor, too frequently without evidence-supported indications. The effectiveness of this technique has not been adequately studied outside of male factor infertility. In the 2012 American Society for Reproductive Medicine committee opinion regarding the use of ICSI for non-male factor infertility, it is stated that there are no studies looking at the benefit of ICSI in advanced maternal age. This is the first study to investigate the value of ICSI when normal semen parameters are present per the 2010 WHO criteria.

Study design, size, duration: This retrospective cohort study involved 720 women, aged 40–43 years, who underwent IVF between January 2012 and December 2014 for non-male factor infertility. 229 had conventional IVF, 491 used ICSI for fertilization. Women <50% fertilization at previous IVF were excluded. Patients were included once. All eligible subjects were included. Subjects had a semen analysis with at least: 1.5 ml, 15 million sperm/ml, 39 million total sperm, progressive motility 32%, total motility 40% and morphology 4%.

Participants/materials, setting, methods: All subjects had at least 1 year of primary or secondary infertility. Participants were treated with either the midluteal long gonadotropin releasing hormone agonist (GnRH-ag), GnRH-ag microdose flare or GnRH antagonist protocols. Indications for care included tubal factor, advanced age, unexplained infertility, decreased ovarian reserve,

and anovulation having failed ovulation induction with insemination. Statistical analyses were performed using logistic regression to control for confounding effects. Data is presented as xÌ ± SD or as percentages.

Main results and the role of chance: Patient characteristics were similar between the two groups with respect to maternal age (p = 0.736), paternal age (p = 0.159), total number of oocytes collected (p = 0.120), BMI (p = 0.207), FSH dose (p = 0.119), protocol type (p = 0.188) and number of smokers (p = 0.232). The only differences between the groups noted were number of MII oocytes collected (ICSI 5.1 ± 3.82, IVF 6.1 ± 4.55; p = 0.002), day of transfer (ICSI 3.3 ± 1.2, IVF 3.5 ± 1.2; p = 0.003) and previous IVF attempts (ICSI 1.1 ± 1.0, IVF 0.65 ± 0.9, p = 0.001). Rates of fertilization failure did not differ between ICSI and IVF groups (3 vs. 4% respectively, p = 0.57). IVF resulted in more blastocyst formation than ICSI (p = 0.008). Pregnancy rates were comparable (ICSI 24.6%, IVF 29.7%; p = 0.449) as were live birth rates (ICSI 10.2%, IVF 11.9%; p = 0.345) when controlling for confounders.

When sub-selecting patients with decreased ovarian reserve (defined as total FSH dose ≥3,000 IU or ≤3 MII oocytes retrieved), clinical pregnancy and live birth rates did not differ between IVF and ICSI (FSH dose ≥3000 IU (N = 506): p = 0.78, p = 0.58 respectively) (MII 3 (N = 99): p = 0.45, p = 0.80 respectively).

Limitations, reasons for caution: This retrospective cohort study was not randomized therefore this may be a source of undetected bias. However, given the robust sample size, it is unlikely that these results are due to chance alone and the probability of bias is minimized.

Wider implications of the findings: ICSI is often used in women of advanced age to prevent unforeseen failed or low fertilization. This study suggests ICSI does not improve pregnancy outcomes or fertilization rates. Conventional IVF improves blastocyst formation rate, which may offer benefit. ICSI in women aged 40–43 with normal semen parameters is not supported.

Trial registration number: N/A.

O-107 Pre-zygotic transfer (PZT): a pilot study in poor prognosis patients

D. Payne[1], K. Yumoto[1], K. Iwata[1], C. Mizoguchi[1], M. Sugishima[1], M. Tsuneto[1], Y. Mio[1]

[1]*Mio Fertility Clinic, IVF Laboratory, Yonago, Japan*

Study question: Can transfer of one pre-zygote (PZ) to the uterus within 60 min of extruding the second PB result in live births for poor prognosis patients?

Summary answer: 5 live births and 0 miscarriages from 69 PZTs compared with 4 live births and 7 miscarriages from 191 previous embryo transfers.

What is known already: Despite improved embryo selection using extended culture and time-lapse recording, there remains a group of poor prognosis IVF patients for whom live births are rare. In rat studies, the environment during pronuclear (PN) formation was critical for live births, and significantly lower birth rates arose from oocytes fertilized *in vitro* compared with oocytes fertilized *in vivo*. Extrusion of the second polar body 2–3 h after ICSI is predictive of normal fertilization, and transfer of PZs after extrusion of the second PB should eliminate any risk of transferring abnormally fertilized oocytes and may improve outcomes for poor prognosis patients.

Study design, size, duration: A prospective study of 43 women with previous poor cycle outcomes and/or advanced age was conducted in Mio Fertility Clinic from August 2012 to August 2015. Participants had an average age of 38.5 years (31–46) and they had 203 (range 1–13) previous IVF/ICSI cycles and 191 single embryo transfers (sET) resulting in only 4 term pregnancies and 7 miscarriages. All participants gave informed consent for the trial.

Participants/materials, setting, methods: Oocytes were collected in stimulated cycles and cultured for 2–6 h. Mature oocytes were injected with one sperm and then cultured in a time-lapse imaging incubator (Embryoscope®), so extrusion of the second polar body could be clearly identified and timed. Single PZs with a second polar body were transferred to the uterus under ultrasound guidance within 60 min of the second polar body being extruded.

Main results and the role of chance: 43 women completed 69 PZT cycles. A total of 574 oocytes were collected in these cycles, of which 419 had extruded the first polar body. ICSI resulted in 69 PZs that were transferred within 60 min of second polar body extrusion, and 218 normally fertilized (2PN, 2PB) oocytes that were cultured for cryopreservation. In the 69 PZs, the second PB was extruded 2.71 ± 0.73 h post-ICSI. A similar pregnancy rate between PZT and routine sETs (7.2% cf 5.4%, p = 0.66) was observed. However, significantly better outcomes, five live births (7.2%), were established compared to four live births (1.9%) in the 191 previous embryo transfers (p = 0.04).

Limitations, reasons for caution: The utility of PZT has not been established in good prognosis patients, and the low number of pregnancies means the Central Limit Theorem may not apply and the resultant p values may be invalid.

Wider implications of the findings: These PZT results demonstrate that the uterus can support the development and implantation of pre-zygotes, and *in vivo* development may improve pregnancy outcomes for poor prognosis patients. Furthermore, PZT may provide a viable low cost alternative to extended culture, especially if combined with minimal stimulation without cryopreservation.

Trial registration number: None.

O-108 Cleavage-stage embryo cryopreservation/warming and blastocyst stage embryo transfer is more beneficial over blastocyst stage embryo cryopreservation/warming strategy in good responder patients

M. Kavrut[1], M. Gultomruk[2], N. Findikli[3], F.K. Boynukalin[1], G. Karlikaya[1], C. Celik[4], M. Bahceci[1]

[1]*Bahceci Fulya IVF Centre, Infertility Clinic, Istanbul, Turkey*

[2]*Bahceci Fulya IVF Centre, R&D Laboratory, Istanbul, Turkey*

[3]*Bahceci Fulya IVF Centre, Embryology Laboratory, Istanbul, Turkey*

[4]*Bahceci Umut IVF Centre, Infertility Clinic, Istanbul, Turkey*

Study question: This study is performed to evaluate the possible beneficial effects of cleavage- and blastocyst-stage embryo cryopreservation, subsequent warming/culture and transfer at the blastocyst stage strategies.

Summary answer: Cleavage-stage embryo cryopreservation, culture after warming and subsequent transfer at blastocyst stage is more beneficial over blastocyst-stage embryo cryopreservation and warming.

What is known already: High survival and implantation rates after transfer of vitrified embryos lead many IVF clinics to adapt to freeze-all policy progressively. There exists a tendency to cryopreserve embryos at the blastocyst-stage, especially in good responder patients. Several studies have already shown acceptable results with frozen embryo transfer (FET) cycles in comparison with fresh embryo transfers. However, the number of studies analyzing the efficiency of FET over fresh ET at various embryo developmental stages is scarce and there is a lack of consensus over which stage of embryo cryopreservation is optimal for optimal clinical outcome.

Study design, size, duration: This retrospective cohort study includes 1,497 antagonist cycles performed between January 2013 and December 2015 in Bahceci Fulya IVF Centre. Good responder female patients with ≤38 years of age and male partners with normo-oligospermia were enrolled into the study. Exclusion criteria included poor response to controlled ovarian hyperstimulation, repeated implantation failure (≥3 IVF failure), pooling embryos (more than 2 oocyte pick-up cycles without embryo transfer) and using testis sperm for ICSI.

Participants/materials, setting, methods: Cycles included in the study were grouped into three: Group I included cycles in which embryos were cryopreserved & warmed on day 3, cultured to day 5 and transferred; Group II consisted of cycles in which embryos were cryopreserved & warmed on day 5/transferred on day 5; and Group III included cycles in which embryos were transferred on day 5 as fresh, without any prior cryopreservation. Every patient involved in the study only once.

Main results and the role of chance: The differences in clinical outcome among three study groups were compared. Patient characteristics such as age, BMI and sperm parameters were comparable among groups (p > 0.05). There were statistical significant differences between biochemical (BPR) and clinical pregnancy rates (CPR) among groups (p < 0.001). CPR in Group I (75.3%) was significantly higher than both Group II (65.2%) and Group III (63.0%) respectively (p < 0.001 p = 0.005). On the other hand, similar pregnancy rates were observed between Group II and Group III (p = 0.602). There were also no statistical significant differences among abortion rates in all groups (18.5, 13.5 and 15.9% respectively; p = 0.198).

Limitations, reasons for caution: The main limitation of our study was its retrospective nature, since numerous confounding factors that can affect the ART outcome may be overlooked. Also, cumulative pregnancy rates of cycles included in the study have not been taken into account in this analysis.

Wider implications of the findings: Our study indicates that extended embryo culture after warming may positively affect the pregnancy outcome. However,

well-designed additional prospective studies with large sample sizes will be needed to draw a firm conclusion on which development stage embryos must be cryopreserved.
Trial registration number: None.

O-109 Development of a normogram for early warning based on the relationship of key performance indicators with fresh *in vitro* fertilization cycle outcomes

U.N. Jindal[1], S. Maheshwari[2], D. Gill[2]
[1]*Jindal IVF & Sant Memorial Nursing Home, Chandigarh, India*
[2]*Jindal IVF & Sant Memorial Nursing Home, Embryology, Chandigarh, India*

Study question: Can deterioration of key performance indicators (KPI) serve as early warning signs (EWS) for early intervention and improvement in the *in vitro* fertilization (IVF) laboratory?
Summary answer: Higher clinical pregnancy rates (CPR) were significantly associated with KPI remaining above the mean and lower CPR with clustering of KPI below the mean.
What is known already: KPI which include metaphase-II oocyte (M-II), fertilization, cleavage and embryo quality rates depend upon oocyte quality and IVF laboratory conditions, e.g., temperature, pH, humidity, air quality, disposables and media etc. The impact of deterioration in IVF laboratory quality is reflected in CPR and implantation rates (IR). However, these indices are available much later. There is no way to go back in time and institute remedial interventions in order to salvage the remaining cases. Moreover it is very difficult to evaluate the offending factors retrospectively. EWS, if available can give timely alerts and help in trouble shooting.
Study design, size, duration: This is a retrospective study of 259 fresh IVF embryo transfer (ET) cycles over a period of 1 year. KPI analysed were M-II, fertilization, cleavage and embryo quality rates. Comparison was done using independent *t*-test between KPI of β human chorionic gonadotrophins (β-hCG) and clinical pregnancy (CP) positive and negative groups. Normograms were charted using mean of KPI with error bars set at ±3 standard deviations (SD) and tested against CPR and IR.
Participants/materials, setting, methods: The cases included were standard IVF cycles and fresh ET conducted at a tertiary care center in northern India. β-hCG positivity was considered with blood level > 100 mIU/ml on day-14 post ET and clinical pregnancy positivity was diagnosed with minimum one gestational sac with cardiac pulse detected on ultrasonography done after 6 weeks post ET. All cases were performed in 20 batches, each lasting for 12–15 days.
Main results and the role of chance: In β hCG positive group, the mean M-II, IVF fertilization, ICSI fertilization, cleavage and embryo quality rates were 87.98, 93.19, 94.12, 91.97 and 93.02% respectively while in pregnancy negative group, these were 80.37, 88.96, 86.14, 86.21 and 89.71% respectively. In CP positive group, the mean M-II, IVF fertilization, ICSI fertilization, cleavage and embryo quality rates were 88.21, 93.01, 95.43, 93.00 and 93.83% respectively while in pregnancy negative group, these were 81.47, 89.57, 86.31, 86.72 and 89.78% respectively. These differences were significant for M-II, ICSI fertilization and cleavage rates (p = 0.021, 0.001 and 0.001 respectively) and insignificant for IVF fertilization and embryo quality rates (p value = 0.269, 0.060 respectively). The highest positive correlation of β hCG positivity, CPR and IR was observed with cleavage rate (standardized β coefficient = 0.422) amongst various KPI analysed. During the batch with worst outcome, a decline in KPI of more than one standard deviation from the mean was observed. A fall in KPI of more than two standard deviations from mean and clustering of events over period of 1–2 days was associated with the poor outcome. IVF outcome was better when KPI remained above the mean values.
Limitations, reasons for caution: Besides KPI, there are many other variables which may affect the IVF outcome like oocyte quality, endometrium, day and number of embryos transferred. These factors were not considered in analysis. A knee jerk reaction and changes in IVF laboratory protocol on the basis of few events may also be counterproductive.
Wider implications of the findings: The normograms of KPI of individual IVF laboratory can serve as objective markers for evaluation of any intervention in IVF laboratory protocols. A decline and clustering of daily events charted over these normograms should serve as warning signs.
Trial registration number: Since it was a retrospective analysis of data, trial registration number was not sought.

[4]*Faculty of Health University of Aarhus, Department of Clinical Medicine, Aarhus, Denmark*
[5]*School of Medicine of the University of Zagreb, Department of Obstetrics and Gynaecology, Zagreb, Croatia*

Study question: Is there any added-value in assessing endometrial thickness (EMT) on the day of ovulation triggering to predict (LBR) in modern-day *in vitro* fertilization (IVF)?
Summary answer: An increase in EMT is independently associated with an increase in LBR.
What is known already: Previous studies have shown that EMT has a controversial effect on IVF pregnancy outcomes. Specifically, while some researchers have shown that it may affect surrogate outcomes, such as clinical pregnancy and miscarriage rates, studies thus far have failed to show any influence on live birth. However, the extrapolation of these results to modern-day practice may be limited by their sample size and potential unmeasured confounding factors, such as body mass index (BMI) and the late-follicular-phase endocrine profile. With the constant enhancement of IVF, one can only postulate if EMT still has any role in predicting pregnancy outcomes.
Study design, size, duration: We performed a single-centre retrospective cohort analysis of 3,351 gonadotropin-releasing hormone (GnRH) antagonist down-regulated cycles with a fresh embryo transfer performed in a tertiary hospital between January 2010 and October 2014. The sample was categorized according to the following regular 2-millimeter-intervalled groups of EMT on the day of ovulation triggering: <7.0 mm, 7.0–8.9 mm, 9.0–10.9 mm, 11.0–12.9 mm and 13 mm. LBR was the main outcome measure.
Participants/materials, setting, methods: Cycles using preimplantation genetic diagnosis, *in vitro* maturation and donor oocytes were excluded. We performed multivariable regression adjusting the standard errors for the clustering of cycles repeated in the same patient and accounting for the following potential confounders: female age, BMI, cycle rank, total dose of exogenous follicle-stimulating hormone (FSH), the late-follicular-phase endocrine profile [specifically, estradiol (E2) and progesterone (P) levels], the number of embryos produced and the number, stage and grade of the embryos transferred.
Main results and the role of chance: The mean female age of our sample was 32.5 years and 62.3% of the patients were undergoing their first or second IVF attempt.

An increase in BMI was linearly related to an increase in EMT. On the other hand, the following variables were associated with a significant decrease in EMT on the day of ovulation triggering: total FSH dose <750 IU, late-follicular

E2<1,000 pg/mL or P < 0.5 ng/mL. All variables with an effect on EMT were considered as potential effect-modifiers of the influence of EMT on live birth and assessed for their significance as interaction terms in the multivariable logistic regression model.

In the multivariable logistic regression model, EMT was an independent predictor of live birth in our sample, even after accounting for the before-mentioned potential confounders (predicted live-birth rates by ascending order of EMT thickness: 18.2, 25.4, 28.7, 30.2 and 26.2%, respectively).

Limitations, reasons for caution: This study should be interpreted with caution owning to its retrospective design and the potential for unmeasured confounding such as female smoking habits and previous uterine surgery. Furthermore, these results should not be extrapolated to other perinatal outcomes, such as prematurity and live birth weight.

Wider implications of the findings: By accounting for the concealing effect of multiple confounders, we associated, for the first time, EMT to a greater than expected influence on IVF outcomes, specifically LBR. These results reestablish the role for EMT assessment in modern-day IVF, where cycle monitoring and elective embryo cryopreservation may adequately circumvent this issue.

Trial registration number: Not applicable.

O-112 Is endometrial thickness associated with intrauterine growth restriction or placental related pregnancy complications in fresh IVF cycles?

G. Oron[1], S. Rona[1], O. Sapir[1], L. Hirsch[1], Y. Shufaro[1], B. Fisch[1], A. Ben-Haroush[1]
[1]*Beilinson, Infertility and IVF Unit, Helen Schneider Hospital for Women, Rabin Medical Center, Beilinson Hospital, Petach Tikva, Israel*

Study question: Our objective was to evaluate the association between endometrial thickness, on day of hCG trigger in fresh IVF cycles and intrauterine growth restriction (IUGR) and placental related obstetric complications.

Summary answer: Univariate analysis shows that a thin endometrial thickness (<8 mm) is associated with increased risk of intrauterine growth restriction and grouped placental-related pregnancy complications.

What is known already: IVF pregnancies in general appear to be associated with worse obstetric and perinatal outcomes such as preterm delivery and low birth weight compared to spontaneous conceptions. A previous study has shown that a thick endometrial lining (>12 mm) is associated with an increased risk for placenta previa. We conducted a study evaluating the association between endometrial thickness and the resulting neonatal birth weight and placental related pregnancy complications.

Study design, size, duration: A retrospective analysis of 1,002 consecutive singleton live births from a cohort of 6,350 fresh ET cycles performed between July 2007 and December 2014. Data for confounding variables were available for 849 singleton deliveries. Intrauterine growth restriction was defined as <10% according to a national population-based live born infant birth weight curves.

Participants/materials, setting, methods: We analyzed patient variables (maternal age, smoking, BMI), treatment cycle parameters (stimulation protocol, total gonadotropin dose, ICSI/IVF) and pregnancy outcome (mode of delivery, gestational age, birth weight and pregnancy complications). Composite placental related pregnancy complications included preeclampsia and pregnancy induced hypertension, placenta previa, placental abruption and intrauterine growth restriction)

Main results and the role of chance: Univariate analysis shows a significant association between a thin endometrium (<8 mm) and intrauterine growth restriction (35/199, 17.6% and 67/650, 10.3%; $p = 0.006$). Thin endometrium was significantly associated with composite adverse outcome (19.9 and 12.8%, $p = 0.014$). In a multivariate logistic regression analysis, adjusting for confounding factors including age, smoking, BMI, parity, chronic hypertension, pre-gestational diabetes and gestational diabetes, endometrial thickness was not a significant predictor of intrauterine growth restriction or placental-related pregnancy complications.

Limitations, reasons for caution: The limitation of the study is the retrospective nature of the study. Medical charts were reviewed for patients who delivered at our hospital. Pregnancy outcome was recorded as part of routine prospective patient follow-up by telephone surveillance and documented in the patient chart for patients that delivered out of hospital.

Wider implications of the findings: Univariate analysis shows a strong association between endometrial thickness and placental-related complications and IUGR. When adjusting for maternal risk factors such as advanced age, smoking, BMI, chronic hypertension and pre-gestational diabetes this effect is non-significant. Further larger studies are needed to dispute or confirm these findings.

Trial registration number: None.

O-113 ER map: a new comprehensive and reliable endometrial receptivity test

J.A. Horcajadas Almansa[1], M. Enciso[2], J. Sarasa[2], J.P. Carrascosa[3], P.A. Martínez-Ortiz[4], J. Aizpurua[4], S. Munné[5]
[1]*Universidad Pablo de Olavide, Genetics, Sevilla, Spain*
[2]*iGLS, Genetics Department, Alicante, Spain*
[3]*CABD, Genetics, Sevilla, Spain*
[4]*IVF Spain, Reproductive Medicine, Alicante, Spain*
[5]*Reprogenetics, Research, Livingston, NJ, USA*

Study question: Is it possible to determine the receptivity status of an endometrium by combined qRT-PCR expression analysis of genes involved in endometrial proliferation and immune response?

Summary answer: The new ER Map test can predict endometrial receptivity status by qRT-PCR using a panel of 16 genes involved in endometrial proliferation and immune response.

What is known already: The endometrium reaches a receptive status for embryonic implantation around day 19–21 of the menstrual cycle. During this period, known as the window of implantation (WOI), the endometrium shows a specific gene expression profile suitable for endometrial function evaluation. The number of molecular diagnostic tools available to characterize this process is very limited and lack key elements for the accurate determination of the WOI, such as immune response genes, crucial for embryo implantation. In this study, qRT-PCR analyses of genes involved not only in endometrial receptivity development but also in the immune response metabolism is performed for the first time.

Study design, size, duration: A comprehensive solution to analyse the endometrial transcriptomic signature at the WOI is explored. ER Map validation was achieved on 130 endometrial samples including fertile women and patients undergoing fertility treatment between July 2014 and December 2015. Expression analyses of 192 genes involved in endometrial receptivity and immune response were performed. All patient samples were additionally tested with an independent endometrial receptivity assay (ERA) to verify their endometrial status.

Participants/materials, setting, methods: A total of 96 fertile women (18–34 y.o) and 34 ART patients participated in the study. Endometrial biopsy samples were obtained at LH + 2 and LH + 7 in fertile subjects and at P + 5 (progesterone) in patients. Total RNA was purified using RNeasy Mini Kit (Qiagen) and quality-checked using Agilent Bioanalyzer. Oligonucleotides for the amplification of the 192 selected genes were designed by using GeneFisher 2.0 platform. Gene expression was quantified by qRT-PCR using Biomark-HD platform (Fluidigm).

Main results and the role of chance: The new ER Map test can predict endometrial receptivity status by qRT-PCR using a new panel of 16 genes involved in endometrial proliferation and immune response. Mean gene expression of 96 out of the 192 selected genes was found to be statistically different when comparing LH + 2 and LH + 7 samples (*T*-test, $p < 0.05$). Those genes were mainly related to the cell division, tissue proliferation and immune system metabolism. Principal Component Analysis showed that more than 90% of the gene expression variance of the set of samples studied was explained by 16 key genes. These genes allowed accurate classification of samples into 4 endometrial receptivity status: non-receptive, pre-receptive, receptive and post-receptive in both groups, fertile women and infertile patients. Using a discriminant model based on the 16 selected genes, 100% cases were correctly classified. In the group of fertile donors, 100% of LH + 2 samples were categorised as non-receptive, and all LH + 7 samples were classified as receptive. Within the patient group, ER Map classification matched the endometrial biopsy status prediction of the independent diagnostic tool ERA in all 100% samples.

Limitations, reasons for caution: A higher number of samples are desirable to fine receptivity status prediction and minimise no results. A clinical trial to evaluate IVF treatment success following ER Map application is required to assess the advantages of this new test for accurate prediction of the WOI and improvement of implantation.

Wider implications of the findings: A new comprehensive system for human endometrial evaluation based on receptivity and immunology-linked genes has been developed. This molecular tool has been optimised in the diagnostic

platform, BioMark-HD (Fluidigm) that allows high-throughput gene expression analyses at a lower cost than other methods.
Trial registration number: Not applicable.

O-114 How to limit the risk of early pregnancy loss in frozen embryo transfer protocols?

I. Hatoum[1], L. Bellon[1], M. Ouazana[1], N. Swierkowski[1], S. Bouba[1], K. Fathallah[1], B. Paillusson[1], M. Bailly[1], F. Boitrelle[2], L. Alter[2], M. Bergère[2], J. Selva[2], R. Wainer[1]
[1]*ART Unit, Obstetrics and Gynecology, Poissy, France*
[2]*Biology and Cytogenetics Laboratory of the ART Unit, Obstetrics and Gynecology, Poissy, France*

Study question: Does the cycle regimen used for endometrial preparation affect the endometrial receptivity and thus the reproductive outcomes in frozen embryo transfer (FET)?
Summary answer: The early pregnancy loss rate increases when using artificial cycles (estrogen E2 and progesterone P) for endometrial preparation compared to stimulated cycles (follicle-stimulating hormone FSH) in FET.
What is known already: When comparing live birth and clinical pregnancy rates, a Cochrane review in 2010 (natural, stimulated and artificial cycles) (1), a meta-analysis published in Human Reproduction Update 2013 (2) and a retrospective study by Tomas et al.(3) (natural cycle with or without ovulation induction and artificial cycles) could not demonstrate the superiority of one regimen over another. But according to Tomas et al., there was a significantly higher early pregnancy loss ($P < 0001$) in the artificial cycles group. Only the type of protocol used correlated to the pregnancy loss (3). Moreover the optimal endometrial thickness for FET is yet to be defined because of controversies (1, 4).
Study design, size, duration: Our retrospective comparative study included 1,926 FET cycles performed during a period of 3.5 years (January 2012–June 2015) in the Fertility unit of the intercommunal hospital center of Poissy-Saint-Germain-en-Laye in France. The outcomes of assisted reproductive technology in terms of clinical pregnancy and early pregnancy loss between January 2012 and June 2015 at a single institution were retrospectively evaluated. The embryos were derived from either *In Vitro* Fecondation or intracytoplasmic sperm injection treatment cycles.
Participants/materials, setting, methods: We retrospectively evaluated clinical pregnancy and pregnancy loss rates in 1,926 cycles (substituted cycles: estrogen 4–6 mg daily orally or vaginally followed by vaginal progesterone (P) supplementation 400–600 mg daily before embryo transfer and until the 12th gestational week if pregnancy occurred) and stimulated cycle with FSH from day 4, followed 2 days after ovulation triggering by a measure of progesteronemia). Vaginal ultrasound was used for endometrial and ovarian monitoring. The pregnancy test was performed 14 days after ET.
Main results and the role of chance: Before embryo transfer ET, a substituted cycle was used for endometrium preparation in 865 cases (45%) whereas a stimulated cycle was used in 1,061 ET (55%). Baseline characteristics (age, body mass index, duration of infertility, etiology of infertility and number of embryo transferred) were similar in the two groups. According to Guidelines for clinical practice by the French College of Gynaecologists and Obstetricians in 2014 a miscarriage is defined by the loss of pregnancy <14 weeks after a clinical pregnancy was identified. A biochemical pregnancy is defined by a rate of BHCG < 100. We define early pregnancy loss (EPL) as biochemical pregnancies (preclinical losses) and miscarriages. EPL rate was 34.2% in stimulated cycles vs. 56.9% in substituted cycles.

Independently of patient's age, BMI, duration of infertility and number of embryo transferred, substituted cycles had an increased risk of miscarriage nearly 2 times that of stimulated cycles while live birth rate is significantly higher (2 times) in stimulated cycles than in substituted cycles (59.7 vs. 29.1% respectively).
Limitations, reasons for caution: The compliance of patients to treatment in artificial cycles is important for analysis of these findings in term of efficacy, even if patients are given written prescription to continue hormonal supplementation to 12 weeks. Due to retrospective nature of our study selection or information bias could be found.
Wider implications of the findings: Stimulated cycles provide a "physiologic" hormonal support *via* the corpus luteum that could lead to more live births and less early pregnancy loss in FET candidates but should be carefully used in ovarian polycystic syndrome. A prospective randomized study is needed to a better analysis of the efficacy of protocols.
Trial registration number: 0

O-115 Enhanced SUMOylation of HOXA10 impairs endometrial receptivity and embryo implantation

R. Jiang[1], Q. Zhang[2], Q. Yan[1], N. Kong[1], J. Liu[1], Z. Diao[1], L. Ding[1], H. Sun[1], G. Yan[1]
[1]*The Affiliated Drumtower Hospital, Reproductive Medicine Center, Nanjing, Jiangsu, China*
[2]*The Affiliated Drumtower Hospital, Obstetrics and Gynecology, Nanjing, Jiangsu, China*

Study question: Does SUMOylation of homeobox a10 (HOXA10) regulate the endometrium receptivity and embryo implantation?
Summary answer: HOXA10 SUMOylation at K164 impairs endometrium receptivity and embryo implantation through decreasing protein nuclear localization and repressing transcriptional activity.
What is known already: HOXA10 plays a critical role in the endometrium receptivity and embryo implantation by regulating the expression of downstream target genes, including β3-integrin (ITGβ3) and matrix metalloproteinase-26. Recently, the acetylation of HOXA10 has been demonstrated to impair embryo implantation by inhibiting ITGβ3 protein expression.
Study design, size, duration: The mid-secretory phase endometrium tissues from fertile controls ($n = 22$) and patients with recurrent implantation failure (RIF) ($n = 22$) were collected for investigation of SUMOylation level. HEK293T and Ishikawa cells were used to investigate the molecular mechanisms *in vitro* analysis. This is an experiment study lasted 1 year.
Participants/materials, setting, methods: HEK293T and Ishikawa cells were used as study models. A luciferase reporter assay, Western blotting, quantitative PCR and confocal immunofluorenscence analysis were used to determine the effect of small ubiquitin-like modifier 1 (SUMO-1) on HOXA10 protein nuclear localization and transcriptional activity. The effect of HOXA10 SUMOylation on embryo implantation was evaluated using a BeWo spheroid attachment assay with adenovirus-mediated overexpression of HOXA10 and SUMO-1.
Main results and the role of chance: We found increased SUMO-1 conjugation to substrate proteins with 50–90 KD molecular weight in the endometrium of patients with RIF compared to fertile controls ($P < 0.05$). HOXA10 was covalently modified by SUMO-1 on a phylogenetically conserved lysine 164 and increased amount of SUMO-1 expression led to progressive increment of SUMOylated HOXA10. A combination of estrogen and progesterone stimulation in Ishikawa cells contributed to decreased SUMOylated HOXA10 level. HOXA10 protein (Wild Type) was expressed preferentially in the nucleus as expected, while the SUMOylation deficient K164R mutant protein was prevalently localized in the cytoplasm. SUMO-1 modification attenuated the HOXA10-mediated ITGβ3 transcription by 35% ($P < 0.01$). Interestingly, HOXA10 mutant (K164R) had high basal transcriptional activity. Furthermore, the adenovirus-mediated overexpression of HOXA10 and SUMO-1 in Ishikawa cells markedly diminished BeWo spheroid adhesion by 33% compared to the HOXA10 alone ($P < 0.05$).
Limitations, reasons for caution: This is an *in vitro* study utilizing Ishikawa and 293T cells. The effect of SUMOylation on HOXA10 protein stability and its relationship with ubiquitylation were not evaluated. Furthermore, the results should be confirmed in a mouse model of overexpressed HOXA10 mutant (K164R) in endometrium *in vivo*.
Wider implications of the findings: Our identification of SUMOylation as a novel post-translational modification of HOXA10 suggests SUMOylation plays an important role in endometrium receptivity and embryo implantation, and this may subsequently provide novel insights to our comprehensive understanding about the pathological physiological mechanisms of embryo implantation.
Trial registration number: None.

O-116 Impact of S100A10 protein silencing on the decidualization process and secretory transformation of endometrial stromal and epithelial cells, of fertile women

L. Bissonnette[1], D. Haouzi[2], L. Drissennek[3], Y. Antoine[2], F. Bissonnette[1], I.J. Kadoch[4], S. Hamamah[5]
[1]*Clinique Ovo, Fertility, Montreal, QC, Canada*
[2]*CHRU Montpellier, INSERM, U1203, Montpellier, France*
[3]*Université Montpellier, Faculté de Médecine, Montpellier, France*
[4]*Clinique Ovo, Research and Development, Montreal, QC, Canada*
[5]*CHU Montpellier, Département de Biologie de la Reproduction, Hôpital Arnaud de Villeneuve, Montpellier, France*

Study question: Determine whether a human endometrial receptivity biomarker (S100A10) plays a role in the decidualization and secretory transformation of endometrial cells in normal responder patients.
Summary answer: S100A10 protein silencing inhibited prolactin secretion in stromal endometrial cells, but significantly enhanced it in epithelial endometrial cells.
What is known already: The role(s) of human biomarkers of endometrial receptivity during the implantation window are rarely determined. Stromal cells decidualization and epithelial cells secretory transformation are critical for the establishment of uterine receptivity, and consequently, for successful implantation. Decidualization characterizes the differentiation of endometrial stromal fibroblasts into specialized secretory decidual cells that expressed specific markers such as prolactin. Decidualization is endowed with the secretory transformation of the uterine glands. As for decidualization, uterine gland maturation is mediated through cAMP allowing expression of implantation-related factors including the prolactin. The behaviour of epithelial cells during the decidualization of stromal cells has rarely been studied.
Study design, size, duration: Primary epithelial and stromal cells were purified from endometrial biopsies obtained during the implantation window of two fertile patients. Then, we targeted the extinction of the S100A10 using shRNA in each endometrial cell type. The obtained phenotype was analyzed in regards of the decidualization and the secretory transformation of stromal and epithelial cells respectively.
Participants/materials, setting, methods: Primary endometrial cell cultures of epithelial and stromal cells were performed. Then, to determine whether S100A10 had a role in the decidualization of endometrial stromal cells and the secretory transformation of epithelial cells, each cell type transduced with S100A10 shRNA or control shRNA were incubated or not with 8-Br-cAMP for 9 days. Spent culture medium was collected for prolactin quantification with the automated immunoassay system BRAHMS KRYPTOR.
Main results and the role of chance: The incubation with 8-Br-cAMP of the stromal and epithelial endometrial cells transduced with control shRNA, induced a typical decidual phenotype and prolactin secretion. In the stromal cells, prolactin secretion was increased by 16.3-fold in the culture medium of 8-Br-cAMP treated cells transduced with control shRNA compared with untreated cells (215 ± 33 vs. 13 ± 1 µUI/ml, $P < 0.0001$) and only by 8.3-fold in S100A10 silenced cells (110 ± 10 µUI/ml, $P = 0.009$) compared to control shRNA. These data indicate that for the stromal endometrial cells there is an inhibitory effect of prolactin secretion in S100A10 silenced cells. In endometrial epithelial cells, 8-Br-cAMP treatment induced prolactin secretion in both cells transduced with control shRNA (62 ± 11 vs.13 ± 1 µUI/ml, $P < 0.0001$) compared to untreated cells and with the S100A10 shRNA (98 ± 10 µUI/ml, $P = 0.025$) compared to control shRNA, indicating that in epithelial endometrial cells, S100A10 silencing promotes prolactin secretion. Therefore, S100A10 silencing inhibited prolactin secretion in stromal endometrial cells, but significantly enhanced it in epithelial endometrial cells.
Limitations, reasons for caution: Culture of luminal and glandular epithelial cells, as well as co-culture system between epithelial and stromal cells, should be considered to better understand cross-talk between these cellular compartments.
Wider implications of the findings: This study should open new perspectives in the understanding of molecular mechanisms regulating human endometrial receptivity and reveals the key role of S100A10 as a player in endometrial receptivity acquisition.
Trial registration number: Not applicable.

Study question: Is it possible to detect and quantify low frequency heteroplasmic variants, large deletions and single nucleotide variants (SNV) in the mtDNA of single cells?
Summary answer: Our method detects heteroplasmic SNVs and large deletions in single cells; data on single oocytes provides interesting insight on SNV segregation during oogenesis
What is known already: The advent of MPS has opened new possibilities for the analysis of low frequency heteroplasmies in the mtDNA, but no methods are currently available to accurately detect and quantify low frequency SNVs and large deletions. Mutations in the mtDNA have been previously reported in ART-derived oocytes and embryos, as well as methods for the analysis of individual mutations in preimplantation genetic diagnosis. Conversely, up to now, it has not been possible to identify all mutations in one single cell simultaneously, nor to establish their mutation load
Study design, size, duration: We developed a method to analyze large deletions and SNVs in DNA samples and scaled it down to the level of single cells. We sequenced six single fibroblasts from a control individual, two muscle fibers from a patient with mtDNA deletions, and 11 oocytes from three different patients treated at our IVF center (5 GV, 3 MI, 3 MII)
Participants/materials, setting, methods: Single cells were lysed in alkaline lysis buffer. MtDNA was enriched by long-range PCR. Sequencing was done at 6,000×. SNVs called with CLCBio Genomic Workbench and large deletions were identified using BLAST. Mutation load was established using the sequencing depth. The lower detection limits are linked to the number of PCR cycles needed, down to loads for deletions and SNVs of 0.5 and 1.5% at 35 cycles, and 0.5 and 2% at 45 cycles, respectively
Main results and the role of chance: The single fibroblasts revealed somatic mosaicism, with two variants appearing in 1/6 of the cells at high loads, and not present in the other cells. The muscle fibers showed a low number of large deletions at a high frequency and most of them were also identified in the blood sample of the same patient. In the oocytes, one large deletion at 0.51% was found in the cohort analyzed. We detected SNVs in 9/11 oocytes, at frequencies ranging from 1.5 to 20%. The same SNVs were found recurrently in the oocytes from the same donor but often at different frequencies. In one patient we observed a variant in 3/4 oocytes at loads of 5, 15 and 20%. In the same patient, another variant was detected in 2/4 oocytes at frequencies of 5 and 15%. In 2/4 oocytes from a different patient, a third SNV was detected at frequencies of 2.5 and 3%. Half of the detected variants mapped to the hypervariable region (12/24) and only one variant at load of 4% was predicted to be pathogenic. There was no correlation between the oocyte maturation stage and the presence of variants
Limitations, reasons for caution: The results we obtained with the oocytes must be matched with the variants in somatic tissues of the same patient to have a full validation of the variants called and to follow the variants' segregation
Wider implications of the findings: Our method for low frequency detection can be used to study mtDNA variants in single cells with high accuracy. This tool can be applied also to the diagnostic of mitochondrial diseases involving large deletions or SNVs. Finally, our data provides interesting preliminary information about heteroplasmy shifts during gametogenesis.
Trial registration number: N.A.

O-118 Design, validation and clinical application of a novel next-generation sequencing protocol for detection of mitochondrial disease and simultaneous aneuploidy screening in preimplantation embryos

K. Spath[1,2], J. Sarasa[2], D. Babariya[1,2], M. Konstantinidis[3], T. Griffiths[4], J. Spencer[4], K. Turner[4], C. McCaffrey[5], B. Gangrade[6], T. Child[4], J. Grifo[5], S. Patel[6], S. Munne[3], D. Wells[1,2]

[1]University of Oxford, Nuffield Department of Obstetrics and Gynaecology, Oxford, UK

[4]Oxford Fertility, Institute of Reproductive Sciences, Oxford, UK
[5]NYU Fertility Center, New York, NY, USA
[6]Center for Reproductive Medicine, Orlando, FL, USA

Study question: Can a next-generation sequencing (NGS) protocol be clinically applied to perform preimplantation genetic diagnosis (PGD) of mitochondrial DNA (mtDNA) disease and aneuploidy in preimplantation embryos?
Summary answer: The NGS technique enables accurate PGD of mtDNA disease in cleavage- and blastocyst-stage biopsies. Additionally, comprehensive chromosome screening (CCS) can be incorporated in the protocol.
What is known already: Maternally inherited mutations can be present in all (homoplasmy) or a fraction (heteroplasmy) of mtDNA copies. Although most female carriers are phenotypically unaffected, due to low mutation load, high levels can be present in oocytes and passed to the offspring resulting in mtDNA disease. To prevent transmission, PGD can be performed to select embryos free of the mutation or unlikely to be affected by disease. Current PGD techniques of mtDNA disease do not allow incorporation of CCS. Since aneuploidy is extremely common in preimplantation embryos, we aimed to develop a test that enables accurate mtDNA mutation detection and aneuploidy screening.
Study design, size, duration: To combine mtDNA mutation and aneuploidy screening, the technique was developed and optimised on whole genome amplified (WGA) DNA. This was then subjected to targeted sequencing of the mtDNA for PGD and to microarray comparative genomic hybridisation (aCGH) or NGS for the purpose of CCS. Prior to clinical application, the protocol was extensively validated on genomic DNA and isolated buccal cells and/or lymphocytes, derived from four mtDNA mutation carriers presenting varying mutation levels (50–100%).
Participants/materials, setting, methods: The method was applied to developmentally competent and arrested embryos and unfertilised oocytes from three patients, each having a child affected by Leigh Syndrome (Patient 1 and 2: m.8993T > G; Patient 3: m.10191T > C). The mutation was not detectable in somatic cells of Patients 1 and 3, however children of both presented with heteroplasmy (95 and 78% mutant mtDNA, respectively). Somatic heteroplasmy of 56% was detected in Patient 2 who had a child homoplasmic for the mutation.
Main results and the role of chance: The NGS method provided qualitative (DNA sequence) information and also quantitative data (proportion of mtDNA molecules with the mutation). Initial validation using genomic DNA and cells of mutation carriers yielded 100% diagnostic accuracy. Five PGD cycles were performed with 50 specimens analysed: 19 blastocyst- and cleavage-stage embryos, three unfertilised oocytes, eight arrested embryos. Additionally, three embryos were divided into 20 single sister blastomeres. Patient 1 generated 14 blastocysts. None carried detectable mutation levels, but four were aneuploid. No mutations were detected in one unfertilised oocyte, one arrested embryo and 16 sister blastomeres from two embryos. The patient underwent a single embryo transfer and is pregnant (delivery in May). Patient 2 generated one blastocyst after two cycles, which was unaffected by the mutation, but aneuploid. One unfertilised oocyte and 2 arrested embryos carried 91, 89 and 0% of mutated mtDNA copies, respectively. Patient 3 produced four embryos from two cycles, which were assessed at the cleavage-stage. None carried the mutation, but two were aneuploid. No mutation was detected in one unfertilised oocyte, four arrested embryos and four sister blastomeres of one embryo. Transfer of a single embryo yielded no pregnancy and the patient is awaiting transfer of the second euploid embryo.
Limitations, reasons for caution: The accuracy of PGD for mtDNA mutation analysis may be reduced due to possible biological variations in mutation levels between the biopsy specimen and the remaining embryo. Hence verification by prenatal testing should be performed to confirm that the fetus is not affected by mtDNA disease.
Wider implications of the findings: This is the first study utilising NGS for the detection and quantification of mtDNA mutations in preimplantation embryos. The protocol was to be demonstrated highly accurate and can be combined with chromosome screening. The study provided evidence of low recurrence risk of mtDNA disease in patients with undetectable somatic mutations.
Trial registration number: NA.

O-119 Mitochondrial quantification during human embryogenesis *via* next-generation sequencing: relation to nuclear ploidy status

N. Arrach[1], S.H. Wood[2], E.S. Sills[3]
[1]Progenesis, Reproductive Genetics, San Diego, CA, USA
[2]Reproductvie Sciences Medical Center, Division of Reproductive Endocrinology & Infertility, San Diego, CA, USA
[3]Center for Advanced Genetics, Reproductive Research Section, Carlsbad, CA, USA

Study question: What is the association between embryo mitochondrial load and nuclear ploidy status during early human embryo development?
Summary answer: Mitochondrial quantity appears to vary throughout the sequence of human embryo development and does correlate with nuclear ploidy status.
What is known already: Mitochondria are recognized as the critical source of cellular ATP although they are also involved in redox & calcium homeostasis, provide intermediary metabolites, and store proapoptotic factors. They are maternally transmitted, deriving from a restricted founder population amplified during oogenesis. While mitochondrial segregation to blastomeres during early embryogenesis is strictly regulated, the distribution of mitochondria during this critical phase remains poorly understood.
Study design, size, duration: This retrospective, multi-cohort pilot study was undertaken to quantify mitochondrial load during early embryogenesis and to assess the relation of mtDNA to nuclear ploidy status. Data from embryos (n = 325) were reviewed for patients undergoing IVF at a single institution during the 9 month interval ending December 2015.
Participants/materials, setting, methods: Embryo records were evaluated from patients (n = 69) who completed IVF treatment with preimplantation screening at an urban referral fertility unit in southern California. High throughput sequencing of mitochondrial and nuclear DNA was achieved simultaneously after whole genome amplification using an ion semiconductor platform (ThermoFisher Scientific, Inc). Nuclear and mitochondrial DNA ratios were then tabulated according to time of single biopsy: day 3 (n = 90), day 4 (n = 145), or day 5 (n = 90).
Main results and the role of chance: Successively declining mitochondria quantities were observed from the blastomere stage (d3) compared to morula (day-4) and blastocyst stage (day-5), validating a prior observation that mitochondria are not newly made during the first 5 days of human embryo development. Among euploid embryos, we noted a relatively high mitochondria load at d3 but successively fewer mitochondria at d4 and d5 vs. aneuploid embryos.
Limitations, reasons for caution: Absolute quantity of mitochondria may not always correlate to mtDNA copy number estimates, so additional study is planned to measure discrete mitochondrial parameters at our center in the future. These data also cautiously align with previous work in that fewer mitochondria were present in embryos obtained from older IVF patients.
Wider implications of the findings: We hypothesize that the observed decline in mitochondrial load at d4 and d5 among euploid embryos results from an enhanced metabolic milieu, where less ATP is needed to execute vital cellular processes. Additionally, impaired cell fission may allow aggregation of mtDNA that would otherwise be dispersed in "healthy" embryo cells.
Trial registration number: N/A.

O-120 The impact of simultaneous mitochondrial DNA (mtDNA) content assessment in comprehensive chromosomal screening (CCS): a prospective pilot study

M. Gultomruk[1], F.K. Boynukalin[2], C. Ogur[1], A. Díz-Juan[3], C. Cinnioglu[4], N. Findikli[5], M. Bahceci[2]
[1]Bahceci Fulya IVF Centre, R&D Laboratory, Istanbul, Turkey
[2]Bahceci Fulya IVF Centre, Infertility Clinic, Istanbul, Turkey
[3]Igenomix, Product Development, Valencia, Spain
[4]Ivigen, Genetics Laboratory, Los Angeles, CA, USA
[5]Bahceci Fulya IVF Centre, Embryology Laboratory, Istanbul, Turkey

Study question: Does simultaneous mtDNA copy number assessment bring additional benefit on cycle outcome in frozen embryo transfer cycles where euploid blastocysts are replaced after CCS?
Summary answer: Our study shows a high correlation between mitochondrial DNA copy number assessment and implantation potential of euploid human embryos in CCS cases.

What is known already: Recent studies indicate that, besides its developmental stage and morphology, successful implantation after the transfer of a chromosomally normal human embryo is highly correlated with its low mtDNA content. On the other hand, although the quantity of mtDNA is found to be higher in older women and is associated with aneuploidy, the data regarding its clinical relevance in euploid embryos is scarce.
Study design, size, duration: This prospective pilot study was performed in Bahçeci Fulya IVF Centre between May and July 2015. It includes 120 blastocyst-stage human embryos from 38 patients undergoing consecutive CCS cycles for advanced maternal age, recurrent implantation failure, recurrent first trimester abortions or a combination of these indications.
Participants/materials, setting, methods: Whole genome amplification products of 52 embryos that were found to be euploid (52/120; 43.3%) after CCS were further processed for mtDNA content assessment (Mitoscore analysis) by qPCR. Embryo transfers were performed prospectively and blinded for Mitoscore results (by using CCS results only). Clinical outcome data and individual Mitoscore results of each embryo transferred have been paired and analyzed retrospectively with the known implantation data (KID) at the end of the study.
Main results and the role of chance: Of 52 embryos analyzed by Mitoscore, 24 (46.2%) were found to have high (Group A), 26 (50.0%) were found to have average (Group B) and 2 (3.8%) were found to have low (Group C) implantation potential respectively according to a previous validation study. In 30 embryo transfer cycles, uterine replacement of 31 mitoscore-tested blastocysts resulted in 53.3% clinical pregnancy rate. When the same data were analyzed according to Mitoscore groups, clinical pregnancy and implantation rates were found to be 69.2% and 71.4% for Group A and 46.6% and 53.3% for Group B embryos respectively. There were two embryos in Group C and both embryos failed to create a viable pregnancy after uterine replacement. Also, no correlation was found among blastocyst morphology, day of trophectoderm biopsy and Mitocsore results.
Limitations, reasons for caution: Although a higher pregnancy and implantation rates were observed with embryos with low mtDNA content, this study should be expanded to include larger sample sizes with an adequate statistical power. Such work is currently under way in the Authors' institutions.
Wider implications of the findings: The results of this pilot study, when confirmed in a wider study population will modify our current CCS concept and create a platform in which mtDNA-based analyses can become an integral part of the CCS procedures in order to maximize the clinical outcome.
Trial registration number: None.

O-121 RNA-Seq reveals distinct transcriptomes in normal and trisomic human pre-implantation embryos

F. Licciardi[1], Y. Kramer[2], Y. Zhang[3], A. Tsirigos[4], T. Lhakhang[3], A. Heguy[4]
[1]*New York, NY, USA*
[2]*NYU Langone Medical Center, OBGYN, New York, NY, USA*
[3]*NYU Langone Medical Center, OCS, New York, NY, USA*
[4]*NYU Langone Medical Center, Pathology, New York, NY, USA*

Study question: What do RNA seq-profiles tell us about gene activity in pre-implantation embryos known to be normal vs. trisomic for chromosomes 21, 18, 15 and 22.
Summary answer: RNA-Seq profiles are karyotype-dependent and appear to correlate with viability. X and Y transcription is surprisingly active at the pre-implantation stage.
What is known already: Embryonic karyotypic abnormalities are the most common cause of implantation failure and miscarriage. Some such embryos can progress to viability as evidenced by the birth of children with Trisomy 21, 18 and 15. An abnormal karyotype dictates developmental aberrations, and for these differences to affect phenotype, variations in gene expression must occur in the developing embryo. We set out to determine if such changes could be identified in embryos as early as the pre-implantation stage.
Study design, size, duration: We used a cohort of 19 pre-implantation embryos (day 5 and 6 blastocysts); three being normal, five trisomy 15, two trisomy 22, three trisomy 21 and three trisomy 18, and three of unknown karyotype.
Participants/materials, setting, methods: After written consent, analysis was performed on high quality embryos that previously underwent trophectoderm biopsy with array comparative genomic hybridization (aCGH) or next generation sequencing (NGS) for 24-chromosome aneuploidy screening and vitrified. Blastocysts were lysed immediately after thawing, and cDNA was synthesized and amplified, followed by RNA-Seq library preparation for deep Illumina-based sequencing. Sex and chromosomal aneuploidy were used as parameters for comparative analysis using a bioinformatics pipeline using a sensitivity of 0.05.
Main results and the role of chance: Principal Component analysis (PCA) revealed that normal embryos clustered in proximity to trisomies 21 and 18, while 15 and 22 clustered separately. This suggested that early gene expression may correlate with viability. PCA did not distinguish between male and female embryos. Differential gene expression was calculated using DESEQ2, an R package that estimates the variance-mean dependence and tests for differential expression using a model using the negative binomial distribution. A comparison of sex-specific gene expression showed that the top differentially expressed genes were on the sex chromosomes, including various Y-linked transcription factors, helicases, and ribosomal proteins, as well as a testis-specific regulatory transcript, and >200 X-chromosome genes. Trisomy 21 embryos were the closest to normal embryos, with only 3 genes on chromosome 21 expressed more highly in the trisomic embryos. In contrast, trisomy 22 embryos (non viable), had 684 differentially expressed genes, 32 of which on chromosome 22. Trisomy 18 embryos had only one highly expressed significant gene, and it is located on chromosome 18. Trisomy 15 embryos had 829 differentially expressed genes, of which 83 were in chromosome 15. Our results suggest that the less viable trisomies have bigger gene expression differences, even at this very early stage.
Limitations, reasons for caution: While the karyotypes were analyzed by stringent methods, embryos may have had elements of mosaicism or chromosomal structural abnormalities. The genes identified by RNA-Seq need to be validated using orthogonal methods.
Wider implications **of the findings:** We have expanded the knowledge of the transcriptome of the human pre-implantation embryo as they relate to aneuploidy and sex. This information can now be used to further our understanding of early embryonic development and stem cell biology, and to identify biomarkers for non-invasive preimplantation genomic screening.
Trial registration number: NA.

O-122 Selecting single blastocysts for transfer with next-generation sequencing significantly improves ongoing pregnancy rates for IVF patients: results from a randomized pilot study

Z. Yang[1], J. Lin[2], J. Zhang[3], K. Ieong[4], Y. Kuang[5], J. Liu[6]
[1]*ZytoGen, Clinical Research, Timonium, MD, USA*
[2]*Reproductive Fertility Center, ART, Irvine, CA, USA*
[3]*New Hope Fertility Center, ART, New York, NY, USA*
[4]*Ai Wei Fu Gynecology Center, OBGYN, Macau, China*
[5]*Shanghai Jiao Tong University School of Medicine, ART, Shanghai, China*
[6]*Beijing Jiaen Hospital, ART, Beijing, China*

Study question: Can next-generation sequencing (NGS) be used efficiently for selecting single blastocysts for transfer in patients undergoing IVF treatments?
Summary answer: Our data demonstrate that selection of single blastocysts for transfer with NGS screening results in significantly higher clinical and ongoing pregnancy rates for IVF patients.
What is known already: Early randomized clinical trials with FISH screening of a limited numbers of chromosomes resulted in disappointing pregnancy outcomes. Recent studies with aCGH screening of 24 chromosomes have resulted in a significant increase in ongoing pregnancy and implantation rates for IVF patients. More recent advances in next-generation sequencing have provided new methods for screening embryos from IVF cycles. However, there is still limited information about clinical application of NGS in selecting single blastocysts for transfer in a randomized study.
Study design, size, duration: A total of 204 IVF patients at mean age 31.2 ± 3.6 years were enrolled in this prospective randomized pilot study in our multiple IVF clinics from March 2014 to March 2015. The cohort patients met the inclusion criteria for enrollment in this study and singed consents for selecting single embryos for transfer in order to avoid multiple pregnancies.
Participants/materials, setting, methods: The enrolled patients were randomized into NGS (Group A, n = 103) and non-NGS control (Group B, n = 101). For both groups, all embryos were cultured to blastocyst stage. Blastocysts were vitrified after biopsy on day 5 (up to 10:00 p.m.). A single euploid blastocyst was selected for transfer to individual patients based on NGS results in Group A and morphological assessment alone in Group B.

Main results and the role of chance: This is the first randomized clinical study on the efficiency of NGS for selecting single embryo for transfer in IVF patients to avoid multiple pregnancies. Data analysis revealed that the demographic parameters of the enrolled patients in Group A and Group B were similar ($p > 0.05$). The fertilization and blastocyst rates were also comparable between the two groups ($p > 0.05$). Clinical pregnancy rate was significantly higher in Group A compared to group B (70.8 vs. 47.5%, respectively, $p < 0.05$). The observed ongoing pregnancy rate in Group A was also higher than that of Group B (69.9 vs. 45.5%, respectively, $p < 0.05$). There were no multiple pregnancies in both groups.
Limitations, reasons for caution: Although NGS brings distinct clinical benefits for many IVF patients, the approach is not for all patients, especially those with diminished ovarian reserve and with balanced translocations. Further randomized studies with a larger sample are needed to define the role of NGS for all age groups of IVF patients.
Wider implications of the findings: With the resulting high ongoing pregnancy rates following transfer of the screened embryos, NGS has demonstrated an efficient, robust high-throughput technology for selecting single blastocysts for transfer. With the enhanced capability of detecting segmental imbalances, NGS may detect aneuploidy and imbalance translocations at the same time.
Trial registration number: No applicable.

O-123 Fewer live-births with repeated single embryo transfer as compared to initial double embryo transfer; time to question the efficacy of embryo cryopreservation?

A.D. Smith[1], K. Tilling[2], D.A. Lawlor[2], S.M. Nelson[3]
[1]*University of West of England, Applied Maths, Bristol, UK*
[2]*University of Bristol, Medical Research Council Integrative Epidemiology Unit at the University of Bristol, Bristol, UK*
[3]*University of Glasgow, School of Medicine, Glasgow, Scotland, UK*

Study question: What is the cumulative live-birth rate, multiple birth rate and number of infants born comparing two single embryo transfers (SET) to one double transfer (DET)?
Summary answer: Cumulative live-birth rates were equivalent after initial eSET or DET in women <37 years but fewer infants were born to all women with repeated eSET.
What is known already: Observational data from national registries and four randomised controlled trials ($N = 42–661$) suggest equivalent live-birth rates of one or more live-births, when repeated SET is compared to DET, but with a markedly lower multiple pregnancy rate. That the RCTs reported fewer total infants born from a repeated eSET strategy as compared to the DET suggests that elective embryo cryopreservation may adversely impact on embryo viability.
Study design, size, duration: Prospective study of 135,950 UK women who received 199,204 IVF ovarian stimulation cycles and 249,602 embryo transfers between 2003 and 2010. Main exposure *in vitro* fertilization, with a cycle defined as an episode of ovarian stimulation and all subsequent separate fresh and frozen embryo transfers.
Participants/materials, setting, methods: We used data on all ART events occurring in the United Kingdom between 1 January 2003 and 31 December 2010, followed up until 30 June 2012, with linkage of cycles to individual women and birth outcomes. We excluded all women with fewer than two embryos available for transfer. Live-birth was defined as one or more infants were born alive after 24 weeks' gestation and surviving longer than 1 month from a singleton or multiple pregnancies.
Main results and the role of chance: The odds of a live-birth were similar between initial SET and initial DET in patients aged less than 37 years or using donor oocytes (adjusted odds ratio 0.98, 95% CI 0.96, 1.01), with a lower live-birth rate with SET in 37- to 39-year olds (adjusted OR 0.79, 95%CI 0.72, 0.86) and in >39-year-olds (adjusted OR 0.60, 95%CI 0.51, 0.69). Comparing the two strategies for the use of the first two embryos available demonstrated that initial transfer of a single embryo and then a single frozen embryo had an equivalent unadjusted live-birth rate (30.8% (6,548 live-births, 6,643 infants from 21,261 cycles) as observed after initial fresh transfer of two embryos (30.9% (55,012 live-births, 70,018 infants from 177,943 cycles)), with a substantially lower risk of multiple pregnancy and number of infants born. Thus the number of infant rates differed between the two approaches (31 vs. 39%) and if we anticipated both groups should have similar infant rates from their first two embryos there are 1,649 fewer infants in the eSET group.
Limitations, reasons for caution: Given the time frame analysed cleavage stage embryos transfers dominated and only 12.7% of SET replacements that did not result in a live birth were followed by a frozen SET replacement.
Wider implications of the findings: Although the overall live-birth rates were equivalent after repeated eSET or DET in young women, fewer infants were born in all women with use of eSET. This suggests that the efficacy of embryo freezing may have been overestimated.
Trial registration number: –

O-124 Use of fertility treatments among female survivors of early onset cancer – a Finnish register-based study

J. Melin[1], L. Madanat-Harjuoja[1], S. Heinävaara[1], N. Malila[1], M. Gissler[2], A. Tiitinen[3]
[1]*Finnish Cancer Registry, Institute for Statistical and Epidemiological Cancer Research, Finnish Cancer Registry, Helsinki, Finland*
[2]*National Institute for Health and Welfare, National Institute for Health and Welfare, Helsinki, Finland*
[3]*Helsinki University Hospital, Department of Obstetrics and Gynecology, Helsinki, Finland*

Study question: Do female early onset cancer survivors giving birth have more fertility treatments compared to female siblings without a history of cancer?
Summary answer: Female cancer survivors giving birth have a statistically increased risk for fertility treatments compared to female siblings.
What is known already: The relative probability of parenthood in former early onset cancer patients has been reported to be reduced by 50% compared to their siblings. Previous studies have shown that female cancer survivors have an increased risk of infertility, especially after radiotherapy and chemotherapy with alkylating agents. One previous study, based on self-reported outcomes, showed female survivors to have more need of fertility treatments than their siblings.
Study design, size, duration: In this retrospective register-based study, nationwide cancer and birth registries were merged to identify 1,974 post diagnosis births of female cancer survivors and 6,107 births of female siblings between January 2004 and December 2013. The birth registry provided information on possible fertility treatments initiating these pregnancies.
Participants/materials, setting, methods: Cancer survivors and siblings with either a pregnancy continuing for at least 22 weeks or a fetus weighting over 500 g were identified from the birth registry. Unconditional logistic regression models were used to estimate the risk for fertility treatments, which were subclassified into assisted reproductive technology (including *in vitro* fertilization, intracytoplasmic sperm injection and frozen embryo transfer), intrauterine insemination and ovulation induction. We adjusted for maternal age, year of delivery, parity and smoking.
Main results and the role of chance: We found a significantly increased risk for overall fertility treatments in survivors compared to siblings (OR 1.84, 95% CI 1.18–2.86, $P = 0.007$). The risk for fertility treatments was highest among survivors who received radiotherapy (OR 2.24, 95% CI 1.01–4.96, $P = 0.015$). Elapsed time from cancer treatment played a central role, increasing the risk for fertility treatments over time, reaching its peak (OR 2.29, 95% CI 1.17–4.52, $P = 0.003$) 11–34 years from cancer treatments. When it came to age at cancer diagnosis, survivors diagnosed as adults (age 25–34 years) had the highest risk for fertility treatments compared to siblings aged 25 years or older when giving birth (OR 2.31, 95% CI 1.01–5.32, $P = 0.016$).
Limitations, reasons for caution: This study measures risk of fertility treatments among survivors and siblings found in the birth register, leaving out treatments not leading to a live- or stillbirth. Not all fertility treatments are documented in the Finnish birth register. The true incidence of fertility treatments may be higher than in our study.
Wider implications of the findings: Our study supports findings showing that cancer survivors have an increased risk for infertility, with radiotherapy being

the biggest risk when it comes to cancer treatments. Time elapsed from cancer treatment increased the risk for fertility treatments compared to siblings indicating that cancer therapies might lead to diminished ovarian reserves.
Trial registration number: National Institute for Health and Welfare (Dnro THL/1/5.05.00/2014).

O-125 Age at menarche, age at menopause, reproductive lifespan and risk of cardiovascular disease (CVD): a cohort study of 256,284 women

S. Iliodromiti[1], D. Lawlor[2], J. Pell[3], N. Sattar[4], A. Fraser[2], S. Nelson[1]
[1]*School of Medicine, University of Glasgow, Obstetrics and Gynaecology, Glasgow, UK*
[2]*University of Bristol, MRC Integrative Epidemiology Unit, Bristol, UK*
[3]*University of Glasgow, Institute of Health and Wellbeing, Glasgow, UK*
[4]*University of Glasgow, Institute of Cardiovascular and Medical Sciences, Glasgow, UK*

Study question: Is a longer reproductive period, an indicator of longer endogenous oestrogen exposure, associated with lower incidence of cardiovascular disease (CVD)?
Summary answer: Longer reproductive lifespan is associated with lower incidence of CVD events (fatal and non fatal).
What is known already: Previous studies suggest that endogenous oestrogen has an atheroprotective effect. Early and late menarche and early menopause have been linked with cardiovascular disease, without being clear whether they contribute to greater incidence of new events. A longer reproductive lifespan (defined as age at menopause minus age at menarche) has been found to be associated with a lower estimated 10-year risk of CVD, but whether this translates into a lower incidence of CVD events (fatal and non-fatal) is not known.
Study design, size, duration: The UK Biobank recruited participants aging 40–70 years between 2006 and 2010. 256,284 of White European women were followed up for an average of 5.07 (IQR: 4.38, 5.74) years. 127,949 had gone through natural menopause at baseline, of which 8,686 and 8,768 had been diagnosed with CVD and diabetes respectively.
Participants/materials, setting, methods: Analysis was restricted to those without CVD and diabetes at baseline and with complete data on exposures, outcomes and covariables. Cox regression with adjustment for confounders (age, body mass index, physical activity, smoking, social deprivation index) was used to estimate hazard ratio (HR) of CVD events (fatal and non fatal). Age at menopause and age at menarche were categorical variables, duration of reproductive lifespan was a continuous variable centered for its mean value.
Main results and the role of chance: During 1,252,915 person-years of follow up, 672 women without CVD at baseline developed or died from CVD. The adjusted HR for early menarche (<11 years) or late menarche (>15 years) for new CVD events were 1.14 (95% CI: 0.78, 1.66) and 1.31 (95% CI: 0.93, 1.84) referent to average menarche at the age of 13 years. The adjusted HR for early menopause (<40 years) for new CVD events was 1.74 (95% CI: 1.00, 3.06) referent to average menopause at the age of 50–51 years. The adjusted HR per 1 year longer reproductive period (referent to average duration of 36.7 ± 5.4 years) was 0.98 (95% CI: 0.96, 0.99).
Limitations, reasons for caution: Age of menarche and menopause are self-recorded. 49.9% of the women were still menstruating at baseline and the follow-up period is relatively short.
Wider implications of the findings: Our findings support the hypothesis that a longer reproductive lifespan is associated with reduced risk of incident CVD in a contemporary population of middle aged white women who have experienced a natural menopause.
Trial registration number: N/A.

O-126 Do infertile immigrants have different fertility quality of life and socio-demographic parameters when assisted reproductive technologies (ART) is funded for all?

J. Takefman[1], J. Hasson[1], T. Shavit[1], T. Shaulov[1], T. Tulandi[1]
[1]*MUHC Reproductive Centre, Obstetrics and Gynecology, Montreal, QC, Canada*

Study question: Is fertility quality of life and socio-demographic characteristics different between infertile immigrants and infertile Canadian citizens attending a governmental funded fertility program?
Summary answer: Despite equal funding of ART, immigrants have lower fertility quality of life implying that removing cost does not fully remove the challenges these patients face
What is known already: Governmental funding for ART, including *in vitro* fertilization (IVF), makes it possible for all infertility patients to access expensive treatments regardless of socio-economic status and provides broader access to a more diverse patient population. Nonetheless, some studies have shown that even when funding is available, cultural and ethnic barriers to fertility treatment persist. Infertile immigrants may face additional stresses due to lack of awareness of available services, language barriers, poor social support and significant cross-cultural differences in views concerning infertility. It is of interest to assess fertility quality of life (QoL) in this population when affordability is removed from the equation.
Study design, size, duration: Questionnaires (English or French) were distributed to patients attending a single academic reproductive center between February and August 2015. At this time governmental funding was provided to all residents to cover 3 fresh IVF cycles and all available frozen embryo transfers, as single embryo transfer was obligatory. All patients, males and females, who attended the clinic, were invited to complete the questionnaires anonymously. Questionnaires included socio-demographic items and the Fertility Quality of Life (FertiQoL) questionnaire.
Participants/materials, setting, methods: Overall, 1,020 patients completed the questionnaires, 601 women and 419 partners. Seven hundred and fifty-two (73.7%) were Canadian citizens and 215 (21%) were resident immigrants or refugees. Mean duration of years in Canada in the immigrant group was 4.15 ± 2.9 years. Comparison between study groups was performed by *t*-test and Chi-square test where applicable.
Main results and the role of chance: Canadians were slightly older (36.4 ± 5.9 vs. 35.1 ± 4.8, $p = 0.002$) with higher rates of secondary infertility compared to immigrant patients (34 vs. 21.8%, $p = 0.001$). Previous IVF attempts and Infertility duration were similar (1.94 vs. 1.74 previous attempts, $p = 0.1$; 2.51 vs. 2.56 years of infertility, $p = 0.6$). While immigrant patients were more likely than their Canadian counterparts to have university or graduate degrees (74.8 vs. 63.5%, $p = 0.004$), they were also more likely to be unemployed and have lower annual household incomes (35.8 vs. 13% unemployed, $p < 0.05$; 62.8 vs. 32.9% income <65,000$, $p < 0.05$,). Immigrants reported poorer QoL than their counterparts: they experienced their infertility with distressing emotions, negative thinking, more physical symptomatology, less social support and experienced clinic environment as more problematic. This is reflected by their lower FertiQoL scores in the corresponding domains: emotional (57.9 vs. 62.2, $p = 0.02$), mind/body (63 vs. 67.4, $p = 0.02$), social (67.3 vs. 71, $p = 0.03$) and environment (67.4 vs. 70.7, $p = 0.03$). Total Core and treatment scores were also lower for immigrants (64.7 vs. 68.1, $p = 0.02$; 65.6 vs. 69.2 $p < 0.001$, respectively), meaning poorer fertility QoL. Scores in the relational and tolerability domains were also higher for Canadian although differences were not statistically significant (70.6 vs. 72.1, $p = 0.3$; 64 vs. 67.1, $p = 0.1$, respectively).
Limitations, reasons for caution: Not all patients agreed to participate in the survey and fill out the questionnaires. Some immigrant patients may have declined participation due to lack of knowledge in both English and French.
Wider implications of the findings: This is the first study indicating cost is not the only factor affecting how patients experience infertility. Ethnic and cultural factors may affect how immigrants cope with infertility. This population may be at greater risk for depression and anxiety (co-morbidity with QoL) and should be flagged for possible psychosocial intervention
Trial registration number: None.

O-127 Predicting the chances of having a baby after one or more complete cycles of *in vitro* fertilisation: analysis of linked cycle data from 113,873 women

D. McLernon[1], E. te Velde[2], E. Steyerberg[3], A. Lee[1], S. Bhattacharya[1]
[1]*University of Aberdeen, Institute of Applied Health Sciences, Aberdeen, UK*
[2]*Utrecht University and Erasmus University, Department of Public Health, Utrecht and Rotterdam, Netherlands*
[3]*Erasmus Medical Center, Department of Public Health, Rotterdam, Netherlands*

Study question: What are the predicted cumulative chances of a live birth following multiple complete cycles of *in vitro* fertilisation (IVF) for couples with different characteristics?

Summary answer: The chance of a live birth for a 30-year-old woman with 2 years unexplained infertility is 80.1% after three IVF cycles (93.3% after six).
What is known already: The predicted chance of a live birth following IVF has traditionally been reported after a single fresh cycle. However, many couples are unsuccessful after their first embryo transfer and wish to know their chances of having a baby after multiple complete cycles – each involving the transfer of fresh as well as frozen-thawed embryos. The ability to estimate the cumulative probability of live birth per woman based on pre-and post-treatment characteristics would enable more informed decisions at different time points tailored to the couple's individual situation.
Study design, size, duration: In this retrospective cohort study, linked cycle data of 113,873 women who had their first IVF treatment attempt in the UK between January 1999 and September 2008 were included. Every complete cycle, defined as all fresh and frozen embryo transfers resulting from one episode of ovarian stimulation, were linked to individual women. All complete cycles were included up to the end of treatment exposure (September 2009) or first live birth occurrence, whichever came first.
Participants/materials, setting, methods: A database containing all UK IVF treatments was obtained from the Human Fertilisation and Embryology Authority (HFEA). Using a logistic regression model, the predicted probability of live birth over six complete cycles of IVF was calculated pre-treatment using couple characteristics and after the first fresh embryo transfer (post-treatment) using both couple and treatment characteristics. The model was assessed for predictive ability using the C-statistic to measure discrimination and calibration plots.
Main results and the role of chance: After exclusions, 113,873 women underwent 184,269 complete cycles. A total of 33,154 (29.1%) women had a live birth in the first complete cycle. In order of importance, the key predictors in the pre-treatment model were female age [odds ratio 0.60, 95% confidence interval (0.58–0.62), (change from 31 to 37 based on interquartile)] and duration of infertility (years) [0.97 (0.97–0.97)]. In the post-treatment model they were number of eggs collected [1.32 (1.29–1.35), (change from 5 to 13 eggs)], cryopreservation of embryos (yes vs. no) [1.95 (1.90–2.00)], female age [0.64 (0.62–0.66)] and stage of embryos transferred [e.g., double blastocyst vs. double cleavage, 1.83 (1.71–1.96)]. The *C*-statistics were 0.635 and 0.750 (cycle 1) for pre- and post-treatment models respectively. Calibration was good. In a couple with 2 years of primary unexplained infertility embarking on IVF, where the female partner is 30 years old, the chance of a baby after three complete cycles is 80.1%. At the point of transfer of a blastocyst in the first fresh cycle in which 15 eggs were collected and any spare embryos cryopreserved, the chance of a live birth updates to 95.8% after three complete cycles. In a woman aged 40 these chances are 39.9 and 74.3% respectively.
Limitations, reasons for caution: Patients who discontinued treatment were censored in the analysis meaning that their future chances of a live birth were assumed to be similar to those who continued which may lead to over-optimistic estimates of predictions. The model has yet to be externally validated in another national IVF registry.
Wider implications of the findings: These clinical prediction models can be used to counsel couples who want to know their overall chances of having a baby over the complete IVF journey. The results may be used by policy-makers to determine the provision of an optimum number of IVF cycles per couple based on their characteristics.
Trial registration number: N/A.

O-128 Poor financial recovery from out-of-pocket payment for assisted reproductive technology (ART) in the public-academic health sector of South Africa

S.J. Dyer[1], L. Vinoos[2], J.E. Ataguba[3]
[1]*Groote Schuur Hospital, Reproductive Medicine Unit, Department of Obstetrics and Gynaecology, Cape Town, South Africa*
[2]*Groote Schuur Hospital, Obstetrics and Gynaecology, Cape Town, South Africa*
[3]*University of Cape Town, Health Economics Unit, Faculty of Health Sciences, Cape Town, South Africa*

Study question: How do households (HHs) recover financially from out-of-pocket payment (OOP) for assisted reproductive technology (ART)?
Summary answer: After a minimum of 2.5 years of follow up, the large majority of HHs (86.3%) had not fully recovered financially.
What is known already: OOP for health is wide spread in developing countries. It is the most inequitable way of financing health care. A previous study involving 135 couples undergoing ART with conventional ovarian stimulation at a level 3 referral institution in the public-academic health sector of South Africa documented that OPP created catastrophic expenditure in 20% of participating HHs. HHs engaged in a range of financial coping strategies, often concomitantly, including accessing savings, borrowing money, selling assets, reducing household expenditure and undertaking additional work.
Study design, size, duration: An observational follow up study was conducted in order to assess the financial recovery of HHs from OOP for ART. Seventy three participants were interviewed 2.5 years or more after the original OOP. Data collection occurred between November 2014 and June 2015
Participants/materials, setting, methods: All contactable informants from the original study were invited to participate. A questionnaire capturing information on socioeconomic status, new financial demands, and financial recovery from the previous OOP for ART was administered. Most interviews were conducted telephonically. Markers of lack of financial recovery included outstanding loans, non-recovery of sold assets or savings, ongoing performance of additional work to supplement income and ongoing reduction of HH expenditure.
Main results and the role of chance: The follow up participation rate was 51%. Only 10 of the 73 HHs (13.7%) reported full recovery, defined as all loans repaid, assets/savings regained and no ongoing reduction in HHs expenditure or performance of additional work. HHs in the highest socioeconomic tertile showed better full or partial recovery when compared to those in the lowest. Forty HHs reported new financial demands because of a baby or other HH events, however no association was found between this and lack of financial recovery. Specific coping strategies utilised and lack of financial recovery were as follows: (1) 35 HHs had taken out loans and 14 (40%) of these were still in debt; (2) 68 HHs had accessed savings which 45 (66.2%) had not regained; (3) 13 HHs had sold assets which 10 had failed to re-purchase (77%); (4) 39 HHs took on additional work which 20 (51.3%) were still performing; (5) 68 HHs had reduced HH expenditure and 51 (75%) continued to do so. The role of chance is minimal.
Limitations, reasons for caution: The number of participants was small and results were dependant on informant recall. Associations shown cannot be interpreted as causality.
Wider implications of the findings: This is the first study assessing financial recovery after OOP for ART. While the results apply to the study group and setting, it is possible that absence of financial risk protection for ART is associated with poor financial recovery from OOP in other settings, especially in low income countries.
Trial registration number: Not applicable.

SESSION 35: AMH: THE PLOT THICKENS

Tuesday 05 July 2016 **Room 101** **10:00–11:30**

O-129 The bone morphogenetic protein 15 up-regulates the anti-Müllerian hormone receptor expression in granulosa cells

A. Pierre[1], A. Estienne[2], C. Racine[1], J.Y. Picard[1], R. Fanchin[1], B. Lahoz[3], J.L. Alabart[3], J. Folch[3], S. Fabre[4], D. Monniaux[2], N. di Clemente[1]
[1]*Univ Paris 7, Inserm U1133, CNRS UMR8251, Paris, France*
[2]*INRA, CNRS UMR85, UMR7247, Univ Tours, IFCE, Nouzilly, France*
[3]*Centro de Investigación y Tecnología Agroalimentaria de Aragón, Unidad de Producción y Sanidad Animal, Zaragoza, Spain*
[4]*INRA, UMR1388, GenPhySE, Univ Toulouse, Castanet, Tolosan, France*

Study question: The study aimed to investigate the regulation of the anti-Müllerian hormone (AMH) receptor gene (*AMHR2)* expression by bone morphogenetic proteins (BMPs) in granulosa cells (GCs).
Summary answer: BMP15 stimulates *AMHR2* expression in GCs from different maturational stages follicles both *in vitro* and *in vivo*.
What is known already: Anti-Müllerian hormone (AMH) is produced by the GCs of growing follicles and inhibits follicular development. BMPs are important regulators of folliculogenesis. Ewes with loss of function mutations in the

oocyte-derived *BMP15* or *GDF9* genes are sterile when the mutation is present at the homozygous stage, but heterozygote ewes are unexpectedly hyperprolific. Recently, several BMPs including BMP15 and the granulosa/theca-derived BMP4 have been shown to enhance *AMH* expression in GCs, but their effect on *AMHR2* expression is unknown.

Study design, size, duration: The effects of BMP15, GDF9 and BMP4 on *AMHR2* expression were studied in human GCs (hGCs) from women undergoing assisted reproduction technology procedures and in ovine GCs (oGCs) from small antral follicles. The effects of BMPs on human *AMHR2* promoter activity were analyzed in oGCs transfected with a luciferase reporter construct. The *in vivo* effect of BMP15 on *AMHR2* expression in GCs was investigated on ewes with genetically impaired BMP15 biological activity.

Participants/materials, setting, methods: mRNA accumulation of *AMHR2*, *AMH* and other BMP target genes was quantified by real-time RT-PCR. The activity of the human *AMHR2* and *AMH* promoter reporter constructs (2,252 and 423 base pairs respectively) was quantified by the measurement of their luciferase activity.

Main results and the role of chance: BMP15 and BMP4 significantly enhanced *AMHR2* mRNA levels in hGCs (1.8-fold, $p < 0.001$ and 2-fold, $p < 0.001$, respectively) and in oGCs (1.4-fold increase, $p < 0.05$ and 1.5-fold increase, $p < 0.001$, respectively) whereas GDF9 acting alone or in combination with BMP15 had no effect. In oGCs, BMP15 and BMP4 enhanced also *AMH* mRNA levels, and GDF9 increased the stimulating effect of BMP15. In keeping with these results, BMP15 and BMP4, but not GDF9, enhanced *AMHR2* promoter activity in oGCs (1.2-fold increase, $p < 0.01$ and 1.3-fold increase $p < 0.05$, respectively), whereas GDF9 increased the stimulating effect of BMP15 on *AMH* promoter activity. Moreover, oCGs from both Lacaune and Rasa Aragonesa ewes, carrying loss-of-function mutations in *BMP15*, had reduced *AMHR2* mRNA levels compared to wild-type animals (6.6-fold decrease, $p < 0.01$ and 3.4-fold decrease, $p < 0.001$, respectively). Interestingly, these mutations had no effect on *AMH* expression. Altogether, these results suggest that the mechanisms of action of BMP15 on *AMHR2* and *AMH* expression are different.

Limitations, reasons for caution: The hCGs were luteinized, but they still express both *AMH* and *AMHR2*. Transfection studies were only performed in oCGs because hCGs are very difficult to transfect.

Wider implications of the findings: Altogether, these results suggest that BMP15 stimulate *AMHR2* expression in GCs of different maturational stages, thereby enhancing AMH actions in the follicular microenvironment. Hyperprolificity in ewes could thus be due to a decrease in both BMP and AMH inhibitory actions at the FSH-dependent phase of terminal follicular development.

Trial registration number: 0

O-130 Comparable inter-laboratory performance of two automated platforms (Roche® and Beckman Coulter®) for Anti-Müllerian Hormone (AMH) evaluation permits greater clinical confidence when assessing functional ovarian reserve

C. Fairbairn[1], M. Gaudoin[1], R. Fleming[1]
[1]*GCRM, Clinical, Glasgow, UK*

Study question: To use multi-centre objective data to compare the performance characteristics of the automated AMH assays from Roche® (Elecsys system) and Beckman Coulter® (Access2 system).

Summary answer: Absolute concentrations showed strong agreement and correlation ($R^2 = 0.971$) between the systems. Inter-laboratory variance was identical, and low, for both assays (less than 5.5%).

What is known already: AMH can be used to predict ovarian responses to stimulation, allowing individualization of stimulation protocols, FSH doses, and prediction of IVF outcome. However, the original manual enzyme-linked immunosorbent assays (ELISA) were prone to methodological errors due to numerous factors, not least the requirement for skilled operators in many laboratories where (semi)-automation was not performed. Consequently, high inter-laboratory variability was observed and confidence in the assay was adversely affected. Two automated assays are now available which use the same antibodies, but deploy different technologies and calibration. The comparability of these assays needs to be established for clinical use.

Study design, size, duration: Objective multicentre comparative cohort study. The reported AMH results from 40 serum samples (distributed in 8 batches) were sent to contributing laboratories running either the Access2 or the Elecsys system from April to November 2015 (inclusive) as part of the UK national quality assurance (NEQAS) accreditation scheme, and were analysed by the NEQAS team prior to reporting by one of the contributing laboratories.

Participants/materials, setting, methods: The absolute concentrations and the inter-laboratory variance were assessed and compared for sample AMH values from the 40 samples analysed in eight batches for the two assay platforms. A total of 1,279 individual results were reported and assessed per assay.

Main results and the role of chance: The reported median concentrations ranged from 0.9 to 30 pmol/L, and there was a close agreement between the two assay methods. The absolute concentrations were determined as: Elecsys = 0.973 × Access2 + 0.69. The Pearson's correlation evaluation was high (R^2 value = 0.971) which demonstrated a high degree of agreement and precision between the two automated assays.

The variance between laboratories was low throughout the series (<5.5% for both assay methods) and there was no difference between them.

Limitations, reasons for caution: These objective multicenter data are strong evidence that the two automated assay systems report very similar absolute values and that although they use different technologies and calibration, the results are equally reliable and, importantly, reproducible in different laboratories. They do not identify how results relate to other assays.

Wider implications of the findings: Both the Roche® (Elecsys) and Beckman Coulter® (Access2) platforms give consistent, reproducible and comparable AMH results. This should minimize the inter- and intra-laboratory variations previously identified, and result in a return of clinicians' confidence in the method of assessing ovarian reserve and assigning treatment protocols based on these results.

Trial registration number: N/A.

O-131 Unraveling the long-term decline of anti-Müllerian hormone

A. de Kat[1], Y. van der Schouw[2], G.C. Herber-Gast[3], R. Eijkemans[2], M. Verschuren[3], F. Broekmans[1]
[1]*University Medical Centre Utrecht, Gynecology and Reproductive Medicine, Utrecht, Netherlands*
[2]*University Medical Centre Utrecht, Julius Center for Health Sciences and Primary Care, Utrecht, Netherlands*
[3]*National Institute for Public Health and the Environment, Centre for Nutrition, Prevention and Health Services, Bilthoven, Netherlands*

Study question: Are long-term serial anti-Müllerian hormone (AMH) measurements consistent in their decline pattern between and within individuals?

Summary answer: In a longitudinal cohort of 3,326 women spanning 20 years, AMH declined in similar fashion between individuals and age-dependent levels remained stable within individuals.

What is known already: AMH is a marker of ovarian reserve and is suggested to aid in the prediction of time to menopause. Although AMH levels are widely known to decrease with age, there is still a lack of information regarding longitudinal AMH decline over a longer period of time.

Study design, size, duration: Our study population consisted of women enrolled in the longitudinal population-based Doetinchem Cohort Study. We included 3,326 women who completed at least one of five consecutive follow-up rounds between 1987 and 2010, leading to a maximum follow-up time of 20 years. At each follow-up round, data collection included a questionnaire, anthropometric measurements and blood withdrawal.

Participants/materials, setting, methods: AMH was measured in 12,929 serum samples with the picoAMH assay (AnshLabs). A latent class analysis was used to determine whether there were distinct decline patterns between individuals. The correlation of age-dependent AMH levels within individuals was studied using a linear mixed model with smoothing splines for age. The variation of the distance of each measurement to the group average at that age was compared to the between-individual variation, resulting in an intra-class correlation coefficient.

Main results and the role of chance: At baseline, mean age was 39 ± 10 years, median AMH [IQR] was 1.00 [0.04–3.07] ng/mL and 86% of the women was premenopausal. The mean number of follow-up rounds per woman was 3.9. Latent class analysis revealed that women could be grouped into one of two distinct decline trajectories with a similar and parallel shape. In both groups, AMH levels decreased slowly until the age of 40 and quickly thereafter, reaching the detection limit (0.002 ng/mL) a few years before and after the age of 50, respectively. After adjustment for confounders, the distances of serial AMH

measurements to the age-specific group average were highly correlated within individuals, with an intra-class correlation coefficient of 0.87.
Limitations, reasons for caution: Absolute measured AMH levels may differ per type of AMH assay, but this is not expected to affect decline trajectories measured with a single assay.
Wider implications of the findings: This is the first large-scale study to measure longitudinal AMH decline over a long period of time. These data will provide further insight into the value of AMH in a clinical setting.
Trial registration number: N/A.

O-132 Anti-Müllerian hormone levels and features of polycystic ovary syndrome in adolescence

M. Caanen[1], H. Peters[1], M. van Hooff[2], C. Lambalk[1]
[1]*VU University Medical Center, Division of Reproductive Medicine, Department of Obstetrics and Gynaecology, Amsterdam, Netherlands*
[2]*Franciscus Hospital, Obstetrics and Gynaecology, Rotterdam, Netherlands*

Study question: Can serum AMH levels at age 15 predict features of polycystic ovary in early adulthood (at 18 years)?
Summary answer: AMH is related to features of PCOS in adolescence.
What is known already: Irregular menstrual cycles during puberty, especially oligo- or secondary amenorrhoea, have been considered to be physiologic. However, frequently oligo- or secondary amenorrhoea is not transient. A considerable part of oligomenorrhoeic adolescents have clinical, endocrine and ultrasound signs of PCOS. Defining appropriate diagnostic criteria for diagnosis of PCOS in adolescence is a relevant challenge. AMH levels are elevated in adult women with PCOS, and therefore increasingly used as a diagnostic feature. The use of adolescent serum AMH levels as reliable predictor of persistent oligo- or secondary amenorrhoea, as part of PCOS, can be of great value in (young) adult life.
Study design, size, duration: Subjects are part of a large, prospective, cross-sectional population-based, observational study that aimed to collect comprehensive data on the endocrinology of menstrual cycle disorders in a general population performed between 1990 and 1993 (van Hooff[4] M, Hum Reprod, 2004). We identified 272 adolescents who underwent blood sampling. In 160 individuals, ultrasound data of the ovaries were also available.
Participants/materials, setting, methods: Participants were categorized at age 15 by menstrual cycle pattern: regular cycle (n = 112), irregular cycle (n = 86), oligomenorrhoea & secondary amenorrhoea (n = 61), primary amenorrhoea (n = 4) and polymenorrhoea (n = 9). The relation between AMH (levels and menstrual cycle pattern, physical examination, hormonal measurements and ultrasound pattern of the ovaries was determined. The predictive value of AMH (age 15) for oligo-amenorrhoea at age 18 was made by a ROC-analysis.
Main results and the role of chance: The mean (±SD) AMH levels (at age 15) in the regular, irregular and oligo-amenorrhoeic group were 3.2 (2.3) µg/L, 3.9 (2.6) µg/L and 5.1 (3.6) µg/L, respectively. The AMH level was significantly higher in the oligo- or secondary amenorrhoea group compared to the regular cycle group ($p < 0.01$).
AMH was positively correlated with signs of hirsutism ($r = 0.20$, $p < 0.01$). AMH was positively correlated with the number of the follicles in the ovaries determined by ultrasound ($r = 0.28$, $p < 0.05$): in both ovaries <5 follicles: AMH 3.2 µg/L; one ovary 5–9 follicles, one ovary <5 follicles: AMH 3.6 µg/L; both ovaries 5–9 follicles: AMH 4.1 µg/L; both ovaries ≥10 follicles: AMH 6.3 µg/L ($p < 0.01$).

An AMH cut-off level of 6.01 µg/L at the age of 15.3 year had a sensitivity of 48.6% and specificity of 85.2% for predicting oligo- or secondary amenorrhoea after 3 years. An AMH cut-off level of 7.99 µg/L at the age of 15.3 year had a sensitivity of 29.7% and specificity of 94.4% to predict oligo- or secondary amenorrhoea after 3 years.
Limitations, reasons for caution: Limitations of our study are that the serum samples were taken in the nineties, and that not all participants could be followed-up after 3 years. The predictive value of AMH with regard to PCOS at older age needs to be established.
Wider implications of the findings: This study contributes to the improvement of prediction on developing PCOS in adolescence and the use of AMH in this diagnostic challenge. Improvement of prediction of PCOS can generate opportunities for starting early secondary prevention and intervention of metabolic and cardiovascular health aspects with regard to PCOS.
Trial registration number: None.

O-133 Phenotypic variation in anti-Mullerian hormone (AMH) production per follicle in women with polycystic ovary syndrome (PCOS) and isolated polycystic ovarian morphology (PCOM)

P. Bhide[1], A. Kulkarni[2], M. Dilgil[2], P. Dhir[3], A. Shah[2], A. Gudi[2], R. Homburg[2]
[1]*London, UK*
[2]*Homerton University Hospital NHS Foundation Trust, Fertility, London, UK*
[3]*Homerton University Hospital NHS Foundation Trust, Biochemistry, London, UK*

Study question: Is there phenotypic variation in the anti-Mullerian hormone production per follicle in polycystic ovary syndrome and what are the parameters associated with this variation?
Summary answer: Anovulatory phenotypes of PCOS have a higher per follicle AMH production as compared to ovulatory phenotypes and PCOM due to intrinsic granulosa cell dysfunction
What is known already: Women with polycystic ovary syndrome (PCOS) have higher levels of anti-Mullerian hormone (AMH) than non-PCOS women. This is due to higher numbers of antral follicles and a greater production of AMH per follicle. AMH plays an inhibitory role in folliculogenesis, reducing the sensitivity of growing follicles to FSH. AMH may have a key role in the pathogenesis of anovulation in PCOS.
Study design, size, duration: The study was a prospective cross-sectional study with 218 participants undergoing evaluation for subfertility from January to December 2015. The study included women with PCOS who met the Rotterdam criteria (n = 156) and women with isolated PCOM (n = 62). Women with PCOS were classified into four phenotypes A, B, C and D based on the inclusion criteria of oligo-anovulation (OA), hyperandrogenism (HA) and polycystic ovarian morphology (PCOM).
Participants/materials, setting, methods: Participants undergoing evaluation for subfertility at the fertility clinic were screened for eligibility. Routinely collected data for age, BMI, waist-hip ratio, modified Ferriman–Gallway score, FSH, LH, testosterone, AMH, AFC and insulin were collated. A ratio of serum AMH to AFC was used as a surrogate marker for per-follicle AMH production. The ratio and above parameters were compared in the four phenotypes of PCOS and isolated PCOM. Data was analysed using the IBM SPSS software, v22.0.
Main results and the role of chance: The median AMH/AFC ratios in the groups were: Group A (OA + HA + PCOM) = 1.44, Group B (OA + HA) = 0.97, Group C (HA + PCOM) = 1.10, Group D (OA + PCOM) = 1.70 and PCOM = 1.20. A significant difference was seen in the AMH/AFC ratio amongst the different phenotypes of PCOS and PCOM ($F = 4.457$, $p = 0.005$). Phenotype B had very small numbers and was excluded from analysis. PCOS oligo-anovulatory phenotypes (group A and D) had a significantly higher per follicle AMH than PCOM ($p = 0.048$ and $p = 0.028$ respectively) and a borderline significant difference with phenotype C ($p = 0.057$). There was no significant difference between the ovulatory PCOS phenotype C and PCOM ($p = 0.999$). (One-way analysis of variance, post-hoc Tukey).

Age, BMI, waist-hip ratio, modified Ferriman-Gallway score, FSH, LH, testosterone and insulin were not significantly different in the four PCOS phenotypes compared. Only testosterone was significantly higher in phenotype group C as per definition as compared to PCOM ($p = 0.017$).

The correlation between testosterone and the AMH/AFC ratio was however found to be non-significant ($r = 0.012$, $p = 0.30$).
Limitations, reasons for caution: The operator variability in AFC measurement and the contribution of follicles less than 2 mm to the AMH may affect the AMH/AFC ratio. The study included women attending the fertility clinic and did not include women with extremes of BMI. The results are hence relevant only to the above population.
Wider implications of the findings: A higher per-follicle AMH production in anovulatory phenotypes of PCOS indicates a key role of AMH in the pathophysiology of anovulation associated with AMH. Lack of correlation of testosterone with AMH/AFC ratio and the highest ratio in phenotype-C of PCOS point to an intrinsic granulosa cell dysfunction leading to anovulation.
Trial registration number: Trial registration not required as observational study.
Local R&D approvals in place.
No ethical approval needed.

O-134 Irrespective of age, serum anti-Müllerian hormone (AMH) levels are related to miscarriage rates in IVF-ET thereby supporting the hypothesis that AMH is a qualitative biomarker

B. Tarasconi[1], T. Tadros[1], E. Adda-Herzog[1], S. Belloc[1], N. Achour Frydman[1], R. Fanchin[1]
[1]*Hospital A. Béclère, Department of Reproductive Medicine, Clamart Cedex, France*

Study question: Are serum AMH levels independently related to miscarriage rates after IVF-ET?
Summary answer: Irrespective of age, patients with low AMH levels display higher miscarriage rates after IVF-ET. This strongly suggests that AMH is a biomarker of oocyte quality.
What is known already: Whereas, by some authors, AMH has been recognized as an age-independent marker of pregnancy rates after IVF-ET, it remains unclear whether this relationship would be a mere result of increased oocyte yield or a consequence of improved oocyte competence. A methodological strategy to gain insights into this issue would be to focus not only on pregnancy rates but also on the analysis of miscarriage rates in age-controlled patients showing different AMH levels. Indeed, miscarriages often result from an abnormal chromosomal status of the embryo, thereby being an additional marker of oocyte-embryo health.
Study design, size, duration: We studied 2,493 non-PCOS patients (AMH levels <7.10 ng/mL) who have had a reference, centralized serum AMH determination within 12 months before IVF-ET. Of them, 2,052 were sorted into two opposite age groups: 34 years (Young group; $n = 1,114$) and 37 years (Old group; $n = 938$). In addition, we determined three AMH groups according to extreme quartile values: low AMH (0.10–1.60 ng/mL; $n = 475$), intermediate AMH (1.61–3.99 ng/mL; $n = 1,046$), and high AMH (4.00–7.10 ng/mL; $n = 531$).
Participants/materials, setting, methods: All patients received conventional controlled ovarian stimulation (COH) for IVF-ET. In the extreme age population (Young and Old groups; $n = 2,052$), the relationship between AMH groups and IVF-ET outcome (clinical pregnancy, miscarriage, and live birth rates) was assessed by Chi-square test. The Kruskall–Wallis test was used when appropriate. In whole population ($n = 2,493$), binary logistic regression was conducted to verify whether predictability of AMH was independent of age.
Main results and the role of chance: As expected, AMH was associated to the intensity of the ovarian response to COH in both age groups. In the Young group, we observed a stepwise increase in clinical pregnancy (26.2, 43.2, and 47.2%; $P < 0.001$) and live birth (19.1, 34.6, and 40.2%; $P < 0.001$) rates across the low, intermediate, and high AMH groups, respectively. Similar figures were observed in the Old group: 21.6, 32.4, and 36.7% ($P < 0.001$) and 14.4, 22.1, and 28.5% ($P < 0.001$). Further, miscarriage rates decreased stepwisely from the low, intermediate, high AMH groups, respectively, in the Young group (22.9, 16.8, and 11.0%) and in the Old group (31.1, 26.2, and 20.7%). Differences of miscarriage rates reached statistical signification only between the low and the high AMH groups in the Young group ($P < 0.05$), probably due to limitations of sample size. Yet, binary logistic regression run over the whole population confirmed the association between serum AMH and miscarriage rates (together with clinical pregnancy and live birth rates) and this independently of age.
Limitations, reasons for caution: Unfortunately, preimplantation aneuploidy screening of embryo in low, intermediate, and high AMH patients was not available in the present investigation. Larger series of clinical pregnancies in older women are needed to confirm the relationship of AMH and miscarriage rates in this subset of patients.
Wider implications of the findings: The independent relationship between AMH and pregnancy outcome suggests that AMH is not only a quantitative but also a qualitative biomarker of oocyte-embryo competence. Young and old patients should be aware of the added value of this marker over age itself for reaching a live birth after IVF-ET.
Trial registration number: Not Applicable.

Abstract text
Study question: In 2012, what was: global utilization of ART as measured by number and type of cycles; effectiveness as measured by clinical pregnancy, miscarriage and live birth rates; safety as measured by multiple births and other complications; and the status of extensive additions and revisions to the ICMART/WHO glossary?
Summary answer: Globally, ART utilization continues to increase but with wide variation in utilization, effectiveness and safety. Participation in data collection is gradually improving. The greatly expanded ICMART/WHO glossary is essential for standardization of concepts, processes, procedures, clinical events and research that is essential for precise communication in ART.
What is known already? ICMART began ART global data collection in 1991. Utilization, effectiveness and safety have continuously improved with more cycles, higher pregnancy rates and lower rates of multiple births, respectively. Wide variations exist globally. Over 6 million ART babies have been born. China does not report. ICMART is helping develop African registries. Data collection and quality remain challenging. The ICMART/WHO glossary has undergone major revisions and expansion. This process is complex and culturally sensitive.
STUDY design, size, duration: Countries and regions annually collect ART data, some prospectively and others retrospectively. ICMART retrospectively requested these data from all known global sources for 2012, analyzed them and presents preliminary results. The ICMART/WHO glossary update involves dozens of reproductive specialists over 3 years in an interactive consensus process.
Participants/materials, setting, methods: The European IVF Monitoring Consortium (EIM), SART, Latin American Network of Assisted Reproduction (REDLARA), Australian/New Zealand Registry, and other countries, totaling approximately 60, contributed national data through standard ICMART forms. Data were reviewed, corrected, analyzed and summarized by ICMART working with the University of Uppsala, Sweden using standard statistical tests.
Main results and the role of chance: Data collection and analysis are ongoing. Preliminary results only will be presented at ESHRE. The ICMART/WHO Glossary has been expanded to include 5 sections: clinical terminologies, outcome terminologies, epidemiology and public health, laboratory including andrology and embryology.

Most previous definitions have been retained but some modified, clarified or expanded. Many new definitions have been added.
The role of chance is minimal.
Limitations, reasons for caution: Global results are limited to reporting countries and clinics, approximately 2/3 of global cycles. Many countries have limited data validation and ICMART can perform only minimal data validation. The ICMART/WHO glossary definitions are based on a consensus process by many experts covering different disciplines, and although difficult, the work ends when universal agreement is reached.
Wider implications of the findings: It is accepted that measurement of human activities improves quality and outcomes. ICMART World Reports standardize data, track trends, enable comparisons, stimulate questions and improve ART quality in clinics, countries, regions and globally. Additionally, better understanding of ART increases societal acceptance and eventually creates broader support for ART research and clinical access. The ICMART/WHO glossary provides a common terminology platform to increase quality of ART research and clinical data and communication.

Abstract text
The need to document utilization, effectiveness and safety of ART is established and met through national and regional data registries in most parts of the world. The International Committee Monitoring Assisted Reproductive Technologies (ICMART) generates annual reports on global data and assists countries and regions in establishing ART registries. There is a need for registry development in sub-Saharan Africa as currently only one national registry exists. ICMART has initiated and facilitated communication among role players in sub-Saharan Africa regarding the formation of a regional ART registry. A project plan has been generated modeled on the Latin American Registry for ART. The Latin American registry software, which captures case-by-case data, has been made freely available to ART centres in sub-Saharan Africa and is currently being piloted. Training materials and standard operating procedures for data collection are being developed. The clinical and laboratory directors of all ART centres in the region will be invited to participate in the registry and to submit data to the regional registry hub. The anonymity of centres and patients will be protected. The registry hub will report back (1) to each centre its own data confidentially; (2) to each country the pooled national data; and (3) to the region the pooled regional data pertaining to utilization, effectiveness and safety of ART. A regional meeting of participants is in planning.

The current absence of data pertaining to utilization, effectiveness and safety of ART in sub-Saharan Africa compromises the evidence-base for ART in the region. This has implications for health care providers, users and planners and other stakeholders. Registry data, once generated, will provide a platform for clinical and health political improvement strategies and for research as well as national and regional benchmarks against which trends and improvements can be monitored.

O-138 3D ultrasound to diagnose uterine anomalies

C. Exacoustos[1], R. Valeria[1], I. Cobuzzi[2], B. Zizolfi[3], A. Di Spiezio[3], E. Zupi[1]
[1]*University of Rome 'Tor Vergataâ,' Department of Biomedicine and Prevention, Obstetrics and Gynecology, Roma, Italy*
[2]*University of Bari, Department of Obstetrics and Gynecology, Bari, Italy*
[3]*University of Napoli, Department of Obstetrics and Gynecology, Napoli, Italy*

Abstract text
After the introduction of ESHRE-ESGE classification of uterine anomalies (2013) a lot of arcuate uteri classified according to ASRM/Salim classification (2003) became partial septate uteri (class U2a). Furthermore also dysmorphic T shaped uteri are difficult to assess in all classification, also the new ESHRE/ESGE classification, class dysmorphic uteri (U1c), for absence of precise diagnostic criteria.

We propose new criteria for the detection of T shaped by means of angle between isthmic cavity and fundal endometrial rim layer and fundal/isthmic cavity widths. We also re-evaluated and reclassified according ESHRE/ESGE classification, 362 stored 3D ultrasound uterine volume of women with previous diagnosis of arcuate uterus.

The assessment of uterine morphology was performed in a 3D coronal plane and following measurements were taken: (1) fundal cavity width (W1) (the distance between the two internal tubal ostia), (2) width of uterine cavity at corpus-isthmic level (W2), (3) uterine fundal wall thickness (M) (the distance from interostial line and the external uterine serosa), (4) the lateral angle between the corpus-isthmic cavity and the two fundal endometrial layers (A right, A left), (5) in case of cavity fundal indentation, the indentation length (L) (the distance from the tip of the fundal indentation to the interostial line) and fundal indentation angle (α) (the angle between the two endometrial layers). Recorded reproductive history of the patients was correlated to the measurements and to normal and subseptate uterus according ESHRE/ESGE classification.

Of the 362 previous arcuate uteri, 189 (52.2%) become septate according to ESHRE classification because the L exceeded the 50% of the fundal uterine wall thickness (M) while 173 (47.8%) were considered slightly dysmorphic or normal uteri. Of the reclassified patients with septate uterus, a higher percentage (but not statistically significant) of women with infertility and at least one miscarriage was observed compared to the patients with normal uterus.

T-shaped uterus had a fundic cavity significantly wider than normal uterus, while the width at corpus-isthmic level was statistically lower in T-uterus compared to normal and septate. Furthermore dysmorphic T shaped uteri showed more acute lateral angles that were absent or wide in the two control groups. Compared to normal uteri a higher rate of infertility in patients with T shaped uterus (61.9 vs. 47.9%) was observed. A higher percentage of miscarriage in women with septate uterus compared to T shaped has been shown (45.8 vs. 23.8%).

ESHRE-ESGE classification arise several diagnostic and clinical implications and may result in difficulties in counseling and in treatment options in women with U2a and U1c uteri who experience infertility and/or miscarriage. The width and not the length of the septum seem to have an impact on reproduction. Dysmorphic T-shaped uterus has a typical different morphology than other uterine anomalies, easily reproducible with standardized measurements. Lateral angles and corpus-isthmic ratio measured on 3D coronal section proposed in this study improve the diagnosis of dysmorphic uteri and could define better selection criteria for hysteroscopic treatment, resulting in improved fertility. The new ESHRE/ESGE classification is not supported by retrospective results and prospective studies of corrective surgery are needed that could help to define selection criteria for metroplasty, resulting in improved long-term outcomes.

O-139 3D ultrasound in early pregnancy

N. Exalto[1], A. Koning[2], E. Steegers[1]
[1]*Erasmus MC, Obstetrics and Gynecology, Rotterdam, Netherlands*
[2]*Erasmus MC, Bioinformatics, Rotterdam, Netherlands*

Abstract text
The last decennium there is an increasing interest in Early Pregnancy ultrasound, not only for determining pregnancy localization and viability but also for the detection of abnormal growth and development, including early detection of various congenital anomalies. Safety issues are served by a reduction of the exposure time due to off-line analysis of transvaginal 3D volumes. Although the 3D US technology has improved further, the images are still presented on a 2D screen without offering natural depth perception. A special volume rendering application (V-Scope®) has been developed at the Erasmus Medical Centre in Rotterdam to create virtual "*holograms"* of the 3D US datasets using projection-based 3D displays as well as a smaller and cheaper 3D desktop VR systems. Manipulation (crop, rotate, resize, and clip plane function) of the holograms is natural, intuitive and very easy to learn even for untrained sonographers. This technology allows very precise and accurate length measurements, even of non-linear structures, as well as semi-automated volume measurements.

With this innovative 3D VR approach first trimester reference curves were constructed for CRL, BPD, HC, AC, umbilical cord length, vitelline duct length, cerebellum, diencephalon, mesencephalon, telencephalon and hand length and hand- and wrist width. Furthermore reference values were established for embryonic volume and volumes of the placenta, gestational sac, yolk sac, and brain cavities. These reference curves serve as background information for evaluation of normal embryonic growth and development. Using 3D VR it is even possible to determine the Carnegie Stages of embryonic development. The use of 3D power Doppler volumes in VR also enables the measurement of the total placenta bed vascular volume and the total placenta vascular volume, these being promising parameters for predicting second and third trimester fetal growth restriction.

3D VR appears to be superior in diagnosing first trimester surface abnormalities and skeletal/limb malformations in comparison to 2D and 3D US. In case of anomalies like TAR syndrome, CNS defects and conjoined twins additional abnormalities were observed using 3D VR as compared to 2D and 3D US. In comparison to normal pregnancies embryonic volume measurements turn out to be smaller in aneuploid pregnancies and some types of structural congenital anomalies. In detecting early abnormal growth the measurement of embryonic volume performs better than CRL measurements. However, embryonic volume does not perform better than CRL in predicting miscarriages.

Studies on genetic and environmental influences in the Rotterdam Predict Study (Steegers-Theunissen et al., 2015), using 3D VR, revealed influences of periconceptional use of folic acid, maternal age, dietary patterns, smoking, alcohol and vitamin B12 levels on normal growth and development. Embryonic growth and development are known to be related to birth weight.

These various findings led to the introduction of the new theme *Embryonic Health* with 3D VR as an important and innovative tool for screening, prediction and diagnosis in this period of pregnancy with an increasing interest of both professionals and pregnant women. Documentation of first trimester physiological omphalocele, clubfoot, embryonic curvature and sex determination are now subject of 3D VR studies, as is the analysis of embryonic movement. With the development of the 3D VR desktop system this new 3D VR technology has become available as a new tool for further collaborative studies and clinical use at outpatient clinics. As 3D TV-screens are also becoming more popular it may be expected that in the near future 3D VR will be build in as a standard feature in ultrasound equipment.

INVITED SESSION

SESSION 38: REPRODUCTIVE ENDOCRINOLOGY/EARLY PREGNANCY

Tuesday 05 July 2016 **Hall 3 DE** **11:45–12:45**

O-140 Monozygotic twinning: to be or not to be monoclonal

B. Reversade[1], L. Ho[1], S. Chng[1], M. Van Dijk[2]
[1]*Institute of Medical Biology, A* STAR, Laboratory of Human Embryology and Genetics, Singapore*
[2]*Academic Medical Centre, Amsterdam Reproduction and Development, Reproductive Biology Laboratory, Amsterdam, Netherlands*

Abstract text

We are polyclonal beings since each person is born of a unique fertilization event.

Rarely however, two babies or more develop from a single embryo, producing monoclonal humans.

Known as identical, monozygotic (MZ) twins are true reproductive clones. Like Dolly, they share a genome yet breathe a sovereign existence.

Through genetic studies in a large kindred with familial MZ twinning, a hitherto unknown hormone ELABELA (ELA) was characterized.

ELA is secreted by human embryonic stem cells and pre-implantations embryos, where it orchestrates pluripotency and possibly the birth of MZ twins.

After implantation, ELA drives cardiovascular development and may serve as a novel therapeutic for pre-eclampsia.

O-141 The biology of dizygotic twinning

D. Boomsma[1]

The biology of dizygotic twinning

Dorret I Boomsma, on behalf of the Twinning GWAS Consortium (TGC)[1*]
Department of Biological Psychology, Vrije Universiteit Amsterdam, Netherlands.

Abstract

The spontaneous rate of twinning is about 1 in 80 live births, which means that about 1 in 40 individuals is a twin. In contrast to Monozygotic (MZ) twinning, Dizygotic (DZ) twinning has a familial component, with mothers of spontaneous DZ twins having a higher number of DZ twin pairs in their pedigrees than the general population. In Caucasians, two-thirds of twins are DZ and dichorionic diamniotic (DCDA), commonly referred to as fraternal twins since they develop from two separate oocytes fertilized at the same time. The underlying biological mechanism for DZ twinning is the release and fertilization of multiple oocytes, for which both animal models and human data suggest multifactorial inheritance. So far, efforts to characterize the genes that contribute to DZ twinning in humans and explain its high prevalence have not been successful. Candidate gene association studies and genome-wide linkage scans have failed to find common variants associated with DZ twinning.

We established the Twinning GWAS Consortium (TGC) to characterize the genetic basis of spontaneous DZ twinning and performed the first genome-wide association study (GWAS). We report for the first time compelling evidence that sequence variation at the FSHB and SMAD3 loci increases the odds of DZ twinning, based on 3 discovery cohorts from the Netherlands, Australia and Minnesota (USA). The findings were replicated in a large cohort from Iceland by Decode. We show that variants in these two genes are significantly associated with a broad range of fertility and reproductive traits in women including age at menarche, age at menopause, age at first and last child, and lifetime parity. We estimate the relative risk of twin birth given the novel alleles and explore the genetic relationship of DZ twinning and fertility traits using polygenic risk scores (PRSs), and show that higher DZ twinning PRS is associated with having children, greater lifetime parity, and earlier age at first child.

We expect substantial interest in the risk estimates for women, who are carriers of these variants, which we report based on population data from Iceland. We hypothesize that the results will also be of importance to investigations into ovarian response to follicle-stimulating hormone (FSH) stimulation for assisted reproductive technology (ART), making these findings relevant to research into female infertility.

Twinning is associated with common perinatal and maternal morbidities and by understanding the genetic basis of human DZ twinning we concomitantly identify loci conferring susceptibility (or conversely resistance) to these prevalent perinatal comorbidities.

Keywords: dizygotic twinning, fertility, genetics, GWAS polygenic risk scores

O-142 Reproductive options for transmen

S. Somers[1], V. Provoost[2], E. Wyverkens[3], I. Raes[2], A. Ravelingien[2], H. Van Parys[3], I. Stuyver[1], A. Buysse[3], G. Pennings[2], P. De Sutter[1]

[3]*Ghent University, Department of Experimental-Clinical and Health Psychology, Ghent, Belgium*

[*] H Mbarek, S Steinberg, DR Nyholt, SD Gordon, MB Miller, AF McRae, JJ Hottenga, FR Day, G Willemsen, EJ de Geus, GE Davies, HC Martin, BW Penninx, R Jansen, K McAloney, JM Vink, J Kaprio, R Plomin, TD Spector, PK Magnusson, B Reversade, RA Harris, K Aagaard, RP Kristjansson, I Olafsson, GI Eyjolfsson, O Sigurdardottir, WG Iacono, CB Lambalk, GW Montgomery, M McGue, KK Ong, JRB Perry, NG Martin, H Stefánsson, K Stefánsson, DI Boomsma

Study question: How do transmen (female-to-male transgender persons) and their female partners experience current and future reproductive options and how do they make decisions about it?
Summary answer: The couples experienced their reproductive options as very limited. Their positive attitude towards treatment with stem cell-derived gametes was linked to traditional family values.
What is known already: The Belgian law states that transgender people who want to change their legal sex have to undergo physical gender adjustment to the extent medically possible and justified. This means that they have to accept the fact that they can no longer reproduce. Yet, fertility preservation options do exist: oocyte freezing and ovarian tissue cryopreservation for female-to-male transgender people and sperm freezing for male-to-female patients. Also, Belgian transgender people can be considered for fertility treatment with donor gametes; they are not excluded on the basis of their background or sexual orientation.
Study design, size, duration: In this study, we included 6 female-to-male transgender people with their female partners. The in-depth semi-structured couple interviews were performed between September 2014 and January 2015. Four reproductive options were discussed: donor conception, adoption, oocyte freezing and stem cell-derived gametes. Data were analysed through step-by-step inductive thematic analysis. A continuous auditing process by the co-authors resulted in themes that were grounded in the data.
Participants/materials, setting, methods: The participants were recruited at the Department of Reproductive Medicine of a University Hospital. Three couples had at least one child as a result of donor insemination with anonymous donor sperm (the first-born was between 7 and 8 years old) and three were either in treatment or pregnant at the time of data collection. Approval of the clinic's Ethics Committee was obtained.
Main results and the role of chance: The couples viewed donor conception as the standard route to become parents. This was also influenced by the fact that the female partners had a strong wish to become pregnant. Adoption was seen as less obvious because of the transgender past and the fact that it was a time-consuming process.

Couples mostly talked about oocyte freezing as a hypothetical situation, since this had not been presented as an option at the time of their transition. Reasons for not wanting to freeze oocytes before the completion of the female-to-male transition were the transgender person's wish to close the chapter of his life in a female body as quickly as possible and the absence of a partner or the wish to become a parent. However, the possibility to have a genetic link with the child was perceived as a benefit of this technique. The importance of *both* parents having a genetic link with the child was reflected in their opinion about the hypothetical option of generating gametes from stem cells. Initial reactions of disbelief or astonishment changed quickly into a positive attitude towards this possible development.
Limitations, reasons for caution: Although we retrieved rich data, a sample size of six is rather small. However, inclusion criteria were adapted to be able to increase inclusion. Nevertheless, three couples refused participation, one did not respond after receiving information about the study and one couple could not be reached after several attempts.
Wider implications of the findings: This study illustrates the experience of female-to-male transgender people and their female partner about reproductive decision-making. Gametes generated from stem cells are a valuable option for these couples. However, transgender people should be counselled about all reproductive options at the time of the transition.
Trial registration number: NA.

O-143 Poor knowledge on age-related fertility decline and *in vitro* fertilization (IVF) among healthcare professionals outside of assisted reproductive technologies (ART)

R. Vassena[1], D. García[2], R. Amelia[3], V. Valerie[3]
[1]*Clinica Eugin, Barcelona, Spain*
[2]*Fundació Eugin, Barcelona, Spain*
[3]*Clinica Eugin, Assisted Reproduction, Barcelona, Spain*

Study question: How knowledgeable are gynecologists, physicians of other specialties, and nurses about fertility, assisted reproduction techniques (ART), and social freezing?
Summary answer: Gynecologists are more knowledgeable about women's fertility and ART than other specialties physicians and nurses, but less open to social freezing.
What is known already: Healthcare professionals are the main source of fertility information and counseling for the general public. However, reproductive knowledge has been shown to be lower than desirable in medical students and female healthcare professionals (nurses, midwives and medical doctors). On the whole, healthcare professional are aware that age-related infertility exist, but are not able to pinpoint when fertility starts to decline and overestimate the chances of achieving a pregnancy (either natural or thorough ART). Conversely, while most healthcare professional agree that age related fertility needs to be discussed during women's annual revision, informing women about social freezing is still controversial.
Study design, size, duration: This cross-sectional study includes 201 healthcare professionals (72 gynecologists, 78 physicians in specialties other than gynecology, and 51 nurses) from 4 public hospitals in Spain. Participants filled in an anonymous survey about fertility, ART and social freezing.
Participants/materials, setting, methods: The survey included 10 questions on age-related infertility, ART (until what age can a woman get pregnant spontaneously/through IVF/through oocyte donation-OD-?), and attitude towards social freezing (should it be offered to every young woman/be financed by the public health system?). Responses among the 3 professional categories were compared by ANOVAs and Student's *t*-tests. Impact of responders' age, gender, having children, stable work and relationship on age-related infertility knowledge was further investigated by multivariate analysis.
Main results and the role of chance: Overall, the reported mean age limit for achieving a pregnancy spontaneously, through IVF, and through OD were 39.5 ± 4.5, 43.7 ± 5.2 and 49.0 ± 6.5 years, respectively. Gynecologists reported a significantly younger limit age for spontaneous pregnancy (37.5 ± 2.8) and for IVF pregnancy (41.0 ± 3.4) than other physicians and nurses ($p < 0.001$). Only 4.2% of gynecologists reported an age limit for a spontaneous pregnancy over 40 years, compared to 40.0% of other physicians and 27.1% of nurses, ($p < 0.001$). Similar results were found for the reported age limit for IVF and OD pregnancies. Gynecologists were more conservative regarding vitrification, with 41.8% considering that social freezing should be offered to every young woman, vs. 62.7% of other physicians and 48.9% of nurses ($p = 0.041$), and 19.4% considering that social freezing should be financed by the public health system (vs. 31.9% of other physicians and 42.2% of nurses, $p = 0.031$). Most gynecologists (47.1%) would not offer social freezing past 35, while 44.6% of other physicians and 57.8% of nurses would offer it until 40. Gynecologists were significantly younger and nurses significantly older and of female gender than the other groups, however the multivariate analysis did not show an effect of age or gender on participant's answers.
Limitations, reasons for caution: We should be aware than 41% of physicians other than gynecologists in our survey were family physicians, who could have a different average fertility knowledge compared to other specialties, since they are primary care physicians with a broad consultation mandate which includes family planning.
Wider implications **of the findings:** Age-related fertility knowledge is poor among healthcare professionals in Spain, and attitudes towards social freezing could be based on mistaken believes; both inaccurate knowledge and personal attitudes could influence the quality of information and counseling given to patients.
Trial registration number: NA.

O-144 Sex counselling for subfertile couples continuing to attempt natural conception

E. Dancet[1], T.M. D'Hooghe[2], K. Peeraer[2], E.T.M. Laan[3], C.B. Lambalk[4], S. Repping[5], I. Custers[5]
[1]*Leuven University Hospital Campus Gasthuisberg, Fertility Centre, Leuven, Belgium*
[2]*Leuven University, Department of Reproduction and Development, Leuven, Belgium*
[3]*Acadamic Medical Center, Department of Sexology, Amsterdam, Netherlands*
[4]*VU University Medical Center, Center for Reproductive Medicine, Amsterdam, Netherlands*
[5]*Acadamic Medical Center, Center of Reproductive Medicine, Amsterdam, Netherlands*

Study question: How would subfertile couples continuing to attempt natural conception like to receive sex counseling?

Summary answer: Subfertile couples would prefer written over face-to-face sexual advice and additionally want advice on stress management, the menstrual cycle and life style behavior.
What is known already: Two underpowered randomized controlled trials (RCTs), suggest that face-to-face sex counseling improves clinical pregnancy rates of couples with unexplained subfertility. In other fields, improvement of sexual functioning of couples has been achieved with web-based sex-counseling. Web-based sex-counseling is less costly than face-to-face sex-counseling. Couples whom are advised "expectant management" (EM), i.e., who are sent home to continue attempting natural conception, are known to suffer from lack of information and support. Subfertile couples are known to value and attempt all strategies likely to improve their pregnancy chance.
Study design, size, duration: This study was conducted in the winter of 2015 and relied on explorative in-depth qualitative interviews with seven heterosexual subfertile couples.
Participants/materials, setting, methods: Couples with unexplained subfertility and a good prognosis on natural conception who underwent at least 6 months of EM were eligible. Couples were recruited from a Dutch and a Belgian fertility clinic. Ten couples were invited by telephone to be interviewed at the clinic or at home. The in-depth interviews were guided by open questions and a topic list and were recorded digitally. They were then transcribed verbatim and subjected to content analysis.
Main results and the role of chance: Seven couples were included and interviews were held with five couples and two women without their partners. All couples had received 6–9 months of EM. Five couples regretted delaying fertility treatment while two valued "giving nature another chance." During EM, all couples had timed intercourse and experienced diminished sexual pleasure. Although not having considered it, all couples could imagine benefitting from sexual advice, especially if it might improve their pregnancy chance. All but one couple preferred web-based over face-to-face sex counseling. Couples wanted to contact professionals *via* email with their questions. Couples did not agree whether they wanted professionals to initiate email contact. Written testimonials from other couples were preferred over interacting directly with them. Couples preferred sexual advice to be evidence-based, concise and endorsed by professionals rather than directly sexually stimulating. Drawings or cartoons were preferred over pictures. Sexual advice would be read, especially by women, and communication and sensate focus exercises would be attempted together. Uptake would have to be voluntary, with an advised rather than a compulsory sequence of exercises. Couples highly valued obtaining additional information on stress-management, the fertile window of the menstrual cycles and life style behavior affecting pregnancy chances.
Limitations, reasons for caution: Data-collection is ongoing as data saturation has not yet been achieved although it is expected by March 2016. Although the participation rate was high (70%), couples willing to participate in this type of interviews might be more positive about sexual advice than those declining participation.
Wider implications of the findings: Once data-saturation is achieved, our group will incorporate the insights from these patient interviews in a new web-based sex-counseling intervention. In a large scale RCT the effect of this intervention will be compared to EM regarding ongoing pregnancy rates, sexual and psychosocial functioning and will examine its feasibility and acceptability.
Trial registration number: Not applicable.

O-145 Comparison of patients – centeredness experience in infertility care in patients fully reimbursed by national insurance and in cross-border self-paying patients

V. Vlaisavljevic[1], J. Muršiₑ, K. Slavica[3]
[1]*Biomedical Research Institute BRIS, IVF Adria Consulting, Maribor, Slovenia*
[2]*University Hospital Maribor, Reproductive Medicine, Maribor, Slovenia*
[3]*Universidade de Evora, Department., Evora, Portugal*

Study question: Is there a difference of patient-centered care (PCC) between national insurance reimbursed patients and cross-border, foreign infertility couples treated in public University clinic?
Summary answer: Slovenian and cross-border patients have different experience in all PCC domains, even though the overall satisfaction with infertility care is high in both groups.
What is known already: Patient-centered care is an important aspect of infertility treatment and high quality of care. Reports of patients' experiences vary across countries and this reflects the differences in individual patients' expectations, staff's competences and provider's organization of care. All EU members allows patients to seek cross-border infertility care but some limitations in reimbursement policy exist across countries. Staff's competences, success rate and out-of-pocket costs are some of drivers which guides patients' decision on choosing a hospital.
Study design, size, duration: This was a prospective, cross-sectional study and included randomly sampled couples who underwent fertility diagnostic procedure or ART in Slovenian fertility clinic during 12 weeks period. All Slovenian patients have six fully reimbursed cycles while cross-borders paid out-of-pocket.
Participants/materials, setting, methods: Difference in the level of patient-centredness was assessed between the groups of 106 Slovenian couples and 69 cross-border couples using a standardized questionnaire. Patient-centredness Questionnaire-Infertility (PCQ-Infertility), with a socio-demographic data included, comprises three assessment levels: total scale, seven domains and 46 single indicators (scale range 0–3). Women and their partners were recruited in clinical setting and fulfilled PCQ-Infertility questionnaire translated into two languages, Slovenian and SCB (Serbian–Croatian–Bosnian), and adapted for both groups of patients.
Main results and the role of chance: The majority of women in both groups (Slovenian 61.16%, cross-border 93.1%) were not pregnant at the moment of fulfilling the questionnaire after embryo transfer. At the domain level, the group of cross-border patients assessed all seven PCC domains higher than Slovenian patients. The biggest score domain gap (SDG) between two group was found in Continuity and transition (SDG 0.99) and Care Organization (SDG 0.84). The lowest SDG was in Accessibility domain (SDG 0.09). Unlike, Staff Competences domain was scored the highest in both groups. Based on the score indicators' gap (SIG), the results shows that Slovenian patients misjudged more indicators than cross-border patients, namely: staff member assigned as contact for any questions or problems (SIG 2.13), waiting time more than 3 weeks for an appointment with the physician (SIG 1.08) and the number of different physicians involved in treatment in the present hospital (SIG 1.54). Indicators that were assessed with the lowest score in both groups were information about psychological and social worker support and how often patients had impression that staff was speaking "about them" instead "to them."
Limitations, reasons for caution: Although we found sufficient response rates, higher number of participants would result in higher confidence of results. Because we only included infertile cross- border couples from ex-Yugoslav countries, we cannot draw conclusions that these results would be universally applicable to other cross-border couples treated in this particular clinic.
Wider implications of the findings: These results can present an incentive, in which we should put more focus on assessing the possible correlation between having a contact person in organisation (who speaks patients native language), number of doctors involved in treatment of each couple, and having a positive experience on continuity of care.
Trial registration number: NA, Future medicine, IPA Adriatic cross border cooperation project.

INVITED SESSION

SESSION 40: THE NEED FOR OXYGEN IN IVF

Tuesday 05 July 2016 **Hall 5 CB** **14:00–15:00**

O-146 Oxygen as a regulatory force during oogenesis and preimplantation embryogenesis: lessons for oocyte and embryo culture in clinical IVF

J. Van Blerkom[1]
[1]*University of Colorado, Developmental Biology, Boulder, CO, USA*

Abstract text
The role of oxygen in oogenesis and preimplantation embryogenesis is usually considered in terms of cellular bioenergetics, i.e., ATP production *via* oxidative phosphorylation, and whether too low a level may compromise synthesis and one that is too high may be detrimental if associated with excess oxidative damage/stress. In clinical IVF however, oxygen concentration is one of the few

operator-controllable variables that can be easily applied to oocyte and embryo culture, with ranges between 5 and 20% (atmospheric) typical. While there have been numerous studies asking whether an optimal concentration exists with respect to normal fertilization, embryogenesis and outcome, most have concluded that levels in the lower range should be routinely used. Although *in vitro* culture conditions attempt to approximate *in vivo* conditions, what oxygen concentrations oocytes and embryos experience in the reproductive tract it is not well understood, nor is the basic question of whether possible changes in ambient oxygen within different regions normally occur that could have stage-specific regulatory influences on developmental competence.

This presentation focuses on what the likely oxygen milieu the oocyte and preimplantation stage embryo experiences within the mature preovulatory follicle, fallopian tube and uterus, respectively. While changes in oxygen concentration *in vitro* can be correlated with quantitative differences in levels of gene expression for certain classes of proteins, comparisons to *in vivo* developed embryos suggest these differences may be more "noise" than signal and likely developmentally benign. This raises the question of how oxygen levels are sensed and can elicit different molecular responses in the early embryo. What will be the focus of these findings is that while near anoxic conditions experienced by an oocyte during the terminal stages of preovulatory nuclear maturation can have negative downstream developmental consequences, the same conditions experienced by the peri-implantation blastocyst *in vivo* may be required to induce or upregulate the expression of certain growth factors likely needed during the invasive phase of implantation. That relatively small changes in ambient oxygen concentration from near anoxic for the oocyte to near anoxic for the embryo may be beneficial with respect to developmental competence may provide novel insights into the role of oxygen in oogenesis and early embryogenesis that may warrant consideration in the design of dynamic *in vitro* culture systems for clinical IVF that better approximate location-specific conditions *in vivo*.

O-147 Is oxygen really harmful to human embryo culture?

J. Dumoulin[1]
[1]*Maastricht University Medical Center, Maastricht, Netherlands*

Abstract text

Preimplantation embryos from different mammalian species have been shown to develop successfully *in vitro* when cultured under atmospheric (~20%) as well as under low (5–7%) oxygen concentrations. Furthermore, high implantation rates and development to birth are obtained with embryos cultured during the preimplantation period under varying oxygen concentrations. Also for human *in vitro* fertilization (IVF) treatments, both atmospheric as well as reduced (5%) O_2 concentrations are widely used and high success rates have been reported. Which oxygen concentration results in the best preimplantation development and in the highest implantation rates is subject for a wide range of studies performed during a period spanning almost five decades.

Theoretically, it can be assumed that culture under a low oxygen concentration is more physiological. Embryos develop *in vivo* under low O_2 levels, as in the oviduct and uterus of various mammalian species O_2 concentrations have been reported to vary between ~1.5–9%. In accordance with this fact, preimplantation embryo development *in vitro* in most animal models is shown to be significantly improved when the culture is performed in reduced oxygen concentrations in the majority of studies. Also in the human, significant improvement of development to the blastocyst stage and an increased number of cells per blastocyst was found in several studies when 5% O_2 was used. Regarding pregnancy and live birth rates however, the methodological quality of most published studies was relatively poor and the sample sizes were too small to detect the relatively small differences in results that were to be expected, resulting in a confusing maze of contradictory outcomes. It was only recently that results from systematic reviews and meta-analysis confirmed that culturing embryos under a low oxygen concentration improves the success rates of IVF and ICSI, when trials were considered in which embryos were transferred on days 5 and 6 at the blastocyst stage (Gomes Sobrinho et al., 2011; Bontekoe et al., 2012).

Besides the above mentioned outcome parameters it is important to realise that during recent years many studies have shown that exposure to atmospheric oxygen leads to a variety of adverse cellular effects ranging from significantly elevated levels of intracellular reactive oxygen species leading to increased apoptosis and DNA damage, altered gene expression and metabolic changes in preimplantation embryos. As is the case with success rates, also with these cellular effects contradictory results were found.

However, altogether, the results of all above mentioned studies provide growing evidence that the use of a reduced oxygen concentration is to be preferred for the culture of mammalian preimplantation embryos and for human *in vitro* fertilization (IVF) treatments.

INVITED SESSION

SESSION 41: INSULIN SENSITIZERS IN REPRODUCTION

Tuesday 05 July 2016 **Hall 5 A** **14:00–15:00**

O-148 Role of metformin and AMPK in reproductive tissues

P. Froment[1], M. Faure[1], J. Dupont[1], M.J. Bertoldo[2]
[1]*Centre INRA Val de Loire, UMR, Physiologie de la Reproduction et des Comportements, Nouzilly, France*
[2]*University of New South Wales, Sydney, School of Women's and Children's Health, Discipline of Obstetrics and Gynaecology, Sydney, NSW, Australia*

Abstract text

Metformin is a drug widely used in the treatment of diabetes mellitus type 2 and can be also used to improve fertility in case of reproductive abnormalities associated with insulin resistance. Indeed, women with polycystic ovary syndrome (PCOS) are treated with clomiphene citrate associated or not with metformin to improve ovulation rate. Its action reduces hepatic glucose output, increases tissue insulin sensitivity and enhances peripheral glucose uptake. To clarify the mechanism of metformin's action in reproductive tissues, several studies have used direct and indirect exposures.

Observations mainly *in vivo* or in ovarian cell culture models have been described in several species (human, rodents, cow and goat) where reductions of estradiol, progesterone from the granulosa and even androgen by human thecal cells was observed *in vivo* and *in vitro* after metformin exposure. Metformin alters differently oocyte maturation in function of the species. Indeed, in bovine and porcine oocytes, metformin blocked meiotic progression to the germinal vesicle stage whereas opposite effects are observed in mice

During pregnancy, metformin has the ability to cross the placenta, and its use raises concerns about potential adverse effects on both the mother and fetus. Some studies have observed that *in utero* exposure to metformin early in pregnancy does not appear to cause any adverse effects or congenital malformations. Despite this, consequences on gonad development of the fetus have not been clearly studied. Hence, *in vitro* studies and *in vivo* experiments in mouse models have reported a decrease in androgens production by human and testis embryonic gonads. The free testosterone index (FTI), which is the ratio used to evaluate the androgen status in humans and is calculated by the total testosterone level divided by the sex hormone binding globulin (SHBG) level, was increased in metformin-exposed male offspring. In addition, an increase in levels in SHBG newborns exposed to metformin during the first trimester of pregnancy has also been reported.

In adult testis, metformin stimulation resulted in a 3-fold increase in lactate production that is an important energy source for male germ cells. Thus, metformin could impact directly male germ cells.

In conclusion, the data are still insufficient to completely confirm or disprove negative effects of metformin. In this review we will provide an overview of the various aspects of metformin in sexual reproduction, and the safety use of metformin.

O-149 Insulin sensitizers in the treatment of metabolic disturbances and infertility in PCOS

L.C. Morin-Papunen[1]
[1]*Oulu University Hospital, Obstetrics and Gynaecology, Oulu, Finland*

Abstract text

Polycystic ovary syndrome (PCOS) affects 6–18% of women of reproductive age and is the most common cause of anovulatory infertility in women. The first-line treatment of the adverse features of PCOS is lifestyle intervention, such as weight loss and exercise. Reduction in weight of as little as 5% can restore regular menses and improve response to ovulation-inducing and fertility medications.

The intrinsic role played by insulin resistance and hyperinsulinemia in the pathogenesis of PCOS has led to the use of insulin-lowering drugs for the treatment of the syndrome. Numerous studies have indicated that metformin improves metabolic abnormalities, e.g., hyperinsulinemia and insulin resistance, decreases androgen levels and improves menstrual pattern in women with PCOS. Previously, several reports and meta-analyses have suggested that metformin may improve ovulation induction 1.5 to 4 times compared to placebo alone. Later, these results could not be confirmed in two large randomized studies, where metformin was significantly less effective than clomiphene, and the combination of the two drugs did not bring any advantages. In the most recent Cochrane meta-analysis the addition of metformin to an ovulation-induction agent significantly improved clinical pregnancy rates (PRs), but not live birth rates (LBRs). Two recent RCTs conducted in Nordic countries, however, showed that a pretreatment of 3 months with metformin improved the PRs and LBRs by 15% after IVF/ICSI in non-obese women, and after its combination with standard infertility treatment in obese women. Altogether, these findings support the use of pre-treatment with metformin for several months before infertility treatment. The last recommendation of the American Association of Clinical Endocrinologists, American College of Endocrinology and AE-PCOS Society is that metformin may be useful as an adjuvant agent in certain groups of women with PCOS, such as obese women.

The efficacy of metformin in addition to gonadotropin stimulation, laparoscopic drilling and/or IVF treatment remains to be defined. Recent studies suggest that metformin improves pregnancy outcome by decreasing early spontaneous miscarriage, but these findings could not be confirmed in recent randomized, prospective, placebo-controlled trials. However, metformin has been shown to decrease significantly the risk of ovary hyperstimulation syndrome during assisted reproductive technology.

Obese women with PCOS are at increased risk for metabolic syndrome (MetS) with impaired glucose tolerance (IGT: 31–35%) and type 2 diabetes mellitus (T2DM: 7.5–10%). Additionally, compared with BMI- and age-matched controls, young lean women with PCOS have lower serum levels of high-density lipoprotein (HDL) size, higher levels of low-density lipoprotein (LDL) and triglycerides. Metformin is efficient in improving weight loss and may prevent conversion of IGT to T2DM as well as reduce features of MetS from 35 to 21% of subjects. Metformin use has also been associated with improvement of dyslipidemia in women with PCOS. In adolescents with PCOS metformin may be used as first-line monotherapy or in combination with oral contraceptive pills to reduce PCOS symptoms.

Drugs in the insulin sensitizing thiazolidinedione class (i.e., pioglitazone) are effective for treating insulin resistance and hyperinsulinemia in PCOS. These drugs, however, are associated with potential serious side effects and are contraindicated during pregnancy and therefore cannot be recommended for use in PCOS.

Inositols are members of the vitamin B complex. They are important mediators of insulin action and therefore classified as "insulin sensitizers." Both isoforms of inositol, D-chiro-inositol and myo-inositol have been reported to improve insulin sensitivity, ovulatory function and hyperandrogenism in women with PCOS as well as pregnancy outcomes in infertile women with poor oocyte quality. However, large placebo controlled studies are needed to confirm these results before insitols can be recommended for the treatment of PCOS.

INVITED SESSION

SESSION 42: EMBRYO AND DOUBLE GAMETE DONATION (PATIENT SESSION)

Tuesday 05 July 2016 **Hall 3 AB** **14:00–15:00**

O-150 Should embryo donation be mandatory? Patients' perspective on Polish law on infertility treatment

A. Krawczak[1]
[1]*Nasz Bocian, Warszawa, Poland*

Abstract text

Should embryo donation be mandatory? Patients' perspective on Polish Law on infertility treatment.

IIn November 2015 the new law on infertility treatment was entered into force in Poland. According to its provisions, surplus embryos must not be destroyed or donated for scientific research. Each embryo with preserved development potential is now guaranteed to be transferred. For tens of thousands of couples who have surplus embryos but do not plan on having any more children this means that they are forced to transfer them despite their reproductive plans or to donate the embryos. The regulations apply to all existing embryos, including embryos created before the new law was enforced. The new regulations apply also to single women and lesbian couples who have no longer the right to undergo any ART or MAR treatment as it is strictly reserved for heterosexual couples. As a consequence single women and lesbian couples are no longer legitimate to transfer the embryos created from their eggs before November 2015. For this group of patients this means that the embryos they recognize as their offspring and are willing to transfer are taken away and dispose by the state. For all the patients who are not legitimate or are not willing to transfer or donate their cryopreserved embryos the above results in compulsory donation. After 20 years of cryo-preservation without their consent or even knowledge the embryos will be overtaken and disposed as so called "embryo adoption."

The new regulations do not seem to comply with the European Directive 2004/23/EU which provides for "voluntary and unpaid donations of tissues and cells." Polish legislative solutions on organ donation are unheard in any other European state. Nevertheless, the new law on infertility treatment has been announced in Polish media to be "a successful compromise between medical liberalism and bioethics."

As it was to be expected the said regulations reverberated in the patients circle. In the presentation I will outline how the Polish patients evaluate this solution and what social and ethical costs will be entailed for people undergoing ART technologies in the past and in the future.

O-151 Comparative analysis on the situation of embryo/double gamete donation in Romania and France

N. Cristea Brunel[1]
[1]*Asociatia SOS Infertilitatea, Public Relations, Bucharest, Romania*

Comparative analysis on the situation of embryo/double gamete donation in two European countries: (1) Romania: This country has no MAR legislation, but only a general one on health, which comprises strict provisions on human cells (as such, as regards double gamete donation, the cross-border reproductive care phenomenon unfolds, Czech Republic and Greece being preferred destinations), and as regards embryo donation, there is no legislation whatsoever.

(2) France: This country has MAR legislation, which forbids double gamete donation (for that type of procedure, the concerned persons use cross-border reproductive care) but allows embryo donation, and many clinics have information and encouragement campaigns for embryo donation.

O-152 Embryo and double gamete donation – talking and telling

C. Spencer[1]
[1]*Donor Conception Network, Head Office, London, UK*

In the UK, increasing numbers of couples and individuals are contemplating and proceeding with using double donation (sperm and egg) and/or using embryo donation (sperm and egg at embryo stage) in order to create or add to a family. It may be that women have reached an age where conception using their own eggs is simply not possible, or have other reasons why their own eggs cannot be used (e.g., genetic issues or premature ovarian failure).

Whatever the reasons for turning to double or embryo donation, couples and individuals then have to decide whether to tell any child/children about how they were conceived. The Donor Conception Network (DC Network) in the UK has worked for over 20 years to support families with children conceived through donor conception and believes openness with donor conceived children is good for the children and the whole family. Although some of the issues are very similar when telling any child they are donor conceived, there appear to be some subtle but important additional considerations, both for the parent and the child, that arise when talking and telling about double and embryo donation. These add an additional layer of complexity. How do you explain this

complicated information to a child under the age of five? How do you tell other people that this is how you conceived your child and what are their reactions likely to be?

This talk will include a personal story and professional experiences (Caroline is a psychotherapist and a facilitator of DC Network workshops as well as a mum) to illustrate how to talk to young children conceived through double and embryo donation about their origins. It will address how this talking may evolve as the child's cognitive ability develops and their interaction with the broader community expands. The talk will also cover the emotional factors that parents of double/embryo donation have to contend with such as their own feelings about having a child with no genetic connection to themselves as well as highlighting some of the key topics that come up in working with prospective and actual double and embryo donation parents.

Recent feedback from donor conceived children in the UK who are part of the DC Network tells us that although many of them feel well supported at home and within the family setting, at school and in the broader community this is not always the case. This talk will draw on both personal examples and professional knowledge to highlight why being appropriately open and honest in its broadest sense is so important in supporting children conceived this way as they grow up.

O-153 Embryo donation – new legislation – the case in Israel

O. Balaban-Kasztelanski[1]
[1]*CHEN-Patient Fertility Association, Holon, Israel*

Double donation/embryo donation – The role of NGOs – the Israeli case.

Non Profit Organizations have an important role in Health laws Promotion at the national health level and international level.

While having ministry of health on one side, Pharma industry on second side, professional doctors on third side – we need to look at the forth and most important actor – the patients that are *via* NGOs that have the most influence in Health laws Promotion.

In Israel, there is a strong and valid legislation with regulations regarding double donation.

Regarding embryo donation there is no legislation yet – we applied to the government to prepare it.

The law and regulations regarding double donation are very clear: If a woman need to have double donation she may get an egg donation from Israeli woman but the sperm must come from abroad. It is preferred to be a non Jewish donor.

The concern is not only religion, but genetically concern – to avoid donations that are close genetically. Women can have an egg donation in 7 out of 28 pubic clinics in Israel from an Israeli donor. The sperm must be from abroad as said. The state covered the cost of egg donation but not the price of the sperm. The patient has to pay 10,000 SHEKELS as part of the payment to the donor that is being done *via* the clinic. All the procedure must take place in the clinic.

Cross border is allowed and the state participates in the costs – about 30% is covered. In this case no regulation regarding the sperm or the egg origin.

Embryos donation – new legislation in Israel: In Israel there are more than 150,000 frozen embryos in the laboratories. This is unbearable situation since nothing can be done with it without the parents' permission.

It is high cost to keep them and the current law allowed only 3 options for the parents: (A) To keep the embryos. (B) To unfreeze the embryos. (C) To donate for research.

The option of donating the embryos to other person is not allowed by law.

We started a new legislation to allowed the forth option according the situation of England, Canada and France.

In Israel, the role of NGOs is so important that they keep the systems work. Without the volunteering organizations the system cannot function at all. We are changing laws for the benefit of the patients, we take care of implantation of the systems.

The problem in Israel is that by religion, it is not allowed to a married coupled to receive an embryo donation.

With consultation and cooperation of the ministry of health it was decided to start the procedure of legislation with the following restrictions: (1) The law will be as an adoption law and not donation (like other gamete donation).

(2) The recipient will be only a single woman – to avoid the problem of a married woman carried a pregnancy that does not contain her husband sperm.

(3) The anonymity situation in donation embryos/double gametes is still unclear. The adoption law allows the child to check about his genetically parents at age 18 years old. This issue has to be discussed.

We started the procedure that probably will take few years in the Israeli political situation.

With the cooperation of the ministry of health we gathered the government and the Kenesstt to work together for the preparation of the law. This is one of the strong abilities of NGO in Israel.

INVITED SESSION

SESSION 43: LEGISLATION AND ECONOMICS OF THE EU TISSUE & CELL LANDSCAPE

Tuesday 05 July 2016 **Hall 3 DE** **14:00–15:00**

O-154 Overview of EU legislation applicable for IVF/ART

O-155 Economics for IVF/ART

O-156 Exchange/Q&A on key concerns for the IVF/ART sector on the current EU legal framework

---

INVITED SESSION

SESSION 44: PARAMEDICAL INVITED SESSION - NURSING

Tuesday 05 July 2016 **Room 101** **14:00–15:00**

O-157 Can nurses and midwives help patients cope with treatment?

H. Ockhuysen[1]
[1]*Nieuwegein, Netherlands*

Women often report that an IVF treatment is an emotional and physical burden that causes high levels of anxiety and stress. The moments most reported as stressful are oocyte retrieval, the 14-day waiting period between embryo transfer and pregnancy test, and being informed that the treatment was unsuccessful. Despite the emotional stress reported during fertility treatment, many women do not seek professional support. The stated reasons for this are often practical, such as costs of counselling, distance to the appointment or being unsure how to arrange an appointment. Although women do not often make use of professional psychosocial help, they expect that ongoing emotional support should be part of a fertility treatment delivered by nurses, midwives and doctors working in the fertility clinic.

Nurses have been working in fertility care since the first IVF baby was born and their specialised roles are continually developing and evolving. Nurses are a constant member of the fertility team and are usually more accessible than other members of the fertility clinic. This approachability gives nurse the opportunity to further develop the challenging task to support patients to cope with the several stages of an IVF treatment. Research shows that most fertility nurses regain knowledge for effective practice by experimental learning and professional development activities. One of the challenges in fertility nursing care is to build a bridge between evidence-based practice and daily practice.

This presentation will give a short overview of some evidence-based interventions and methods available for nurses to help patients cope with the several stages of an IVF treatment. Instruments like the SCREENIVF, to identify women or men at risk for emotional maladjustment before the start of a fertility treatment, or the Positive Reappraisal Coping Intervention, to promote the coping strategy positive reappraisal, are examples of evidence based intervention to help patients cope with treatment but also to improve and further develop fertility nursing care.

O-158 Three psychosocial interventions staff could incorporate in routine care today to support patients

J. Boivin[1]
[1]Cardiff University, Cardiff, Wales, UK

Fertility patients have psychosocial and medical needs. Medical needs are mostly well defined and addressed in myriad ways by clinical and paramedical staff. In contrast, psychosocial needs are often poorly defined and addressed primarily through referral to specialised mental health professionals (MHPs). This state of affairs has proved unsatisfactory for numerous reasons (e.g., patient reluctance to consult with MHPs, practical aspects of arranging consultations) with the most importance consequence being that patients often do not get the psychosocial care required to support them during treatment journey. Medical and paramedical staff members often do want to meet patient psychosocial needs but often lack clarity about what can be done, especially what can be done given the constraints of their workload and skill set.

ESHRE recently produced guidelines that can inform on how best to approach psychosocial care from the perspective of fertility clinic staff ("Routine psychosocial care in infertility and medically assisted reproduction: A guide for fertility staff"). The guidelines specify that to best help patients, staff must be empowered to detect and address psychosocial needs (e.g., behavioural, relational, social, emotional, cognitive needs) using effective assessment and interventions. One of the most important patient preferences expressed identified in the ESHRE guidelines was the need for effective information. In particular written, customised information about the treatment procedures and results, and access to psychosocial care. At the time of publication, the provision of information to fertility patients was the only psychosocial intervention found to be effective. In light of this finding and the constraints on staff time, one way that fertility clinic staff can support patients is through provision of information.

In this presentation Information provision in three topic areas that address patient needs will be discussed (quality of life, oocyte retrieval, expectation management). The presentation will illustrate what has been done and what can be done. Also discussed will be how fertility clinic staff can assess and, if needed, improve their own clinic documents using quality assessment tools designed to evaluate the provision of information.

SELECTED ORAL COMMUNICATIONS

SESSION 45: EMBRYO (EPI)GENETICS AND MIRNAS

Tuesday 05 July 2016 **Hall 1** **15:15–16:30**

O-159 The position of the inner cell mass during blastocyst biopsy does not affect clinical results

H. Blanca[1], J. Ten[1], M. Diaz[1], A. Rodriguez-Arnedo[1], J. Guerrero[1], J. Llacer[2], F. Sellers[2], R. Bernabeu[2]
[1]Instituto Bernabeu, Reproduction Biology, Alicante, Spain
[2]Instituto Bernabeu, Reproductive Medicine, Alicante, Spain

Study question: To evaluate the effect of the inner cell mass (ICM) position at the time of trophectoderm biopsy on clinical outcomes.
Summary answer: The position of the ICM at the time of the biopsy does not affect pregnancy and miscarriage rates.
What is known already: Trophoectoderm biopsy allows more accurate genetic diagnosis without apparent embryo damage. Assisted hatching (AH) prior to the biopsy is performed on day 3 because it promotes embryo hatching, making easier the removal of the cells. This process makes the ICM may be inside, outside or in the herniation in the moment of biopsy. Nothing is known about the relation between the position of the ICM and clinical results, such as clinical pregnancy or miscarriage rates.
Study design, size, duration: Prospective study. We include the known clinical results of 157 euploid embryos: 107 of them with the ICM inside (group I), 32 with the ICM outside (group II) and 18 of them with the ICM in the herniation (group III), transferred to 139 women that underwent comprehensive chromosome screening (CCS) treatments from January 2014 to October 2015.
Participants/materials, setting, methods: At least one euploid embryo was transferred to 139 patients. AH was performed on day 3 using laser pulses (Saturn Active, Research Instruments). On day 5 of development, a conventional trophectoderm biopsy was done. The position of the ICM in the moment of biopsy was recorded. Clinical outcomes were evaluated.
Main results and the role of chance: There was no statistically significant difference in the clinical pregnancy rate when the ICM was inside (group I), outside (group II) or in the herniation (group III) (41.3, 48.3 and 45.5%, respectively, $p = 0.794$). The position of the ICM did not affect biochemical miscarriage (10.9% in group I, 6.9% in group II and 16.7% in group III, $p = 0.638$) or clinical miscarriage (14.6% in group I, 10% in group II and 12.5% in group III, $p = 0.877$).
Limitations, reasons for caution: Study currently under development to increase the number of cases and test the study question.
Wider implications of the findings: These results confirm that the position of the ICM in the moment of trophectoderm biopsy does not affect clinical outcomes. In certain cases, where the ICM is outside the embryo, the maneuver during biopsy is more complicated, but this does not seem to affect the outcome of the embryo.
Trial registration number: N/A.

O-160 Direct unequal cleavages: embryo developmental competence, genetic constitution and clinical outcome

N. Zaninovic[1], Q. Zhan[2], Y. Zhen[2], R. Clarke[2], Z. Rosenwaks[2]
[1]The Center for Reproductive Medicine and Infertility, New York, NY, USA
[2]The Center for Reproductive Medicine and Infertility, Reproductive Medicine, New York, NY, USA

Study question: What is the correlation between embryos with direct uneven cleavages (DUCS) and consequent developmental potential, chromosomal constitution and clinical outcome?
Summary answer: Blastocyst formation and embryo implantation were significantly reduced in embryos expressing DUCS. The euploid rate in DUCS embryos were lower compared to normally cleaving embryos.
What is known already: Published time-lapse studies indicated lower developmental and implantation potential of abnormally dividing (direct cleavage) embryos. The sample size of these studies were small, and only described abnormalities at the first embryo cleavage stage.
Study design, size, duration: A retrospective cohort study conducted from November 2011 to June 2014. A total of 21,261 embryos from 3,155 IVF cycles were analyzed.
Participants/materials, setting, methods: Only normally fertilized (2PN) embryos cultured in time-lapse incubators (EmbryoScope®, Vitrolife, Sweden) were included in the study. A total of 21,261 embryos from 3,155 cycles (2,471 ICSI and 684 standard IVF) were analyzed. DUCS embryos were classified into DUC-1 (first cleavage), DUC-2 (second cleavage), DUC-3 (third cleavage) or DUCSPlus (DUCS occurring more than once). Clinical outcome and PGS results were analyzed for DUCS.
Main results and the role of chance: The total incidence of DUCS were 26.1%: 9.78% in DUC-1, 9.06% in DUC-2, and 3.73% in DUC-3. The occurrence of DUCS were not correlated with female gamete age or source. The incidence of DUC-1 was significantly higher in embryos fertilized by epididymal and testicular sperm (13.6 and 11.4%, respectively) compared to ejaculated sperm (9.05%, all $p < 0.05$). DUC-1 incidence was also greater in IVF embryos (11.5%) vs. ICSI embryos (9.1%). The total incidence of DUCS were strongly correlated with the onset of blastomere multinucleation during the first three divisions. In DUCS embryos, the blastocyst formation rates gradually decreased from 40.2% (DUC-3), 18.8% (DUC-2), 8.2% (DUC-1) and 5.6% (DUCSPlus), $p < 0.001$. The D3 FH rate were 12.42% ($n = 3172$) in Non-DUCS, 6.3% ($n = 127$ ET) in DUC-3, and 2.7% ($n = 260$ ET) in DUC-2 embryos. Zero live births resulted from either DUC-1 ($n = 225$ ET) or DUCSPlus ($n = 100$ ET) embryos. Lower FH rates (33.3%) and similar LB rates (40%) were observed in transferred DUCS blastocyst compared to Non-DUCS. The EUP rate gradually increased from DUC-1, -2, -3 to Non-DUC (12.9, 18.2, 31.6, 43.6%, $p < 0.001$) in Day 3 biopsied embryos. Contrarily, the complex abnormalities (CxA) rate gradually decreased with DUCS onset stage (80.6, 47.7, 36.8, 27.1%; $p < 0.001$).
Limitations, reasons for caution: PGS result were based on varying chromosomal platforms; the mosaicism and ploidy could not be fully investigated due to the methodology limitation. Only good quality embryos were biopsied (day 3 or day 5) and might not reflect the true aneuploidy (ANU) prevalence in embryos.

Wider implications of the findings: DUCS embryos occurring in first two cleavage stages should be deselected from D3 transfers, but might still be considered for day 5 transfer if the embryos achieve good quality blastocyst.
Trial registration number: N/A.

O-161 Methylation level of H19/IGF2 differentially methylated region (DMR) in human blastocysts donated by fertile couples

M. Derakhshan-Horeh[1], F. Abolhassani[1], F. Jafarpour[2], A. Moini[3], K. Karbalaie[4], S.M. Hosseini[2], S. Ostadhosseini[2], M.H. Nasr-Esfahani[2]
[1]Tehran University of Medical Sciences, Anatomy, Tehran, Iran
[2]Royan Institute for Biotechnology – ACECR, Reproductive Biomedicine Research Center, Isfahan, Iran
[3]Tehran University of Medical Sciences, Department of Obstetrics and Gynecology, Tehran, Iran
[4]Royan Institute for Biotechnology – ACECR, Cell Science Research Center, Isfahan, Iran

Study question: Considering the possibility of epigenetic errors due to assisted reproduction techniques (ART), this study investigated the DNA methylation status of H19/IGF2 DMR in human blastocyst.
Summary answer: This study showed that the mean methylation status of H19/IGF2 DMR in high quality human blastocyst donated by healthy couples is around 37.85 ± 4.87%.
What is known already: Imprinted genes are a unique subset of few genes, which have been differentially methylated in a parental-origin dependent manner during gametogenesis. Although imprinted genes are specifically protected from the genome wide waves of epigenetic erasure and rebuild occur during pre-implantation embryo development, increasing evidence suggest particular vulnerability of some differentially methylated region (DMR) to interruptions often incur by assisted reproduction techniques (ART). In this study, we used high quality blastocyst donated by healthy couples without any infertility problem or poor-quality embryos to evaluate the epigenetic risks linked to ART.
Study design, size, duration: A total of 20 ICSI-derived blastocysts were donated from 7 different couples with at least two children of the same sex referring for family balancing. All embryos were collected after obtaining the written informed consents signed by couples. Blastocysts were scored according to Gardner et al. (2012) grading system. The peripheral human lymphocytes were used to validation of our technique. The embryos were collected from 2013 to 2015.
Participants/materials, setting, methods: Only blastocysts with A/B quality were selected. Methylation levels of H19/IGF2 DMR in expanded or expanding blastocysts were analyzed by bisulfite conversion and sequencing at 18 CpG sites (CpGs) located in this region. Methylation status of lymphocyte was used to obtain the pattern of imprinted gene methylation in somatic cells. More than 15 clones were sequenced per replicate.
Main results and the role of chance: Results showed that the overall percentage of methylated CpGs and the proportion of hyper-methylated clones of H19/IGF2 DMR in analyzed blastocysts were 37.85 ± 4.87 and 43.75 ± 5.1%, respectively. For validation of our technique the corresponding methylation levels of peripheral human lymphocytes were defined (49.52 ± 1.86 and 50%, respectively). We observed that the methylation status of H19/IGF2 DMR in human blastocysts is lower than the expected methylation level of somatic cells.
Limitations, reasons for caution: It has been stated that small starting amounts of template material, may create amplification bias.
Wider implications of the findings: Since in this study the high grade blastocysts were derived from fertile couples, one possibility are more likely to justify the cause of the observed methylation level: methylation status of DMR are not rigid during pre-implantation development embryo and can be affected at least in part by the genome-wide demethylation
Trial registration number: 1.

O-162 Comprehensive characterization of the human blastocyst's miRNome from the Inner Cell Mass, the Trophectoderm and their related IVF spent culture media

D. Cimadomo[1], L. Rienzi[1], F.M. Ubaldi[1], A. Giancani[1], L. Noli[2], D. Ilic[2], Y. Khalaf[2], A. Capalbo[3]
[1]Clinica Valle Giulia, G.EN.E.R.A. Centre for Reproductive Medicine, Roma, Italy
[2]King's College of London, Guy's Hospital, Division of Women's Health and Assisted Conception Unit, London, UK
[3]GENETYX, Molecular Genetic Laboratory, Marostica, Italy

Study question: From which section of the human blastocyst are miRNAs secreted in spent culture media (SBM) during IVF cycles?
Summary answer: MicroRNAs in SBMs derive mainly from the trophectoderm (TE) and in part also from the inner cell mass (ICM), as consistently confirmed with multiple qPCR platforms.
What is known already: MicroRNAs are non-coding RNA molecules acting as regulators of gene expression. They can be secreted in the extracellular environment and act upon recipient cells. They seem to be involved in the blastocyst-endometrium dialogue aimed at implantation, and mediate the autocrine communication between the cells composing the blastocyst as well. We recently profiled secreted-miRNAs in SBMs during IVF. They are secreted from the time of blastulation onwards, and 2 miRNAs (miR-20a-5p, miR-30c-5p) are significantly more abundant in SBMs from implanted versus unimplanted blastocysts. MicroRNAs are putative biomarkers of implantation and it is crucial to define whether they originate from ICM and/or the TE.
Study design, size, duration: Experimental study conducted at an IVF clinic (London, UK) between 4/2014 and 12/2015 and licensed by the NHS Research Ethics Committee. 10 excellent quality blastocysts (donated from consenting couples) and blanks were used. MiRNome analyses were conducted according to the TaqMan Low-Density Array cards protocol (TLDA protocol; LifeTechnologies, USA) human panel A + B, and confirmed through the microRNA PCR Human panel I + II (EXIQON protocol; EXIQON, Denmark) and single assays at a molecular biology laboratory (Marostica, Italy). 85% of TLDA and EXIQON panels (n = 754 assays) coincide.
Participants/materials, setting, methods: After warming, 10 blastocysts were singularly cultured in 25 µl-microdrops of Quinn's Advantage blastocyst medium (ORIGIO, USA) in a humidified atmosphere (5% O_2, 6% CO_2) for 12 h. After SBM collection, the ICM was biopsied using a previously validated method. 5 Trios (ICM + TE + SBM) were processed with the TLDA protocol (magnetic beads-based extraction + targeted retrotranscription + preamplification + qPCR; validity criteria: Ct ≤35 in ≥3/5 ICMs/TEs/SBMs). Data were confirmed on the other 5 Trios through the EXIQON protocol (column chromatography-based extraction + universal retrotranscription + LNA primers – SYBR Green-based qPCR; validity criteria: Ct ≤39 in ≥3/5 ICMs/TEs/SBMs).
Main results and the role of chance: The raw data Pearson's correlation according to the TLDA protocol ranged 0.82–0.87 within biological groups (only-ICMs/only-TEs/only-SBMs) and 0.74–0.83 between them. 133 miRNAs (range 127–146) were found valid in the TEs (overall mean Ct: 29.0 ± 4.1, range 13.3–34.9), 64 (72–83) in the ICM (29.3 ± 3.6, 13.0–34.9) and 71 (65–91) in the SBMs (30.0 ± 3.9, 13.9–34.9) according to the TLDA protocol. 49 miRNAs were exclusively expressed by the TEs, 13 and 20 were shared only with the ICMs and the SBMs, respectively. No miRNA was found solely in ICMs or SBMs. 51 miRNAs were shared by all the three biological groups. 55.0% (n = 28/51; 95% CI = 41.35–68.65%) of these last miRNAs were confirmed and validated through the EXIQON protocol.

A pathway analysis was conducted through the DIANA-miRPath software. 91 pathways were significantly predicted to be regulated by these 28 blastocyst-specific miRNAs: 38.5% involved in biosynthesis, apoptosis and differentiation, 28.6% involved in cell signaling and communication, 19.8% in cell growth and cancer and 13.2% in inflammation and angiogenesis.

We performed a differential expression of the normalized data in TEs versus ICMs. 10 and 1 miRNAs were found significantly ($p < 0.05$) upregulated in the ICMs (fold-change range 8–60.7) and in the TEs (fold-change 14.8), respectively. These miRNAs are all involved in promotion/inhibition of cell growth and/or stress-response by directly/indirectly influencing cell cycle regulation and apoptosis.
Limitations, reasons for caution: Due to a different layout, not all miRNAs within the TLDA panels could be confirmed by the independent EXIQON protocol. However, most of the miRNAs common to both the platforms showed a good consistency, as confirmed also through single assays. Only excellent quality blastocysts and relative SBMs were analyzed.
Wider implications of the findings: In this study we outlined the cellular origin of the miRNAs in SBMs and their possible roles within the blastocyst and in the blastocyst-endometrium dialogue. Furthermore, these data represent an initial step to define how miRNAs influence the mechanisms of differentiation/loss of pluripotency at this stage of preimplantation development.
Trial registration number: None.

O-163 MicroRNAs in spent blastocyst culture media: assays have to be improved

A. Reignier[1], J. Lammers[1], C. Splingart[1], A. Catteau[1], L. David[2], P. Barriere[1], T. Freour[1]
[1]*CHU Nantes, Biologie et médecine de la reproduction, Nantes, France*
[2]*INSERM UMR 1064, IPSc Plateform, Nantes, France*

Study question: Is it possible to detect and measure microRNAS (miRNA) in blastocyst spent culture media with enough sensitivity, specificity and reproducibility to use them as biomarkers of implantation potential?
Summary answer: MicroRNAs purification and detection methods have to be improved to fit with small amount of miRNAs and small sample volumes before being used in ART.
What is known already: MiRNAs are now well known to be involved in regulation of gene expression. Human embryos have been shown to secrete miRNAs that can be detected in IVF culture media. It has also been reported in preliminary studies that some of these miRNAs were differentially expressed according to the fertilization method, embryo chromosomal status, and pregnancy outcome. Those miRNAs are likely to be secreted by the trophectoderm.
Study design, size, duration: Spent blastocyst culture media (G2 Plus, Vitrolife) from single transferred blastocyst were prospectively collected on the day of embryo transfer (day 5 or 6 post fertilization) and immediately frozen at –80°C. Sixteen of them were randomly selected to be analyzed. Each sample was analyzed in duplicate.
Participants/materials, setting, methods: Mir-25 and mir-191, two miRNAs previously described as being present in embryo culture media, were assayed after phenol/guanidine-based lysis of samples and silica-membrane–based purification of total RNA (2 eluates for each sample) followed by Reverse Transcription and real time Sybr-Green qPCR (QIAGEN). A Nanodrop (Thermo Fischer) was used to quantify total RNA extraction. DNA samples migration (LabChipGX, PerkinElmer) was then analyzed to validate the specificity of DNA amplification and detection.
Main results and the role of chance: Total RNA extraction led to a mean total amount of 10.91 ± 7.23 ng/µL of RNA in culture medium. The mean CT values for miRNA detection were 33.80 ± 1.71 whereas CT values for blank samples were 58. Two duplicates had more than one gap CT value. Mir-25 and mir-191 had both a good quality detection aspect on the melt-curves for most of the samples. However, only few samples for mir-191 detection and none of the samples for mir-25 detection showed a specific strip (around 65 bp) after migration on a nanochip (Caliper). These results suggest that the assay methods have to be improved to be efficient enough to detect small amount on miRNAs in small volumes and used in clinical research.
Limitations, reasons for caution: Only one Sybr-Green assay has been tested: Taqman technologies and other purification methods may give better results.
Wider implications of the findings: The use of miRNAs as biomarkers of embryo viability and implantation potential still needs to be improved before being used as a way to improve assisted reproductive technologies outcomes.
Trial registration number: None.

O-164 Regeneration of endometrial function such as establishment of pregnancy by endometrial cell sheet transplantation

G. Kuramoto[1], T. Shimizu[2], S. Takagi[2], K. Ishitani[3], T. Okano[2], H. Matsui[3]
[1]*Tokyo Women's Medical University, Department of Obstetrics and Gynecology, Institute of Advanced Biomedical Engineering and Science, Tokyo, Japan*
[2]*Tokyo Women's Medical University, Institute of Advanced Biomedical Engineering and Science, Tokyo, Japan*
[3]*Tokyo Women's Medical University, Department of Obstetrics and Gynecology, Tokyo, Japan*

Study question: Can a regenerative-medicine technique using cell sheets become a new treatment method for endometrial disorder causing female infertility?
Summary answer: Regeneration of the endometrium following the transplant of an endometrial cell sheet created through cell sheet engineering led to a confirmed establishment of pregnancy.
What is known already: Endometrial disorder, i.e., Asherman's syndrome can cause infertility due to severe endometrial adhesions caused by severe endometrial defects including stem cells defects, therefore general therapy such as surgical synechiotomy is ineffective.

A new approach called "cell sheet engineering," which can harvest confluent-culture-cells as a contiguous cell sheet with intact cell–cell junctions and extracellular matrix without enzymatic treatment, has been developed for tissue regeneration.
Study design, size, duration: The control group only underwent resection of the endometrium, whilst the transplantation group received a transplant of a green-fluorescent-protein (GFP) positive cell sheet into the resected endometrium site. The groups were compared using macroscopic findings and histological analysis including immunohistochemistry. Following that, cross breeding was performed to confirm establishment of pregnancy in the regenerated uterus.
Participants/materials, setting, methods: GFP positive endometrial tissues were treated with trypsin/EDTA. Two kinds of cell sheets (epithelium and stroma) were produced from the isolated cells separated by pre-plate method, harvested from temperature-responsive-cell-culture dishes by reducing the temperature. Layered cell sheets were assembled from the two kinds of cell sheets, and transplanted into the endometrial resected site. The regenerated uterus was evaluated for the existence of GFP positive, and establishment of pregnancy was evaluated by ultrasound after crossbreeding.
Main results and the role of chance: At 4 weeks after surgery, in the transplanted cell sheet group, a wide GFP positive site was found. On the other hand, in the control group, a wide area of occlusion was found. In a histological analysis, a large GFP positive area was found, and luminal structure was confirmed uniformly. Endometrial glands were found with CK18 and GFP in a similar to normal uterine structure in the stromal layer.

After cross breeding, a GFP positive gestational sac (GS) was found in the transplantation group. On the other hand, in the control group, no GS was found. And in the cross section of the GS and in a histological analysis, a wide and circumferential area of GFP positive tissue was found.
Limitations, reasons for caution: The results are difficult to apply directly to humans, because the structure and function of rat uteri are different from those of humans.
Wider implications of the findings: Transplantation of endometrial-cell-sheets have a high possibility not only to prevent intrauterine re-adhesion after synechiotomy, but also to regenerate the endometrium. The regenerated endometrial tissues might have a normal function such as menstruation and implantation of a fertilized egg.
Trial registration number: Not applicable.

O-165 Should patients be immobilised after intrauterine insemination? A randomised controlled comparison between 15 min of immobilisation and direct mobilisation

J. van Rijswijk[1], M. Caanen[1], Y. Ammi[1], V. Mijatovic[1], C. Vergouw[1], C. Lambalk[1], R. Schats[1]
[1]*VU medical Center, Division of Reproductive Medicine, Department of Obstetrics and Gynaecology, Amsterdam, Netherlands*

Study question: Does 15 min of immobilisation after intrauterine insemination (IUI) effect pregnancy rates?
Summary answer: Immobilisation of 15 min after IUI does not effect pregnancy rates.
What is known already: IUI is an established treatment for couples with mild male or idiopathic subfertility. It has been shown that several factors are related to pregnancy outcomes, however up to now no consensus exists on whether direct mobilisation is beneficial for pregnancy outcomes. Two recent studies report a beneficial effect of immobilisation, though these studies can be criticised due to a lack of power or low overall pregnancy rates and a variation of the use of ovarian stimulation. Besides, the potential responsible mechanism for the benefit of immobilisation remains unclear.
Study design, size, duration: Single center randomised controlled trial, based in an academic setting. 500 patients were approached between August 2010 and May 2014. To account for an increase of 2–3% per cycle of the ongoing pregnancy rate by immobilisation [as shown by Custers et al. (2009)], the study was calculated to include 229 patients per study-arm (alpha of 5% and beta of 80%).

Participants/materials, setting, methods: 479 patients diagnosed with idiopathic or mild male subfertility and an indication for IUI (1934 cycles) were randomised. Randomisation was stratified for the diagnosis idiopathic or mild male subfertility. 236 participants were assigned to 15 min of immobilisation (950 cycles), and 243 participants to immediate mobilisation (984 cycles). The primary outcome was the cumulative ongoing pregnancy rate per couple.
Main results and the role of chance: Patients characteristics were comparable between the two groups, except for the duration of subfertility [2.4 years (IQR 1.8–3.6) in the immobilisation group, 2.1 years (IQR 1.6–3.0) in the mobilisation group (*p*-value 0.017)]. The cumulative ongoing pregnancy rate per couple was not significantly different between the two groups: in total, 76 ongoing pregnancies (32.2%) were accomplished after 15 min of immobilisation versus 98 ongoing pregnancies (40.3%) after immediate mobilisation [OR 0.70 (95% CI 0.483–1.022), *p*-value 0.065)]. The odds ratio, after correcting for duration of subfertility, did not reach statistical significance either: OR 0.72 (95% CI 0.491–1.044, *p*-value 0.082). The Kaplan–Meier survival curves for time to pregnancy were not found to be different for the immobilisation and mobilisation group (median survival time 15.1 versus 11.7 months, *p*-value log-rank test 0.11).
Limitations, reasons for caution: Due to discontinuation of the treatment (social reasons, treatment alteration) not all participants reached six IUI cycles or an ongoing pregnancy, however this is as expected in IUI treatment and it mirrors clinical practice. These participants were equally distributed over the two groups.
Wider implications of the findings: This study shows that immobilisation after IUI has no positive effect on pregnancy rates. It even tends to the opposite. In our opinion, there is no reason why patients should stay immobilised for 15 min after IUI. This result is in disagreement with the literature, a meta-analysis is needed.
Trial registration number: Dutch Trial Register, NTR 2418.

O-166 Uterine fluid-derived extracellular vesicles as a new non-invasive tool to assess endometrial features

P. Viganò[1], E. Giacomini[1], P. Scaruffi[2], A.M. Sanchez[1], P. Giardina[3], R. Vago[4], S. Stigliani[2], N. Zarovni[5], G. Radano[5], A. Alteri[3], A. Quagliariello[3], D. Del Prato[3], E. Papaleo[3]

[4]*IRCCS San Raffaele Scientific Institute and Università Vita-Salute San Raffaele, Urological Research Institute, Milan, Italy*
[5]*Exosomics Siena S.p.A, R&D, Siena, Italy*

Study question: Do extracellular vesicles (EVs) isolated from uterine fluid contain endometrial status biomarkers?
Summary answer: Molecular characterization of uterine fluid-derived EVs reveals a number of biomolecules (proteins, mRNA, DNA) that could be useful to enhance "liquid biopsy" performance.
What is known already: The potential value of uterine fluid and of its contents as biomarkers of different aspect of human endometrial pathophysiology has been well recognized but so far its use has been limited by the restricted amount of fluid available. For the first time uterine fluid-derived EVs were identified by Hunt Ng et al. (2013). EVs are a heterogeneous group of nanoparticles (~30–1000 nm) that are secreted by a variety of cell types, representing a possible vehicle of clinical and biological information. From a diagnostic standpoint, levels of EVs or their specific content have been recognized as markers for different diseases/physiological mechanisms.
Study design, size, duration: Uterine fluids were aspirated through an IVF transfer catheter from a total of $n = 15$ reproductive age patients undergoing diagnostic hysteroscopy. Experiments have been performed collecting samples of 2–3 µL of uterine fluid or obtained by lavage with 2.5 mL of sterile saline.
Participants/materials, setting, methods: Uterine fluid samples were subjected to differential standard ultracentrifugation to isolate EVs. The nature of the EVs was demonstrated using transmission electron microscopy and by western blot analysis using specific EVs biomarkers. Total RNA from EVs was analyzed by 2100 Bioanalyzer. Amplification of mRNA of genes involved in endometrial pathophysiology was done. A fragment of the mitochondrial MT-7S D-loop region and of the RNAse P gene was specifically amplified.
Main results and the role of chance: Our explorative analysis confirm previous information and indicate that uterine fluid is extremely rich in EVs population, composed by exosomes (30–150 nm) and microvesicles (150–1000 nm). These results tend to support the possibility to isolate a consistent amount of EVs-derived biological material from few microliters of uterine fluid. Importantly, EVs in uterine fluid contain large amounts of multiple and heterogeneous RNA species, that could be used to study levels of expression of genes known in endometrial pathophysiology. Slight quantity of ribosomal RNA (28S and 18S) was detected in the samples analyzed. The PCR amplifications indicate a strong presence of Beta-Actin (ACTB), Cyclooxygenase-2 (COX2) and Wingless-Type MMTV Integration Site Family, Member 4 (WNT4) transcripts and of Aromatase (CYP19) transcripts traces in both exosomal and microvesicular population. These genes are involved in different important endometrial physiological and pathological process such as proliferation, differentiation, inflammation and endometriosis. Interestingly for its rarity, gDNA and mtDNA were detectable in all the uterine fluid-derived EVs tested. Take together these preliminary results help us to bio-characterize the EVs from uterine fluid in order to better understand the extracellular signals carried by uterine fluid.
Limitations, reasons for caution: This is an explorative analysis of a pilot study.
Wider implications of the findings: This study supports the possibility to isolate a consistent amount of uterine fluid-derived EVS from few microliters. The potential use of non-invasive endometrial signals as a "liquid biopsy" represents the novelty of this study. This would potentially allow reducing surgical interventions currently performed to establish endometrial dysfunctions and fertility parameters.
Trial registration number: No clinical trial.

O-167 Controlled ovarian Hyperstimulation (COH) and intrauterine insemination (IUI) vs. *In Vitro* Fertilisation (IVF) for the first line treatment of unexplained subfertility – a randomised controlled trial

A. Nandi[1], A. Gudi[1], A. Shah[1], R. Hooper[2], K. Khan[2], R. Homburg[1]
[1]*Homerton Hospitals NHS Trust, Fertility Unit, Homerton, London, UK*
[2]*Queen Mary University, Blizard Institute, London, UK*

Study question: What is the best first line management option to the treatment of unexplained subfertility, Controlled Ovarian Hyperstimulation (COH, with gonadotrophin) and Intrauterine Insemination (IUI) or *In Vitro* Fertilisation (IVF)?
Summary answer: Results suggest that three cycles of COH (with gonadotrophin) + IUI is as effective as one cycle of IVF with comparable on-going, multiple pregnancy rates.
What is known already: Debate continues whether IVF should be the sole treatment for couples with unexplained subfertility. The 2013 NICE fertility guideline recommends not routinely offering IUI to these couples but proceeding directly to IVF after 2 years of subfertility. The literature indicates that although the per-cycle success rate of IUI is lower than that of IVF, cumulative IUI success rates are comparable to IVF. IUI remains less invasive, less stressful and less time consuming than IVF, with better perinatal outcome for singletons. Only few RCTs have conducted head to head comparison of IUI + COH and IVF in unexplained sub fertility.
Study design, size, duration: This is a single centre parallel group randomised controlled trial (RCT) with balanced randomisation (1:1), conducted in a tertiary referral centre in London, UK. Between June 2013 and June 2015 we recruited 207 couples with unexplained subfertility. They were randomly allocated to three cycles of COH (with gonadotrophin) + IUI ($n = 101$) or one cycle of IVF ($n = 106$).
Participants/materials, setting, methods: Couples with subfertility of minimum 1-year duration, where the female partner was ovulatory, aged 23–38 years, both tubes patent, without any uterine abnormality and the male partner with normal semen parameters (WHO criteria), were recruited. Though the primary outcome was live birth/couple, we report here the on-going pregnancy rate (as the delivery of all participants is not yet complete). Outcomes were analysed according to intention to treat.
Main results and the role of chance: The mean age of the female partner was 31.9 years (SD 3.3), mean BMI 23.6 (SD 3.01), mean AMH of 22.04 (SD 15.8) and mean AFC 16.5 (SD 8.2). The mean duration of subfertility was 3.02 years

(SD 1.8). Out of 101 couples allocated to COH (with gonadotrophin) + IUI, 90 couples started their first cycle and 69 couples completed all three cycles and the on-going pregnancy rate per couple was 22 out of 101 (21.8%), and the cumulative conception rate 31.9%. Out of 106 couples allocated to IVF group, 81 completed one cycle and the on-going pregnancy rate per couple was 36 out of 106 (33.9%). The relative risk of pregnancy was 0.64 (95% CI 0.40–1.01) in IUI + COH compared to IVF. The multiple pregnancy rates per on-going pregnancy were 9.1% after COH + IUI and 8.3% after IVF. All multiple pregnancies in the COH + IUI group were twins. There were one set of triplets and two sets of twins in the IVF group. Out of 207 couples, 18 conceived spontaneously before or in between treatments and 17 couples had on-going pregnancies (8.2% per couple). There were 3 OHSS cases in the IVF group (2.8%).

Limitations, reasons for caution: These are preliminary result based on on-going pregnancy rates without, as yet, the live birth data for all pregnancies.

Wider implications of the findings: The results of this prospective RCT rules out any clinically important benefit of IVF over COH + IUI for unexplained subfertility, with similar on-going and multiple pregnancy rates between the two treatments. This questions the wisdom of directing couples with unexplained subfertility directly to IVF instead of first employing COH + IUI.

Trial registration number: ISRCTN43430382.

O-168 Proteomic assessment of the endometrial fluid the day of embryo transfer as a prognostic factor of implantation in *In Vitro* Fertilization

R. Matorras[1], S. Quevedo[1], B. Corral[2], A. Rabanal[1], M. Ferrando[3], A. Exposito[1], A. Ametzazurra[2], D. Nagore[2]
[1]*Cruces Hospital, Human Reproduction Unit, Baracaldo, Vizcaya, Spain*
[2]*Griffols, Proteomic Unit, Bilbao, Spain*
[3]*IVI Bilbao, Human Reproduction Unit, Bilbao, Spain*

Study question: To evaluate the influence of the proteomic composition of endometrial fluid at embryo transfer in implantation in *In Vitro* Fertilization (IVF) programs.

Summary answer: Endometrial fluid provides information of clinical relevance concerning embryo implantation. Obtaining the endometrial fluid by aspiration at embryo transfer does not impair IVF results.

What is known already: The implantation is a dynamic process that occurs between the blastocyst and endometrium, and an inadequate endometrium can be considered as a determining factor in IVF failure. Endometrial tissue has been studied by several methods and a large number of proteins and other molecules are expressed in the endometrium. Our research group has developed a non-invasive approach to analyse endometrial markers of receptivity in endometrial fluid aspirated (EAF) during the window of implantation

Study design, size, duration: It is a non therapeutical intervention study, without changes in the clinical or pharmacological protocol, except for performing an aspiration of endometrial fluid at the moment of embryo transfer.

For the safety analysis, the control group was constituted by the patients assisted at our unit where EAF was not performed

Participants/materials, setting, methods: The study population consisted of 600 patients subjected to IVF at our center during a 18-month period. They were subjected to standard IVF/ICSI according to our protocol except the performance of endometrial fluid aspiration.

The endometrial fluid sample was aspirated from uterine cavity (50–100 µl) by introducing an "embryo-transfer" cannula and stored at −80°C.

For extraction and identification of the endometrium proteome "electrophoresis 2D" and "mass spectrometry" were performed.

Main results and the role of chance: Differential proteomic pattern was observed in patients achieving pregnancy (A group) and those whom pregnancy had not been achieved (B group).

We identified 31 proteins regulated differentially; fourteen of them are development, cytoskeleton and chaperon-related proteins.

The majority of these proteins were downregulated (n = 10), most of them with 0.4–0.7 fold change in relative abundance between both groups. However, some other proteins (n = 4) were overexpressed with more than 1.5-fold change.

Concerning safety, pregnancy rates were compared between patients subjected to endometrial fluid aspiration (EAF) and patients assisted at our Unit during the same period of time whom EAF was not performed. The rates were similar in both cases, the women subjected to EAF aspiration (33%) as the women whom EAF was not performed (30%).

Limitations, reasons for caution: With the available technology the endometrial fluid and its proteomic analysis (PA-EFA) require a highly complex laboratory and their results are not helpful to modify the embryo transfer policy. Developing a technology that could produce our results in a short period of hours would be useful.

Wider implications of the findings: Endometrial fluid aspiration followed by proteomic assessment could be an important tool in the decision process to ascertain the number of embryos to be transferred as well as the day of the cycle to perform the embryo transfer (ET), or even to delay ET to a later cycle.

Trial registration number: CIC-2010092.

O-169 The sirtuin 1 activator resveratrol modulates the retinoic acid signaling pathway and inhibits the expression of decidual markers in primary human endometrial stromal cells

A. Ochiai[1], K. Kuroda[1], S. Quenby[2], J.J. Brosens[2], R. Ozaki[1], A. Matsumoto[1], S. Takeda[1]
[1]*Juntendo University Faculty of Medicine, Department of Obstetrics and Gynaecology, Tokyo, Japan*
[2]*Warwick Medical School Clinical Science Research Laboratories, Division of Biomedical Sciences, Coventry, UK*

Study question: To investigate the impact of resveratrol on decidualization and the retinoic acid (RA) signaling pathway of human endometrial stromal cells (HESCs) *in vitro*.

Summary answer: Resveratrol induced PPARbeta/delta and PPARgamma and suppressed CRABP2 and RARalpha expression, however, suppressed decidual markers (PRL and IGFBP1) in differentiating HESCs

What is known already: Our previous study has shown that RA signaling pathway plays a significant role in balancing differentiation and apoptosis upon decidualization of the peri-implantation endometrium. The polyphenolic compound resveratrol is a natural activator of SIRT1 and protects against oxidative stress and cellular senescence *via* various signaling cascades, including the RA signaling pathway. Clinically, resveratrol may potentially be useful to protect against ovarian aging, although its effect on endometrial decidualization is not known.

Study design, size, duration: This study was approved by the Local Ethics Committee of Juntendo University, Faculty of Medicine (No. 14-103). Timed endometrial biopsies (LH + 7–11) were processed for primary HESC cultures.

Participants/materials, setting, methods: Primary HESCs were decidualized with 8-bromo-cAMP, progesterone in the presence or absence of resveratrol (100 µM). Various molecular techniques, including immunostaining, RTQ-PCR, and Western blot analysis, were employed to define the role of resveratrol treatment.

Main results and the role of chance: Treatment of HESCs with resveratrol increased the expression of SIRT1. Decidualization of HESCs in the presence of resveratrol selectively inhibited the expression of the RA-binding protein, CRABP2, and RA receptor, RARalpha (associated with apoptosis induction) but induced the expression of the alternative RA receptors, PPARbeta/delta and PPARgamma (associated with cell differentiation). However, resveratrol also inhibited the induction of classical decidual markers, such as PRL and IGFBP1. Transient treatment of HESCs with resveratrol prior to the addition of 8-bromo-cAMP and progesterone did not affect the expression of decidual markers.

Limitations, reasons for caution: *In vitro* findings do not necessarily reflect the complex *in vivo* situation.

Wider implications of the findings: Resveratrol treatment may potentially be useful to attenuate ovarian aging and improve oocyte quality but our findings suggest that it may also adversely impact on implantation by interfering with the decidual transformation of the endometrium. Furthermore, optimal decidual transformation of primary cultures may involve apoptosis or senescence of specific subpopulations.

Trial registration number: None.

O-170 Mono-2-ethylhexyl Phthalate inhibits human extravillous trophoblast invasion *via* PPARγ pathway

F. Gao[1], W. Hu[2], Y. Li[2], H. Shen[1], J. Hu[2]
[1]*People's Hospital, Peking University, Reproductive Center, Beijing, China*
[2]*Peking University, Urban College, Beijing, China*

Study question: Is the invasive potential of the human extravillous trophoblast cell influenced by mono-2-ethylhexyl phthalate (MEHP) – the primary metabolism of Di-(2-ethylhexyl) phthalate (DEHP)?
Summary answer: MEHP exposure inhibited the invasion of extravillous trophoblast *via* peroxisome proliferator-activated receptor γ (PPARγ) even at a concentration found in humans.
What is known already: Di-(2-ethylhexyl) phthalate (DEHP) is one of the most common environmental contaminants. Exposure to DEHP has been associated with early pregnancy loss in humans; however, the involved mechanism remains unclear and the invasive function of extravillous trophoblast exposed to mono-2-ethylhexyl phthalate (MEHP), the primary metabolism of DEHP, have rarely been studied. Extravillous trophoblast invasion is an important physiological step during embryo implantation in early development. However, there is no data concerning the effects of MEHP, the active metabolite of DEHP, on the extravillous trophoblast invasion.
Study design, size, duration: This study was designed to investigate the invasion of the human extravillous trophoblast cell line HTR-8/SVneo treated by MEHP and the underlying mechanism.
Participants/materials, setting, methods: Human extravillous trophoblast cell line HTR-8/SVneo cells were exposed to different concentrations of MEHP (1, 10, 100, 200 and 400 μM). Cell invasion was evaluated using Matrigel-coated transwell chambers and the expression of matrix metalloproteinases (MMPs) and their inhibitors (tissue inhibitor matrix metalloproteinases, TIMPs) involved in cell invasion were analyzed. Both pharmacological inhibitors and shRNA knockdown were used to determine the potential molecular targets responsible for the MEHP-inhibited trophoblast invasion.
Main results and the role of chance: After exposed to MEHP (1, 10, 100, 200 and 400 μM), the invasion index of HTR-8/SVneo was reduced to 89.1 ± 11.1, 74.4 ± 3.6, 64.7 ± 6.9, 62.3 ± 1.4 and 49.1 ± 7.8% of the DMSO control in the 1, 10, 100, 200 and 400 μM MEHP exposure groups, respectively. The concentration of MEHP that significantly inhibited trophoblast invasion was as low as 10 μM ($p < 0.05$), which was at a similar level to the MEHP concentration found in humans reported in previous studies. Down-regulation of MMP-9 expression by MEHP further supported its inhibition of HTR-8/SVneo invasion at the molecular level. Inactivation of PPARγ by either pharmacological inhibitors or shRNA knockdown blocked the MEHP-induced effects on HTR-8/SVneo invasion, accompanying with the recovery of inhibited MMP-9 expression.
Limitations, reasons for caution: Although HTR-8/SVneo cells are functionally similar to primary human trophoblast and widely used to study the invasive behavior of human trophoblast *in vitro*, there may be different between these cells and their *in vivo* counterpart such as gene expression.
Wider implications of the findings: The present study provides the first evidence that MEHP exposure inhibited the invasive function of human trophoblast cells even at a concentration found in humans. These findings may contribute to the DEHP-associated early pregnancy loss, and provided the novel evidence of the potential influence of phthalate on female reproduction.
Trial registration number: There is no trial registration number.

O-171 G-CSF increases Treg cell recruitment to the decidua during the first trimester in women with a history of recurrent miscarriage: possible involvement of β-hCG chemoattraction

N. Mansouri-Attia[1], D. Ritsick[1], M. Campbell[1], K. Carlson[1], A. Vidali[1], J. Braverman[1]
[1]*Braverman Reproductive Immunology, Research Department, New York City, NY, USA*

Study question: The goal of the study was to determine if G-CSF treatment affects regulatory T (Treg) cell recruitment to the decidua during the first trimester.
Summary answer: Our results show that G-CSF enhances normal Treg cell emigration from the peripheral blood, reflecting increased migration of these cells to the decidua.
What is known already: The key role of antigen-specific Treg cells in regulating tolerance to the semi-allogenic fetus in mammals is now well established. Published studies disagree however regarding whether Treg cells increase or decrease in peripheral blood of pregnant human subjects, and the effects of immunomodulatory agents on Treg cells in pregnancy remain largely unknown. A better understanding of Treg cells dynamic during human pregnancy may provide an opportunity for monitoring of immunological function and effects of immunomodulatory agents in pregnant patients.
Study design, size, duration: This retrospective study included women with a history of recurrent miscarriage (RM) treated with G-CSF (Neupogen; "Group B," $N = 74$) or other treatment (Intralipid and/or prednisone; "Group A," $N = 82$).
Participants/materials, setting, methods: Treatment was initiated at ovulation and discontinued at week 12 of pregnancy. Blood was drawn and levels of total white blood cells (WBCs), Treg cells, β-hCG and G-CSF were assessed at various time points (T_0 = pre-pregnancy; T_1 = 4–5 weeks; T_2 = 6–9 weeks; T_3 = 10–12 weeks; T_4 = 13–17 weeks). Treg cells were identified as $CD3^+CD4^+CD25^{hi}CD127^{lo}FoxP3^+$ by flow cytometry.
Main results and the role of chance: Relative to T_0 levels, Treg cells decreased in peripheral blood by 22% at T_1, 39% at T_2, and 42% at T_3 before rebounding back to 50% by T_4 in Group A. G-CSF significantly enhanced the decrease in Treg cell levels at T_1 and T_2, with Treg cells decreasing by 61% ($p < 0.001$) and 56% ($p = 0.09$) at these time points. The G-CSF enhanced the decrease in peripheral blood Treg cells, that was greater at T_1 in patients with ongoing pregnancies as compared with those that subsequently miscarried. Levels of WBCs increased in Group A at T_1–T_4, which was amplified by G-CSF, and levels of WBCs and Treg cells were strongly inversely correlated at all time points in both groups ($R = -0.98$ in Group A and $R = -0.8$ in Group B). Additionally, b-hCG levels were increased in G-CSF-treated patients and were inversely correlated with peripheral blood Treg cell levels. These data confirm previous studies showing a decrease in peripheral blood Treg cell levels during the first trimester due to recruitment to the decidua. The data further show an enhancement of this migration by treatment with G-CSF which is correlated with increased levels of β-hCG, a known chemoattractant for Treg cells which express the LH/CG receptor.
Limitations, reasons for caution: x.
Wider implications of the findings: Increased recruitment of Treg cells to the decidua by G-CSF suggests a mechanism by which this treatment promotes fetal tolerance and pregnancy maintenance in women with a history of RM. We propose a model whereby G-CSF increases trophoblast β-hCG production leading to increased Treg cell chemoattraction to the decidua.
Trial registration number: x.

O-172 Endometrial receptivity and miscarriages: crucial roles of endometrial microRNAs

L. Drissennek[1], D. Haouzi[1], Y. Antoine[1], F. Entezami[2], C. Avril[3], A. Gala[4], T. Mullet[4], S. Hamamah[4]
[1]*INSERM U1203-IRMB, Hôpital Saint-Eloi, CHRU Montpellier, Montpellier, France*
[2]*Laboratoire Eylau-UNILABS-La Muette, Clinique de La Muette-Ramsay-Générale de Santé, Paris, France*
[3]*Clinique Mathilde, Maternité, Roeun, France*
[4]*Hôpital Arnaud de Villeneuve, CHRU Montpellier, Département de Biologie de la Reproduction, Montpellier, France*

Study question: Are there miRNAs in endometrial tissue during the implantation windows predicting early miscarriage after fresh or frozen embryo replacement?
Summary answer: We identified 126 miRNAs differentially expressed in receptive endometrium between pregnant patients ending in a live birth compared with those who have had a miscarriage.
What is known already: The rates of miscarriages within the framework of the replacement of fresh or frozen-thawed embryos in patients under hormone replacement therapy remain a major problem in IVF/ICSI. However, to date, there are extremely few studies analyzing molecular signature in endometrial tissue during the implantation windows in pregnant patients associated to miscarriages.
Study design, size, duration: Endometrial biopsies ($n = 10$) were collected during the implantation windows under hormone replacement therapy

(6–9 days after progesterone administration). Then RNAs were extracted for mRNA and miRNA purification to perform RT-qPCR gene expression and the miRNA expression profile, respectively. The RT-qPCR gene expression consists of measuring the expression level of 13 transcripts associated to the endometrial receptivity by RT-qPCR (Window Implantation Test; Patent EP10305561.2).
Participants/materials, setting, methods: Endometrial biopsies were obtained from 10 patients with repeated implantation failure (≥3). The endometrial receptivity status was asserted. Fresh or frozen-thawed embryo replacement has been performed according to the qRT PCR transcriptomic approach result allowing successful pregnancy and live birth. miRNA expression profiles between the two groups of pregnant patients ending with a miscarriage (n = 5) between 8 and 12 weeks period of amenorrhoea and live birth (n = 5), were evaluated with the *Affymetrix® miRNA 4.1 Array Strips.*
Main results and the role of chance: Using 3 distinct statistical analyses (Student's t test, Wilcoxon signed-rank test and ANOVA), we identified 126 miRNAs differentially expressed pregnant patients achieving live birth versus a miscarriage. These 126 miRNAs were all over-expressed in endometrium analysed during the implantation windows of subsequent pregnant patients succeeding to a miscarriage. Using the Ingenuity software, we first aimed to identify the potential he potential target genes of these microRNAs. We identified 28 microRNAs that are putative regulators of 11,062 genes attached to numerous biological functions including the leukocyte extravasation signalling, the regulation of the epithelial–mesenchymal transition pathway, the complement system, the chemokine signalling, the epithelial adherent junction signalling and the growth hormone signalling that play a crucial in implantation and maintain of pregnancy.
Limitations, reasons for caution: The number of samples used for microRNA analyses are low. However, the relevance of these biomarkers is being validated in independent large cohort of patients.
Wider implications of the findings: The identification of endometrial miRNAs associated to a miscarriage opens new perspectives in patient care management. In addition, it would be possible to select strategies by which miRNA technologies (antagomiRs, agomiRs) might be utilized in novel, non-hormonal therapeutic approaches to avoid miscarriages and consequently, to increase the pregnancy rate.
Trial registration number: Not applicable.

O-173 NLRP7 mutations in spontaneous abortions with multilocus methylation defects at imprinted genes from woman with recurrent pregnancy loss

E. Sazhenova[1], T. Nikitina[1], N. Skryabin[1], I. Lebedev[1]
[1]*Institute of Medical Genetics, Russian Academy, Tomsk, Russia*

Study question: Is there association between mutations in *NLRP7* and multilocus methylation defects (MLMD) in imprinted genes in spontaneous abortions (SA) from women with recurrent pregnancy loss?
Summary answer: We found the association between mutations in *NLRP7* and MLMD in imprinted genes in SA from women with recurrent pregnancy loss.
What is known already: Previously we have reported that the MLMD at imprinted genes may cause karyotypically normal miscarriage in natural cycle, particularly among women experiencing recurrent miscarriage (Lepshin et al., 2014). The *NLRP7*, *NLRP2* and *ZPF57* genes have maternal effect that is essential for maintaining of genomic imprinting (Messerschmidt et al., 2012). In addition, mutations in *NLRP7* were associated with MLMD in imprinted genes at biparental complete hydatidiform mole (BiCHM).
Study design, size, duration: We have been sequenced all 11 exons of *NLRP7* gene in 36 SA with MLMD in two or more imprinted genes: 29 SA from women with recurrent miscarriage and 7 SA from women with sporadic miscarriage. Epimutations were found in *PEG1*, *DLK1*, *PEG10*, *PLAGL1*, *KvDMR*, *PEG3* and *GRB10* genes.
Participants/materials, setting, methods: All spontaneous abortions had the normal karyotype. We performed the direct sequencing of the *NLRP7* exons in SA with MLMD of imprinted genes.
Main results and the role of chance: We found mutations in the *NLRP7* gene in 27% SA from women with recurrent miscarriage (8/29). Moreover, all embryos with mutations in *NLRP7* had three or more methylation defects at imprinted genes. Mutations in *NLRP7* were identified as compound heterozygous or heterozygous state. Most of mutations represent missense mutation in exons 3, 4, 6 and 7, which lead to amino acid substitution. In addition, we identified one embryo with single nucleotide deletion, and another embryo with single nucleotide insertion in exon 7, that leads to a frame-shift.
Limitations, reasons for caution: Today, some other genes (*NLRP2*, ZPF57) are associated with MLMD at imprinted genes. However, in this study, we analyzed gene mutations only in *NLRP7*.
Wider implications of the findings: Mutations in *NLRP7* were detected only among SA with MLMD in imprinted genes from women with recurrent miscarriage that suggest the presence of the mutations in heterozygous state in these couples. Thus, mutations in the *NLRP7* associated not only with the BiCHM, but also with recurrent pregnancy loss.
Trial registration number: Not applicable.

SELECTED ORAL COMMUNICATIONS

SESSION 48: SAFETY AND QUALITY IN ART 1

Tuesday 05 July 2016 **Hall 3 AB** **15:15–16:30**

O-174 Double embryo transfer (DET): just for women taller than 1.65 m?

T. Simoes[1,2], A. Queiros[3], A. Marujo[4], S. Valdoleiros[5], A. Coelho[4]
[1]*Maternidade Alfredo Da Costa, Reproductive Medicine, Lisboa, Portugal*
[2]*University Nova de Lisboa, Gynecology, Lisbon, Portugal*
[3]*Maternidade Dr. Alfredo da Costa, Ultrasound Department, Lisbon, Portugal*
[4]*Maternidade Dr. Alfredo da Costa, Materno-fetal Medicine, Lisbon, Portugal*
[5]*Maternidade Dr. Alfredo da Costa, Materno-fetal Medicine, Lisbon, Portugal*

Study question: Should maternal height in nulliparous women be taken in to account when opting for DET in ART treatments?
Summary answer: Possibly. We observed that a maternal height ≥165 cm positively influenced (statistically significant) the obstetric results of twin pregnancies in nulliparous women.
What is known already: In a study by Dickey et al., the authors found an inverse correlation between maternal height and the risk of preterm births. Maternal height 176 cm was associated with a 14% reduction in the preterm birth rate in twins (statistically significant). An increased risk of preterm birth for women shorter than 150 cm was statistically significant in singletons, but not in twins. A different study by Blickstein et al. analyzed triplets and found that taller women (>165 cm) were more likely to deliver heavier triplets and were at lower risk of delivering triplets with very low birth weight.
Study design, size, duration: Retrospective cohort study evaluating pregnancies followed at Maternity Dr. Alfredo Da Costa – CHLC, between 1995 and 2015. Of the 2200 pregnancies followed in that period, 754 nulliparous women with dichorionic pregnancies were selected. Two groups were considered: (A) maternal height ≥165 cm (N = 271), and (B) maternal height <165 cm (N = 483). The following obstetric results were compared: gestational age at birth, delivery <28 weeks, delivery <32 weeks, average weight of newborns, newborns with weight at birth <1500 and <2500 g.
Participants/materials, setting, methods: Obstetrical outcome of nulliparous women with dichorionic-diamniotic pregnancies (N = 754). Women with height ≥165 cm (N = 271) versus women with height <165 cm (N = 483).
Main results and the role of chance: No statistically significant differences in maternal age (30.7 ± 4.8 versus 30.7 ± 5.2), pregnancy etiology (spontaneous versus ART) and mean BMI (23.0 ± 4.1 versus 22.8 ± 4.2 kg/m^2). Statistically significant differences in mean gestation age at birth (35.8 ± 2.8 weeks (wks) versus 34.8 ± 3.6 weeks, p < 0.001), delivery <28 weeks (4/271 (1.5%) versus 24/483 (5.0%), p = 0.01; delivery <32 weeks 12/271 (4.4%) versus 54/483 (11%), p < 0.001), average birth weight of newborns (2369 ± 444 versus 2179 ± 553 g, p < 0.001), newborns <1500 g (3.9 versus 10.9%, p < 0.001), newborns <2500 g (59.2 versus 68.7%, p < 0.001). With respect to complications during pregnancy, the only statistically significant differences found were in the rate of preterm labor (39.9 versus 47.8%, p = 0.03). No statistically significant differences between the two groups were found with respect to hypertension disorders and gestational diabetes.
Limitations, reasons for caution: Only nulliparous women were considered, so the findings may not apply to multiparous women.

Wider implications of the findings: Previous studies had already suggested that, in triplets, maternal height >165 cm was positively associated with gestational age at birth. According to our study, the same is true for twins. Increased pregnancy risk in nulliparous women shorter than 165 cm should be taken into consideration in double embryo transfers.
Trial registration number: We do not have a trial registration number.

O-175 Critical appraisal of the content of high quality clinical practice guidelines for fertility preservation

Ö. Baysal[1], J. Hamilton[1], C. Hamilton[2], D. Braat[1], C. Beerendonk[1], W. Nelen[1]
[1]*Radboud University Medical Center, Obstetrics and Gynaecology, Nijmegen, Netherlands*
[2]*Jeroen Bosch Hospital, Obstetrics and Gynaecology, 's-Hertogenbosch, Netherlands*

Study question: What are the recommendations of the best clinical practice guidelines (CPGs) on fertility preservation (FP) in young women?
Summary answer: Seventeen relevant topics were identified in seven high quality CPGs. Two topics were discussed in all seven CPGs, while four were discussed by only one.
What is known already: It is vital that women who have to undergo gonadotoxic treatment and want to secure their fertility receive the best possible care related to FP. Current FP care, however, is far from optimal. One way to facilitate moving towards optimal care is by developing high quality CPGs which can guide clinicians in caring for their patients. The quality of a CPG may influence the quality of the recommendations made and indirectly the quality of care.
Study design, size, duration: An extensive literature search to identify all (inter)national CPGs on the subject of FP care in young women was conducted in February 2015 and updated in July 2015. A total of 32 CPGs were included and appraised for methodological quality (MQ) by four appraisers each. The content of the CPGs that scored high for their "rigour of development," was extracted and studied. The recommendations were categorised according to different phases in FP care.
Participants/materials, setting, methods: The list of CPGs found was reviewed for missing CPGs by an (inter)national panel of experts in the field of reproductive medicine or FP. 32 experts appraised the MQ of the included CPGs by using the Appraisal of Guidelines for Research and Evaluation (AGREE)-II Instrument. The content of the CPGs scoring >60% of points for their "rigour of development" was extracted independently by two members of the research team.
Main results and the role of chance: Of the total of 1,808 documents found, 30 CPGs were included into our study. After consulting (inter)national experts, two additional CPGs were included. Seven of these 32 CPGs scored high on MQ. These were the CPGs developed by the ASCO, the COSA, the NVOG, Italian Hematology Society, the RCOG, the SIGN and the NICE-RCOG. Five out of these seven guidelines were developed by European organisations.

The 17 identified topics of the recommendations provided by these seven CPGs were categorised in one of the following phases in FP care: diagnosis, discussion with oncological healthcare provider, referral, discussion with reproductive medicine specialist, FP treatment procedure, gonadotoxic treatment phase, fertility follow-up, (counselling) about wish to conceive, pregnancy and long term consequences. CPGs published prior to 2013 lack to discuss topics as reproduction after gonadotoxic treatment in contrast to CPGs published from 2013 on. Furthermore, the CPGs developed before 2013 discuss less topics (4–8 out of 17) than the CPGs developed after 2013 (7–12 out of 17). While the most complete CPG discussed 12 topics (ASCO), another CPG (COSA) provided the most recommendations for the most number of topics (5 or more recommendations on four topics) discussed.
Limitations, reasons for caution: Documents with recommendations published by established organisations were included and graded as if they were CPGs, which might be a limitation. Although we conducted an extensive search, CPGs may have been missed. Finally, CPGs were assessed on MQ, but the medical quality of the content was not taken into account.
Wider implications of the findings: Healthcare providers can use the extracted recommendations of the best CPGs in daily practice right away. The recommendations found can also be used for the development of quality indicators which will be helpful to monitor the quality of current FP care or to evaluate improvement initiatives.
Trial registration number: –.

O-176 Oocyte retrieval simulator: a safe and efficient tool for training

I. Piva[1], I. Streuli[2], R. Marci[1]
[1]*Arcispedale S. Anna, Morphology, Surgery and Experimental Medicine, Ferrara, Italy*
[2]*University Hospital of Geneva, Division of Obstetrics and Gynecology, Geneva, Switzerland*

Study question: The aim of this study was to establish the usefulness of an oocyte retrieval simulator (PICKUPSIM™, Accurate srl) for training gynaecologists in basic oocyte pick-up techniques.
Summary answer: The PICKUPSIM proves to be an adequate and safe training tool for oocyte pick-up, for both novice and non-novice gynaecologists.
What is known already: Oocyte retrieval is a common surgical procedure in assisted reproduction treatment. Standard practice is currently to perform a recommended number of procedures under supervision, until the trainee reaches proficiency, but this approach is not tailored on the individual nor safe for the patient. On the contrary, simulator-based training may provide a safe and controlled environment for learning basic skills.
Study design, size, duration: Prospective, single-centre study at Ferrara University Hospital including a total of 13 participants (5 "non novices," accounting for Group A and 8 "novices" accounting for Group B) who performed two simulation sessions 1 week apart from each other.
Participants/materials, setting, methods: The PICKUPSIM™ is a box simulator, equipped with a transvaginal probe, a needle and a foot pedal pump for aspiration of the follicles. The haptic feedback simulates the resistance to penetration of the soft tissues traversed by the Ovum Aspiration Needle, in particular the ovarian surface and the ovarian follicle. Scenarios are based on real clinical images and displayed on a wide-view monitor. The participants also completed a questionnaire on the training system.
Main results and the role of chance: The non-novices (Group A) aspired a significantly higher number of follicles in the first try, but proved to be generally slower than the novices (Group B). As to the second try, Group A showed better results in terms of time, while keeping constant the average number of aspired follicles. The novices significantly increased the average number of follicles aspired, reaching results comparable to those of Group A and slightly reduced the medium time needed to complete the procedure. Overall, the two groups improved their performances both in terms of time and efficiency. Most of the participants (81.8%) considered the box simulator useful for the training and for improving hand-eye coordination and wanted to use it for training in the future. They also agreed that the feedback from the trainer during the training course was very useful. Accordingly, 72.7% participants wanted to attend an oocyte retrieval training course using the box simulator in the next future.
Limitations, reasons for caution: The small sample size limits the power of our study.
Wider implications of the findings: The PICKUPSIM™ allows acquiring basic skills in oocyte pick-up without risk to patients. Simulator-based training should be considered for developing knowledge as an adjunct to more traditional training on real patients.
Trial registration number: No.

O-177 Coasting (withholding gonadotrophins) for preventing ovarian hyperstimulation syndrome

R. Hassan[1], A. D'Angelo[1], N. Amso[1]
[1]*Cardiff University, Gynaecology, Cardiff, UK*

Study question: To assess the effect of withholding gonadotrophins (coasting) on the prevention of ovarian hyperstimulation syndrome (OHSS) in assisted reproduction cycles.
Summary answer: This updated systematic review shows there is evidence of a benefit of using coasting compared with no coasting to prevent moderate to severe OHSS.
What is known already: Previous systematic review suggest there was no evidence of a difference in the incidence of moderate and severe OHSS, live birth or in the clinical pregnancy rate between costing versus no coasting or coasting versus other interventions such as early unilateral follicular aspiration or gonadotrophin-releasing hormone agonist (GRHa). Significantly fewer oocytes were retrieved in coasting groups compared with GnRHa or no coasting.
Study design, size, duration: For the update of this Cochrane systematic review we conducted a search according to the Cochrane Gynaecology and Fertility search strategy for randomised controlled trials (RCTs) in which coasting

was used to prevent OHSS from inception to July 2015. Twenty four studies were identified and six met inclusion criteria. Two review authors independently selected trials and extracted data.
Participants/materials, setting, methods: Only randomised controlled trials (RCTs) in which coasting was used to prevent OHSS were included. The intervention comparisons were coasting versus no coasting or early unilateral follicular aspiration (EUFA) or GnRHa or follicle stimulating hormone administration with HCG trigger (FSH co-trigger). The inclusion criteria for coasting was when estradiol levels were >2500 pg/mL or >9000 pmol/L. Statistical analysis was performed in accordance with the Cochrane Gynaecology and subfertility Group guidelines.
Main results and the role of chance: There was a significant difference in the incidence of OHSS [odds ratio (OR) 0.11, 95% CI 0.05–0.24] in the coasting groups compared to no coasting and in the coasting group compared to the FSH co-trigger group (OR 43.74, CI 2.54–754.58). There was no evidence of a difference in the other intervention groups. There was no significant difference in clinical pregnancy rate in all groups. Significantly fewer oocytes were retrieved in coasting groups compared with no coasting or the other interventions.
Limitations, reasons for caution: There was heterogeneity between the trials and several of the trials were only published as conference abstracts. There may be other relevant data which have not been reported (LBR, implantation rate). The results of the systematic review must therefore be interpreted with caution.
Wider implications of the findings: Coasting remains beneficial at preventing moderate to severe OHSS without affecting clinical outcomes. However there is emerging evidence that other interventions such as FSH administration with HCG trigger may prevent OHSS but more studies are needed to investigate this further.
Trial registration number: Not a trial.

O-178 Interventions for the prevention of ovarian hyperstimulation syndrome (OHSS) in assisted reproductive technology (ART) cycles: an overview of Cochrane reviews

J. Brown[1], S. Mourad[2], F. Cynthia[3]
[1]*Liggins Institute, University of Auckland, Auckland, New Zealand*
[2]*Radboudumc Medical Centre, Department of Obstetrics and Gynaecology, Nijmegen, Netherlands*
[3]*Cochrane Gynaecology and Fertility, Department of Obstetrics and Gynaecology, University of Auckland, Auckland, New Zealand*

Study question: What is the current evidence on the prevention of OHSS in ART cycles published in the Cochrane library?
Summary answer: Twenty-seven, mainly high-quality, Cochrane reviews reporting on OHSS were included, of which nine showed evidence of significant reduction in OHSS between interventions.
What is known already: OHSS is a serious and potentially life-threatening complication of ART cycles, with an estimated incidence of 3–8%. This incidence is even higher in groups of high risk patients, such as women with polycystic ovary syndrome (PCOS), women with excessive follicle growth, a large number of retrieved follicles or high Estradiol levels during stimulation. In the Cochrane Database of Systematic Reviews, there are four reviews describing interventions for the prevention of OHSS. Other Cochrane reviews on ART cycles also report on OHSS as a secondary outcome and may help to identify potentially useful interventions to prevent OHSS.
Study design, size, duration: A systematic search of the Cochrane Database of Systematic Reviews was performed in November 2015 to identify all available systematic reviews of randomised controlled trials (RCTs) that report on the incidence and prevention of OHSS in ART cycles as a primary or secondary outcome. We identified published systematic reviews and review protocols.
Participants/materials, setting, methods: All ART reviews that report on OHSS as a primary or secondary outcome were eligible for inclusion. For each review, characteristics were summarised: number of included studies and patients, outcome reporting, timing of intervention, main limitations, effect size and quality of evidence. The GRADE (Grading of Recommendations Assessment, Development and Evaluation) and AMSTAR (A Measurement Tool to Assess Systematic Reviews) tools were used to assess the quality of included evidence and reviews respectively.
Main results and the role of chance: In total, 27 Cochrane reviews reporting on OHSS (variously defined) as a clinical outcome could be identified, including 87,340 patients. As these reviews followed the Cochrane standards of reporting, the methodological quality, as assessed by AMSTAR, was high. Nine of the interventions showed evidence of a reduction in the rate of OHSS (e.g., metformin adjuvant therapy in PCOS women, use of Gonadotrophin-releasing hormone antagonists and use of progesterone for luteal support). For 13 intervention reviews however, there was no difference in OHSS rates between intervention and control groups. In general, GRADE ratings showed that the available evidence was of very low to moderate quality. This was mainly due to failure to include any or only few studies per comparison and a low proportion of primary studies reporting data on OHSS. Of the reviews that did report on OHSS, three only reported on "severe OHSS," and 21 only reported on "total OHSS," which includes the clinically less important cases of "mild OHSS." This heterogeneous method of reporting fails to truly recognise the incidence of the clinically important moderate and severe cases, resulting in an evidence gap on this important adverse outcome of ART cycles.
Limitations, reasons for caution: Only 12/27 reviews were updated in the past 3 years, whereas nine were being updated at the time of our search. Reviews were hampered by poor reporting of subgroups "moderate" and "severe" OHSS in primary studies, making comparisons between interventions difficult.
Wider implications of the findings: There is a need to improve the reporting of OHSS as an outcome in RCTs on ART cycles. We advise trial investigators to report on the subgroups "moderate" and "severe" OHSS separately in future RCTs, as this provides more clinically useful information than merely reporting on "total" and "severe" OHSS.
Trial registration number: Not applicable.

SESSION 49: STEM CELLS

Tuesday 05 July 2016 **Hall 3 DE** **15:15–16:30**

O-179 Influence of female age on expression of mesenchymal stem cell-related markers and differentiation potential of aspirated follicular cells derived from women in the IVF programme

S. Omejec[1], M. Stimpfel[1], P. Cerkovnik[2], S. Novakovic[2], I. Virant-Klun[1]
[1]*University Medical Centre Ljubljana, Reproductive Unit, Department of Obstetrics and Gynaecology, Ljubljana, Slovenia*
[2]*Institute of Oncology Ljubljana, Department of Molecular Diagnostics, Ljubljana, Slovenia*

Study question: Do mesenchymal stem cell-specific characteristics of aspirated follicular cells in follicular fluid depend on age of women included in the *in vitro* fertilization (IVF) programme?
Summary answer: The increasing female age doesn't affect the expression of mesenchymal stem cell-related markers of aspirated follicular cells, while it negatively correlates with their differentiation potential.
What is known already: In the IVF procedure ovarian follicular fluid aspirates are daily discarded after oocyte pick-up. In these follicular aspirates granulosa cells (GCs) represent the majority of cells, along with blood and epithelial cells. They play an important role in growth and development of ovarian follicle. Moreover, they contain a subpopulation of GCs expressing some stem cell characteristics. When isolated from follicular aspirates, they can be maintained *in vitro* for prolonged periods of time, can express mesenchymal stem cell (MSC)-related markers and are able to differentiate *in vitro* into different cell types.
Study design, size, duration: Altogether 12 samples of follicular aspirates were collected from 12 women included in the IVF programme at our department. Women belong to four different age groups consisted of three women each: (1) ≤30 years (Group A), (2) 31–35 years (Group B), (3) 36–39 years (Group C) and (4) 40–43 years (Group D). From follicular fluid of each woman cell culture was established to study the effect of female age on stemness of follicular cells.
Participants/materials, setting, methods: The aspirated follicular cells were isolated from follicular fluid with hypoosmotic technique and cultured in DMEM/F12 culture medium, supplemented with 15% of fetal bovine serum and 0.003 IU/mL of FSH. Cultured cells were analyzed with Human Mesenchymal Stem Cell RT^2 Profiler PCR Array and immunocytochemistry to evaluate the expression of MSC-related markers. After exposure of cultured follicular

cells to different induction media differentiation of cells into adipogenic and osteogenic lineage was confirmed by tissue-specific staining.
Main results and the **role of chance:** Most of follicular cell cultures were able to grow *in vitro* for 1.5 months (3–4 passages, splitting ratio 1:3) and few of them were even able to proliferate for 3 months (10 passages). The immunocytochemistry revealed that aspirated follicular cells expressed MSCs-related markers H-CAM, M-CAM, STRO-1, and CD90, regardless of female age. There was no difference in the proportion of positive cells between different age groups, possibly due to two reasons: first, in all groups 80–90% of cells were positive for H-CAM and 5–10% of cells for STRO-1, and, secondly, high variability for CD90 and M-CAM-positivity was observed within groups (0–90% for CD90 and 10–80% for M-CAM) because of unknown reason. *In vitro* cultured follicular cells from women of all age groups were able to differentiate into adipogenic cells. Although, the proportion of differentiated cells depends on female age: in Groups A and B more then 50% of cells differentiated, while in Groups C and D this proportion was smaller (5–25%). Interestingly, osteogenic differentiation was observed only in young women of Group A. Gene expression analysis confirmed the expression of above mentioned and other tested MSCs-related markers (CD105, CD73, CD166, CD340, VCAM1) although these genes were down-regulated in comparison to bone-marrow derived MSCs.
Limitations, reasons for caution: A higher number of samples should be included in each group due to high variability of samples, a common issue in stem cell research.
Wider implications of the findings: The properties of follicular cells in follicular fluid aspirates could be correlated with quality of corresponding oocytes and outcome of IVF treatment. Because these cells are discarded in medical practice, further studies are needed to evaluate, if they have a potential to be used for cell therapies in regenerative medicine.
Trial registration number: /.

O-180 Massive parallel sequencing uncovers chromosomal mosaicism in human embryonic stem cells in both primed and naive culture conditions

M. Popovic[1], M. Van der Jeught[1], F. Speleman[2], F. Van Nieuwerburgh[3], P. De Sutter[1], B. Menten[2], B. Heindryckx[1]
[1]Ghent University Hospital, Ghent Fertility and Stem Cell Team G-FaST, Department of Reproductive Medicine, Ghent, Belgium
[2]Ghent University Hospital, Center for Medical Genetics, Ghent, Belgium
[3]Ghent University, Laboratory of Pharmaceutical Biotechnology, Faculty of Pharmaceutical Sciences, Ghent, Belgium

Study question: Can massive parallel sequencing reliably detect copy number variations (CNVs) at high specificity, sensitivity and resolution in human embryonic stem cell (hESC) cultures?
Summary answer: Shallow whole-genome sequencing of hESC lines down to the single cell level efficiently identified CNVs as small as 4 Mb and revealed genetically heterogeneous cultures.
What is known already: HESCs harbour a propensity for genomic instability in culture. Numerous aberrations have been reported, from whole-chromosome aneuploidies to CNVs, ranging from a few kb to several Mb in size. Nonetheless, studies have been restricted to bulk analysis of DNA obtained from copious cells, which limits detection of low-abundance variants, masked by the genetic heterogeneity of cultures. With the advent of single cell whole-genome sequencing, preliminary insights into the mosaic nature of hESCs have been attained. However, all current data are exclusive to primed hESCs. With various naive conversion protocols recently established, high-resolution whole-genome characterisation of naive hESCs is paramount.
Study design, size, duration: Shallow whole-genome sequencing was performed on bulk cell (>200,000 cells), 3–5 cell and single hESC samples. Samples were obtained from two independent, in-house derived, primed hESC lines and their naive counterparts. The direct comparison of genomic profiles validated our approach and allowed for CNV detection at high resolution.
Participants/materials, setting, methods: Samples were collected from primed hESC cultures at time of passage, with remaining cells seeded into our established naive conditions. Subsequently, naive hESC samples were collected at passage 2 during conversion and every second passage thereafter, for at least 10 passages. Whole genome amplification was performed only on single cell and 3–5 cell samples, prior to library preparation. Shallow whole genome sequencing was performed on an Ion Proton instrument using 400 flows.
Main results and the role of chance: A number of unique Mb scale structural variants were detected in a high proportion of cells in both primed and naive bulk samples. The first primed hESC line carried a trisomy 17 and gains of 11q23.1 and 20q13.2. These aberrations were also present in some, but not all, 3–5 and single cell samples. They further persisted in naive hESC cultures across all passages analysed. For the same cell line, a further trisomy 3 was observed in one of the naive single cell samples. In the second primed hESC line we detected an amplification of 1q32.1 in most samples. In the respective naive line, this gain seemed to be present in a higher fraction of the bulk cells. The 20q13.2 amplification was the smallest called CNV at 4 Mb. This served to define our sequencing resolution and exceeded those previously reported for whole-genome single cell hESC microarrays.
Limitations, reasons for caution: To thoroughly investigate the genomic effects of naive culture, expanding our study to incorporate further cell lines across lower and higher passages is necessary. The known bottlenecks of whole-genome single cell sequencing, such as uneven genome fragmentation and amplification, as well as inability to verify results, warrant careful interpretation.
Wider implications of the findings: High-resolution single cell whole-genome analysis holds unprecedented potential for evaluating the genetic diversity of hESCs. Investigating their heterogeneity, particularly during cellular transformations, may help unravel driving mechanisms of genomic instability. Ultimately, this could facilitate safer clinical implementation of hESCs.
Trial registration number: N/A.

O-181 Human menstrual blood-derived mesenchymal stem cells repair injured endometrium by angiogenesis *via* activating AKT and ERK pathways

Y. Zhang[1], L. Xiaona[1], H. Xiaoxiao[1], D. Yongdong[1], Z. Haiyan[1], Z. Songying[1]
[1]Sir Run Run Shaw Hospital, School of Medicine, Zhejiang University, Department of Gynecology and Obstetrics, Hangzhou, China

Study question: Do human menstrual blood-derived mesenchymal stem cells (MB-MSCs) play a role in repairing injured endometrium?
Summary answer**:** Endometrial thickness and mice fertility were improved after MB-MSCs transplant in endometrium injury mice, probably by promoting endometrial angiogenesis.
What is known already: Intrauterine adhesion (IUA) is a common acquired endometrial disorder secondary to endometrium injury such as trauma, curettage and infection. Ischemia is thought to be the major insult leading to the development of postoperative intra-abdominal and pelvic adhesions such as peritoneal adhesion and IUA. Stem cell-based therapy has shown prospective therapeutic effects on ischemic disease and tissue regeneration.
Study design, size, duration: Endometrium injury model were established with ICR mice ($n = 106$). In MB-MSCs group, MB-MSCs were transplanted by tail vein injection. In control group, normal saline was injected. Uterine were collected at Day 7 ($n = 17$ for MB-MSCs group, $n = 16$ for control group) and Day 14 ($n = 13$ for MB-MSCs group, $n = 11$ for control group) after MB-MSCs transplant for the histopathological observations. Seven days after MB-MSCs transplantation, female mice were mated with male mice ($n = 28$ for MB-MSCs group, $n = 14$ for control group).
Participants/materials, setting, methods: *In vivo*, we evaluate endometrial thickness, microvessel density and fertility function in mice model after MB-MSCs transplantation. *In vitro*, MB-MSCs conditioned medium (MB-MSCs CM) were collected and HUVECs were treated by MB-MSCs CM. Proliferation, apoptosis, migration and angiogenesis assay in HUVECs were performed and phosphorylated and total AKT, p38, JNK, ERK levels in HUVECs were determined by western blot. Furthermore, qPCR was applied to determine transcriptional level of downstream angiogenesis-related genes of AKT and ERK.
Main results and the role of chance: *In vivo*, we could find that Dil-labeled MB-MSCs engraf in the injured endometrium at Day 7 and Day 14 by small animal imaging. Seven days after transplantation, endometrial thickness and microvessel density presented a significant increase after MB-MSCs transplantation compared with that of control group ($p = 0.002$ for thickness, $p = 0.007$ for MVD respectively). Conception occurred in all the undamaged horns. In MB-MSCs group 15 of 28 damaged horns conceived, whereas only 2 of 14 in control group conceived ($p = 0.014$, *Chi*-square). The embryo number from the damaged horns in MB-MSCs group were obviously higher than control group (3.1 ± 0.6 vs. 0.9 ± 0.7, $p = 0.030$). *In vitro*, MB-MSCs CM promoted HUVECs growth and migration, while decreased apoptosis. Formation of vascular-like

networks was also remarkably enhanced after MB-MSCs CM treatment. Quantitative analysis of loop numbers, tube length, and vessel area showed that MB-MSCs CM improved HUVECs angiogenesis ($p < 0.05$). For mechanism, AKT and ERK phosphorylation levels in HUVECs increased after MB-MSCs CM treatment. Furthermore, qPCR showed that expressions of *eNOS*, *VEGFA*, *VEGFR1*, *VEGFR2*, and *TIE2* which are downstream genes of AKT and ERK in HUVECs were increased after MB-MSCs CM treatment.
Limitations, reasons for caution: MB-MSCs CM may secrete many factors favoring angiogenesis, immunity, and inflammation. However, factors that really works in our experiment was not clear. Additional work is needed to look for these factors.
Wider implications of the findings: MB-MSCs restore injured endometrium and improve mice fertility, which is promoted by angiogenetic effect of MB-MSCs, indicating its potential application in uterine repair and IUA prevention.
Trial registration number: No.

O-182 Detection, isolation and characterization of differentiation-resistant human embryonic stem cells

A. Keller[1], D. Dziedzicka[1], K. Sermon[1], M. Geens[1]
[1]*Vrije Universiteit Brussel, Research Group Reproduction and Genetics, Jette, Belgium*

Study question: Can we quantify, isolate and characterize differentiation-resistant human embryonic stem cells to investigate the mechanisms that lay at the origin of their differentiation deficiency?
Summary answer: Residual undifferentiated stem cells (rSC) can be detected down to the level of 0.02%, isolated from differentiated populations and further propagated for characterization.
What is known already: Often during differentiation of human embryonic stem cells (hESC), rSC that apparently have lost differentiation capacity are observed. The transplantation of differentiated cell populations containing these cells may pose a high risk of tumor formation in patients and therefore represent a major hurdle to exploit the full therapeutic potential of hPSC. However, very little research on the mechanisms by which cells remain undifferentiated is currently available.
Study design, size, duration: Three undifferentiated hESC lines (VUB02, VUB03_DM1 and VUB14) and their differentiated subpopulations were used in this study. Cells were let to spontaneously differentiate by applying medium containing serum, while omitting bFGF supplementation. Cultures were considered fully differentiated after 21 days.
Participants/materials, setting, methods: We have developed detection methods utilizing a variety of techniques, including flow cytometry, immunofluorescence, a colony formation assay and real-time PCR. Line specific standard curves were generated by spiking of defined numbers of undifferentiated cells in fibroblast populations. Isolation of rSC was achieved through the use of a novel replating technique, whereby small amounts of a differentiated population were re-introduced into culture conditions that favor undifferentiated hPSC proliferation.
Main results and the role of chance: While we readily detected rSCs within differentiated populations, detection ranged from 0.023 to 8.1%, depending on the line under investigation and the applied detection technique. Several possible sources of error in our estimates make the exact quantity of rSC difficult to evaluate. Nonetheless, ranking of the three lines based on the number of rSC detected was identical for the different techniques applied.

The plating technique allowed for the clonal growth of rSC colonies that could easily be isolated. Residual SC lines were isolated and propagated from two out of three hESC lines after 21 days of differentiation. Of these two, one line was karyotypically normal prior to the start of differentiation. The rSC line obtained, however, was abnormal and displayed a chr20p deletion and chr20q amplification, suggesting a possible link between copy number variations and the occurrence of rSC.
Limitations, reasons for caution: Although a well-characterized mutation at 20q11.21 has been shown to give hESC a significant growth advantage, due to the size of the observed mutation, we cannot confirm whether the same driver gene is involved in the change of differentiation potential.
Wider implications of the findings: We demonstrate the high occurrence of rSC in differentiated populations, a possible safety risk in the clinical application of hPSC-derived products. Our rSC isolation method, however, can be an important tool for further research into the mechanisms causing rSC and for the unraveling of pluripotency mechanisms.
Trial registration number: N/A.

O-183 Opposing effects of FGF2 and TGF-β/Activin/Nodal signalling inhibition on BMP-mediated trophoblast differentiation in hESCs

M. Koel[1], U. Võsa[2], K. Krjutškov[1], E. Einarsdottir[3], J. Kere[3], J. Tapanainen[4], S. Katayama[3], S. Ingerpuu[5], V. Jaks[5], U.H. Stenman[6], K. Lundin[4], T. Tuuri[4], A. Salumets[1]
[1]*Competence Centre on Health Technologies, Tartu, Estonia*
[2]*Institute of Molecular and Cell Biology, University of Tartu, Department of Biotechnology, Tartu, Estonia*
[3]*Karolinska Institutet, Department of Biosciences and Nutrition, Huddinge, Sweden*
[4]*University of Helsinki and Helsinki University Hospital, Department of Obstetrics and Gynecology, Helsinki, Finland*
[5]*Institute of Molecular and Cell Biology, University of Tartu, Department of Cell Biology, Tartu, Estonia*
[6]*University of Helsinki, Department of Clinical Chemistry, Helsinki, Finland*

Study question: What is the effect of inhibiting fibroblast growth factor 2 (FGF2) and transforming growth factor beta (TGF-β)/Activin/Nodal signalling in bone morphogenic protein 4 (BMP4)-induced trophoblast differentiation?
Summary answer: Inhibition of FGF2 and TGF-β/Activin/Nodal signalling had opposing effects on BMP4-mediated differentiation of human embryonic stem cells (hESCs) into trophoblast-like cells.
What is known already: Several studies have demonstrated that hESCs can be differentiated into trophoblast-like cells if exposed to BMP4 and/or inhibitors of FGF2 and the TGF-b/Activin/Nodal signalling pathways. However, how much the inhibitors of these pathways can improve the efficiency of hESC differentiation compared to basic BMP4 treatment, and the individual effects and synergy between the inhibitors, remain unknown.
Study design, size, duration: Full transcriptome analysis by RNA sequencing was used to analyse the effects of inhibitor combinations on the differentiation of the hESC line H9 into trophoblast-like cells over 12 days. Two biological replicates for four different conditions were analysed over seven time points.
Participants/materials, setting, methods: For each time point, genes differentially expressed to those in untreated cells were identified by the edgeR package. Additionally, expression of total chorionic gonadotropin (hCG) and its hyperglycosylated form (hCG-H) were determined by immunoassay from culture media.
Main results and the role of chance: FGF2 inhibition directs hESCs toward a similarity with placental tissue, up-regulates syncytiotrophoblast-specific genes (*CGA*, *CGB*, *CYP11A1* and *HOPX*) and induces several molecular pathways involved in embryo implantation. In addition, we demonstrated that the inhibition of FGF2 is the key trigger of hCG-H production. In contrast, inhibition of the TGF-β/Activin/Nodal pathway decreases the ability of hESCs to form trophoblast-like cells.
Limitations, reasons for caution: In this study, the hESC line H9 was used as an *in vitro* model system. The effects of inhibited FGF2 and/or TGF-β/Activin/Nodal signalling pathways were exclusively assessed *via* cell differentiation. Other potentially relevant pathways were not investigated.
Wider implications of the findings: A better understanding of the key players in the differentiation of trophoblast cells from hESCs will help us to develop an optimal model for studying the early development of human trophoblasts in normal pregnancy and pregnancy complications.
Trial registration number: This study is basic study.

SELECTED ORAL COMMUNICATIONS

SESSION 50: EFFECTS OF AGE AND HEALTH ON SEMEN PARAMETERS AND SPERM DNA INTEGRITY

Tuesday 05 July 2016 **Room 101** **15:15–16:30**

O-184 A comprehensive study into the effects of advancing male age on semen parameters, sperm genetic integrity and the outcome of assisted reproductive treatments

A. Raberi[1], G. Rozis[2], S. Alfarawati[3], K. Glynn[2], L. Lansdowne[3], S. Batha[2], D. Wells[4]
[1]*Institute of Reproductive Sciences, Nuffield Department of Obstetrics and Gynaecology, Oxford, UK*

[2]Lister Fertility Clinic, N/A, London, UK
[3]Reprogenetics UK, N/A, Oxford, UK
[4]Reprogenetics UK, Nuffield Department of Obstetrics and Gynaecology, Oxford, UK

Study question: What is the impact of advancing male age on conventional semen parameters, sperm DNA integrity and aneuploidy, fertilisation, embryo development and pregnancy?
Summary answer: Based on this study advanced paternal age can have an adverse effect on sperm DNA integrity and the outcome of assisted reproductive treatments.
What is known already: Numerous investigations have demonstrated the influence of female age on fertility and IVF outcomes. However, the role of male age has received far less attention and remains relatively poorly understood. Some studies suggest that natural fertility declines with advancing male age. Others have demonstrated a correlation between elevated paternal age and incidence of certain genetic disorders. Furthermore, increased sperm DNA fragmentation with age has also been reported. Despite this data, the impact of male age on fertility is considered controversial and requires further investigation. We sort to shed light on this question through a large study examining multiple semen parameters.
Study design, size, duration: This was a retrospective study of 590 men from infertile couples undergoing assisted reproduction techniques. Data was available corresponding to fourteen parameters, which were descriptive of semen quality, sperm function and treatment outcome. Together, this data allowed a comprehensive review of the impact of age on male reproductive function. Additionally, relationships between individual parameter, independent of age, were also evaluated.
Participants/materials, setting, methods: Factors considered with respect to paternal age included multiple traditional sperm parameters, sperm DNA integrity, sperm aneuploidy rate, fertilization rate and 2PN cleaved embryo rate and live birth rate. Life-style factors and prior medical history were also noted. DNA fragmentation analysis involved the Sperm Chromatin Dispersion (SCD) test, while cytogenetic analysis utilised fluorescence in situ hybridisation (FISH) for five chromosomes in >2,000 sperm. Statistical evaluation was performed using correlation (Pearson test) and linear regression.
Main results and the role of chance: Analysis of the data revealed that most traditional sperm parameters, such as concentration and sperm abnormality were not affected by paternal age. The only exception being motility, which was significantly reduced with paternal age (partners aged more than 35 were excluded) [$F(1, 97) = 7.98$, $p < 0.05$, $R^2 = 0.076$]. Linear regression analysis also showed that advanced male age was associated with increasing sperm DNA fragmentation (SDF) [$F(1, 551) = 4.556$, $p < 0.05$, $R^2 = 0.008$] and elevated DNA degradation [$F(1, 570) = 23.49$, $p < 0.001$, $R^2 = 0.04$]. Regardless of age, alcohol intake was observed to adversely affect SDF rates [$F(1, 104) = 5.685$, $p < 0.05$, $R^2 = 0.052$]. Furthermore, increased male age was associated with a decrease in the average number of 2PN cleaved embryos ($p < 0.05$), fertilization rate ($p < 0.05$) and ultimate birth rate ($p < 0.001$). Advance paternal age and alcohol consumption in male patient independently elevated the SDF and SDFI and subsequently alteration in these two factors disclosed their negative effects on the number of 2PN cleaved embryos form IVF cycles ($p < 0.05$).
Limitations, reasons for caution: A potential limitation of this study is that we did not have access to a fertile population. A great proportion of the data was based on subfertile patients attending an IVF clinic and therefore might not be representative of the actual male population.
Wider implications of the findings: A negative impact of male age on assisted reproductive treatments was confirmed, leading to decreased birth rates. Results obtained provide evidence that factors such as sperm DNA damage may contribute to this age-effect, suggesting that measuring this parameter, and attempting to mitigate elevated levels, may be valuable for older patients.
Trial registration number: N/A.

O-185 The effects of age on sperm DNA damage: an evaluation of 2,178 semen samples

R.L.R. Baruffi[1,2], C.G. Petersen[1,2], A.L. Mauri[1,2], L.D. Vagnini[2], A. Renzi[2], G.R. Oliveira-Pelegrin[2], J. Ricci[1], M. Cavagna[1,2,3], F. Dieamant[1,2], J.B.A. Oliveira[1,2], J.G. Franco Jr.[1,2]
[1]Centre for Human Reproduction Prof. Franco Jr, Research, Ribeirao Preto, Brazil
[2]Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil
[3]Women's Health Reference Center Perola Byington Hospital, Research, Sao Paulo, Brazil

Study question: What are the effects of aging on sperm DNA damage?
Summary answer: Sperm DNA fragmentation worsened with age and seems to be associated with mitochondrial damage. The observed increase in protamination with age needs further analysis.
What is known already: Evidence suggests that there are declines in semen quality and male fertility associated with increasing male age. Advanced paternal age has been implicated in the increase in the frequencies of abortions, autosomal dominant diseases, aneuploidy, and other diseases. Advanced male age has also been correlated with infant mortality. One plausible explanation for these results is that older men may have more sperm with damaged DNA. Chromatin damage has been associated with male infertility, conception problems, and difficulty sustaining pregnancy. There is also evidence linking DNA damage in sperm with the risk of mutations and birth defects in the offspring.
Study design, size, duration: A cross-sectional study of semen samples obtained from 2,178 men (37.9 ± 6.4 years) from couples who attended an infertility clinic was conducted. The semen analysis results from one semen sample from each man were recorded. For DNA integrity analysis, the following percentages were determined:

- Spermatozoa with DNA fragmentation using the TUNEL assay;
- Spermatozoa with abnormal chromatin packaging/underprotamination using chromomycin A3 (CMA3);
- Spermatozoa with abnormal mitochondrial membrane potential (MMP) using MitoTracker Green;
- Spermatozoa in apoptosis using annexin-V.

Participants/materials, setting, methods: For two-group comparisons, the subjects were categorized according to age into three groups: ≤35 years, 36–44 years and ≥45 years. Associations between age and sperm parameters were assessed using Spearman correlation. At least 200 spermatozoa were examined in each evaluation. Potential confounders (abstinence time, smoking, alcohol, and varicocele) were also observed. A sample size of 300 subjects in each group has 80% power (alpha 0.05) to detect a difference of 15% between groups.
Main results and the role of chance: Sperm DNA damage seems to be influenced by the aging process. Although the influence of aging on sperm apoptosis was not observed, sperm DNA fragmentation and MMP (mitochondrial damage) worsened with age. However, chromatin packaging (protamination) increased with age. Tables 1 and 2 show the results.

No correlations between abstinence, smoking, alcohol, and varicocele were shown.

Table 1. Men's age × semen parameters: Spearman's correlation.

Outcomes	Correlation coefficient	*p*
DNA fragmentation (%)	0.10	0.002
Abnormal MMP (%)	0.14	<0.0001
Apoptosis (%)	0.03	0.28
CMA3 positivity (%)	−0.13	<0.0001

Table 2. Men's age × semen parameters: group comparisons. Values within rows with the same superscript letter were significantly different.

Outcomes	≤35	36–44	≥45	*p*
n	852	1014	312	
DNA fragmentation (%)	14.7 ± 8.3[a,b]	15.9 ± 8.7[a]	16.1 ± 8.4[b]	0.002[a], 0.009[b]
Abnormal MMP (%)	24.6 ± 16.4[a]	25.6 ± 16.0[b]	29.0 ± 17.1[a,b]	0.006[a], 0.04[b]
Apoptosis (%)	19.1 ± 8.0	19.3 ± 7.9	19.3 ± 7.8	0.85
CMA3 positivity (%)	57.7 ± 15.0[a,b]	55.7 ± 15.1[a,c]	52.9 ± 15.6[b,c]	0.01[a], <0.0001[b], 0.01[c]

Limitations, reasons for caution: These data are cross-sectional and specifically focus on the association between age and DNA damage. Only men from infertile couples were sampled.
Wider implications of the findings: The age-related increase in sperm DNA damage suggests that delaying childbearing, not only in women but also in men, may jeopardise reproductive capacity. The increase in chromatin packaging may

represent a protective feature for DNA. Additional studies should be performed to confirm the results concerning chromatin packaging (chromatin protamination) in sperm.
Trial registration number: Not applicable. The local ethics committee authorised this study.

O-186 Semen parameters in men with varicocele: DNA fragmentation, chromatin packaging, mitochondrial membrane potential, and apoptosis

A. Nicoletti[1], C.G. Petersen[1,2], A.L. Mauri[1,2], L.D. Vagnini[2], A. Renzi[2], G.R. Oliveira-Pelegrin[2], M. Cavagna[1,2,3], F. Diaemant[1,2], J.B.A. Oliveira[1,2], R.L.R. Baruffi[1,2], J.G. Franco Jr[1,2]
[1]Centre for Human Reproduction Prof Franco Jr, Research, Ribeirao Preto, Brazil
[2]Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil
[3]Women's Health Reference Center Perola Byington Hospital, Research, Sao Paulo, Brazil

Study question: Does varicocele affect the sperm DNA integrity?
Summary answer: Individuals with varicocele show increased DNA damage associated with an increase in abnormal mitochondrial activity and an increase in abnormal chromatin packaging (underprotamination).
What is known already: Sperm DNA integrity is considered a marker of spermatogenesis integrity and male fertility potential. High levels of sperm DNA damage have been significantly linked to lower rates of spontaneous conception and assisted reproductive pregnancies. Varicocele have been associated with increased levels of reactive oxygen species and decreased seminal antioxidant capacity, increased sperm DNA damage, and defective spermatogenesis in affected patients. Although there is literature examining the possible effects of varicocele on semen DNA, the sample sizes in several studies are insufficient to generate significant results.
Study design, size, duration: A cross-sectional study was conducted with semen samples from 2,399 men randomly selected from couples who attended an infertility clinic. A total of 16.3% (391/2,399) of the men had varicocele. A physical examination and ultrasound were used to diagnose varicocele. Statistical analysis was performed using logistic regression.
Participants/materials, setting, methods: In each semen sample, which was collected after sexual abstinence of 2–5 days, at least 200 spermatozoa were examined (in each evaluation), and the percentages of the following parameters were measured:

- Spermatozoa with DNA fragmentation using the TUNEL assay.
- Abnormal chromatin packaging using chromomycin A3 (CMA3).
- Abnormal mitochondrial membrane potential (MMP) using MitoTracker Green.
- Apoptosis using annexin-V.

Samples were also evaluated according to WHO guidelines/morphology-motile sperm organelle morphology examination/MSOME. Potential confounder parameters (age, abstinence, BMI, smoking, and alcohol) were also observed.
Main results and the role of chance: Regression analysis revealed that the percentages of TUNEL-positive sperm, CMA3-positive sperm, and abnormal MMP sperm were significantly increased in individuals with varicocele compared to men without varicocele. Apoptosis was not influenced by varicocele. General semen parameters were significantly worse in individuals with varicocele. Table 1 shows the data.

Table 1. Logistic regression: varicocele and semen parameters.

	Varicocele		Logistic regression		
	Yes	No	Odds ratio	95% Confidence Interval	*p*
n	391	2008

Limitations, reasons for caution: The sperm were obtained from men who underwent fertility evaluations. Generalisation of these results to the general population should be performed with caution.
Wider implications of the findings: The presence of varicocele may impair sperm DNA integrity and fertility. Given the extant literature, varicocele repair and antioxidant intake should be considered to reduce DNA damage in sperm.
Trial registration number: Not applicable. The local ethics committee authorised the study.

O-187 Association between body mass index (BMI) and sperm quality or sperm DNA integrity. A large population study

J.B.A. Oliveira[1,2], C.G. Petersen[1,2], A.L. Mauri[1,2], L.D. Vagnini[2], A. Renzi[2], G.R. Oliveira-Pelegrin[2], A. Nicoletti[1], M. Cavagna[1,2,3], F. Dieamant[1,2], R.L.R. Baruffi[1,2], J.G. Franco Jr[1,2]
[1]Centre for Human Reproduction Prof Franco Jr, Research, Ribeirao Preto, Brazil
[2]Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil
[3]Women's Health Reference Center Perola Byington Hospital, Research, Sao Paulo, Brazil

Study question: Is overweight associated with a decrease in sperm quality or impaired sperm DNA integrity?
Summary answer: High BMI negatively impacts sperm quality. High BMI is not associated with sperm DNA fragmentation, apoptosis, or protamination but is associated with increased mitochondrial damage.
What is known already: Obesity appears to influence male infertility and male reproductive dysfunction negatively. Overweight and obesity have been associated with significant reductions in the levels of total testosterone, free testosterone, and sex hormone-binding globulin and with elevated levels of estrogens. In addition, the accumulation of suprapubic and inner fat may cause scrotal hyperthermia, which is a probable cause of elevated oxidative stress. Some studies have highlighted impairments of sperm quality for patients with BMI, but the results are conflicting. Sperm DNA integrity is another factor that may be affected in obese men; however, previous studies have shown controversial results regarding this influence.
Study design, size, duration: A cohort of 1,824 men from couples who underwent infertility evaluations was recruited, and BMI measurements were made at this time. Pathological conditions of the genital tract/azoospermia were exclusion criteria. The semen analysis results from one semen sample from each man were recorded (WHO criteria/morphology-motile sperm organelle morphology examination/MSOME). For DNA integrity analysis, the percentages of DNA fragmentation (by TUNEL assay), abnormal chromatin packaging/underprotamination (by chromomycin A3/CMA3), abnormal mitochondrial membrane potential (MMP/by MitoTracker Green), and apoptosis (by annexin-V) were recorded.
Participants/materials, setting, methods: For two-group comparisons, the subjects were categorized according to BMI into three groups: ≤24.9, 25.0–29.9 (overweight) and ≥30.0 kg/m² (obese). Associations between BMI and these outcomes were assessed using Spearman correlation. At least 200 spermatozoa were examined in each evaluation. Potential confounders (age, abstinence time, smoking, alcohol, and varicocele) were also observed. A sample size of 250 subjects in each group has 80% power (alpha 0.05) to detect a difference of 15% between groups.
Main results and the role of chance: No correlations between BMI and age, abstinence, smoking, alcohol, and varicocele were observed. The regression analysis showed significant decreases in the sperm concentration, motility,

normal morphology, and vitality with increasing male BMI. Conversely, there was a significant positive correlation between the percentage of spermatozoa with abnormal MMP (mitochondrial damage) and BMI (Table 1). Similarly, in two-group comparisons, sperm concentration, progressive motility, morphology, vitality, and mitochondrial membrane potential worsened with the increase of BMI (Table 2).

Table 1. BMI × semen parameters: Spearman's correlation.

Outcomes	Correlation coefficient	*p*
pH	0.04	0.10
Volume (ml)	0.02	0.34
Concentration (ml × 10^6)	−0.18	<0.0001
Progressive motility (%)	−0.19	<0.0001

Leukocytes (×10^6/ml)	0.03	0.13
Vitality (%)	0.17	<0.0001
DNA fragmentation (%)	0.01	0.76
Apoptosis (%)	0.01	0.81
CMA3 positivity (%)	0.02	0.37
Abnormal MMP (%)	0.24	<0.0001

Table 2. BMI × semen parameters: group comparisons.

Outcomes	BMI: ≤24.9 kg/m²	BMI: 25–29.9 kg/m²	BMI: ≥30 kg/m²	*p*
n	370	856	598	
pH	8.0 ± 0.3	8.0 ± 0.3	8.1 ± 0.4	0.94
Volume (ml)	2.8 ± 1.5	2.9 ± 1.6	2.8 ± 1.6	0.53
Concentration (ml × 10^6)	83.5 ± 62[a]	77.1 ± 56.3[b]	58.8 ± 51.1[a,b]	<0.0001[a,b]
Progressive motility (%)	58.6 ± 13.8[a]	56.8 ± 14.6[b]	51.5 ± 17.5[a,b]	<0.0001[a,b]
Normal forms (%)	0.7 ± 0.9[a]	0.6 ± 0.8[b]	0.4 ± 0.7[a,b]	<0.0001[a,b]
Leukocytes (×10^6/ml)	0.3 ± 0.6	0.4 ± 0.9	0.4 ± 1.1	0.66
Vitality (%)	67.6 ± 12.3[a,b]	65.0 ± 13.6[a,c]	60.8 ± 15.6[b,c]	0.009[a], <0.0001[b,c]
DNA fragmentation (%)	14.4 ± 7.5	14.5 ± 8.2	14.5 ± 7.4	0.74
Apoptosis (%)	19.5 ± 8.1	19.2 ± 8.0	19.1 ± 7.6	0.75
CMA3 positivity (%)	56.3 ± 15.5	55.7 ± 15.1	56.4 ± 15.1	0.73
Abnormal MMP (%)	20.6 ± 13.1[a,b]	25.3 ± 15.7[a,c]	30.9 ± 18.3[b,c]	0.0004[a], <0.0001[b], 0.0001[c]

Limitations, reasons for caution: A limitation might be the cross-sectional nature of the data. Furthermore, this study was conducted in couples who sought fertility treatment and could therefore be biased toward infertility. The generalisation of these results to the general population should be performed with caution.

Wider implications of the findings: Given the adverse consequences of obesity, the benefits of weight reduction should be discussed when counselling couples interested in fertility treatment. The exact mechanisms that mediate the effects of obesity on the mitochondrial damage of sperm require additional investigation.

Trial registration number: Not applicable. The local ethics committee authorised this study.

O-188 Prevalence of human papilloma virus in sperm, Sperm DNA Fragmentation Index (DFI %) and ART success in couples with repeated implantation failure

G. Sinem Caglar[1], E. Pabuccu[1], Y. Tasci[2], S. Tangal[3], A.H. Haliloglu[3], K. Yararbas[4], R. Pabuccu[5]
[1]*Ufuk University School of Medicine, Obstetrics and Gynecology, Ankara, Turkey*
[2]*Zekai Tahir Burak Women's Health, Research and Education Hospital, Obstetrics and Gynecology, Ankara, Turkey*
[3]*Ufuk University School of Medicine, Department of Urology, Ankara, Turkey*
[4]*Maltepe University School of Medicine, Medical Biology and Genetics, Istanbul, Turkey*
[5]*Centrum Clinic ART Centre, Reproductive Endocrinology, Ankara, Turkey*

Study question: What is the sperm HPV prevalence in males with RIF history and potential impact on sperm parameters, sperm DNA fragmentation index (DFI) and reproductive outcomes in couples with RIF?

Summary answer: Overall HPV prevalence was 7.7% (9/119) with a mean DFI of 39.1%. Semen parameters and implantation rates were similar between those with or without HPV.

What is known already: HPV infection is associated with reduced sperm motility contributing to male infertility. Moreover, HPV infected spermatozoa was also linked with increased miscarriages.

Study design, size, duration: A total of 117 male partners of couples with RIF history undergoing ART were included in this cross-sectional study between 2014 and 2015.

One ART cycle of each patient was included in the study.

Demographic characteristics, hormone profiles, ART cycle outcomes, semen parameters, sperm DFI (%) and reproductive outcomes were compared among those with or without HPV in spermatozoa.

Participants/materials, setting, methods: A total of 117 couples with RIF history were enrolled to the study in a single ART centre.

The seminal plasma was used for detection of HPV by a commercially available kit.

TUNNEL assay was performed to detect DFI by commercially available kit. In each sample 300 spermatozoa was counted at fluorescent microscope.

Ovarian stimulation was carried out using antagonist protocol.

Semen parameters, DFI and reproductive outcomes were compared among those with or without HPV DNA.

Main results and the role of chance: Overall sperm-HPV rate was 7.7% (9/119) in male subjects of couples with RIF history.

Demographic characteristics and basal hormonal profiles were similar among those with or without HPV in spermatozoa.

Semen parameters including volume, count and motility were similar among those with or without HPV in spermatozoa.

Overall Sperm DFI was detected as 39.1% and was found to be similar between the two groups (37.6 vs. 38.3% in HPV and HPV groups respectively, $p > 0.05$).

Fertilization (82.5 vs. 76.5%), implantation (29.1 vs. 33.3%) and ongoing pregnancy rates (11.1 vs. 28.7%) were comparable among groups without significant difference. Relatively higher miscarriages were detected in HPV+ group without reaching a statistically significant difference (33.3 vs. 10.2%).

Limitations, reasons for caution: Relatively small sample size of our cohort.

Further studies are needed to confirm the correlation between HPV male infection and reproductive outcomes of couples with repeated ART failures.

Wider implications of the findings: Overall HPV prevalence of 7.7% is in accordance with the previously reported prevalence (7, 8–11%).

Also, HPV infection did not seem to affect semen quality.

HPV infection of men can be another factor for lower ongoing pregnancy rates and higher miscarriages in couples with high sperm DFI and RIF history.

Trial registration number: ACTRN12614000188639.

SESSION 51: OOCYTE AND SPERM QUALITY

Tuesday 05 July 2016 **Hall 1** **17:00–18:00**

O-189 Follicular size is a confounding factor for gene expression analysis in cumulus cells

C. Pirkevi Çetinkaya[1], S. Kahraman[1], M.A. Tüfekçi[1], M. Çetinkaya[1], M. Montag[2]
[1]*Istanbul Memorial Hospital, Assisted Reproductive Technologies and Reproductive Genetics Center, Istanbul, Turkey*
[2]*ilabcomm GmbH, Sankt Augustin, Germany*

Study question: Does follicular size have an influence on the level of cumulus cell gene expression in embryos that develop to blastocyst or arrest during development?

Summary answer: Gene expression varies in developing blastocysts according to follicular size and between arrested embryos and those developing to blastocyst.

What is known already: Many studies have been performed on cumulus gene expression with the aim of correlating gene expression levels with different outcome measures. However, the results were not consistent between different studies. Although the field has been extensively investigated, no predictive marker has been identified so far. A possible explanation is the rather small number of COC samples that was available in these studies. Another aspect that has not been studied so far is the potential effect of confounding factors that may have an influence on cumulus gene expression.
Study design, size, duration: This study was performed between July 2014 and September 2015. Strict inclusion (<2 previous treatment cycles, age ≤39 years, ≥8 oocytes retrieved) and exclusion criteria (PGD or PGS indication, >24 COC during pickup) were applied. Oocytes were injected and cultured to blastocyst stage at 6% CO_2 and 5% O_2 using a single-step culture medium (Global) with change on day 3. Cumulus cells were collected from a total of 2560 COC for further subgroup analysis.
Participants/materials, setting, methods: Cumulus gene expression was studied in small (<17 mm on OPU day; $n = 699$) vs. large ($n = 788$) follicles and in embryos that arrested ($n = 682$) or reached blastocyst on day 5 ($n = 805$). We used 5 genes for qRT-PCR analysis of RNA expression levels (Lightcycler 480). In addition 41 cumulus samples representing embryos from small and large follicles that developed to blastocysts or arrested before day 3 were analyzed by whole genome expression analysis (Affymetrix Genechip Human Gene 2.0ST Array).
Main results and the role of chance: We first applied qRT-PCR to analyze well-described genes that are expressed in cumulus cells (HAS2, PTSG2, PTX3, TNFAIP6 and GDF9). When compared to arrested embryos, embryos that developed to blastocysts showed a significant downregulation for HAS2, PTSG2 and TNAFIP6 ($p < 0.05$). Looking at follicular origin, HAS2 and PTSG2 were downregulated for all embryos from small compared to large follicles ($p < 0.0005$). When we combined embryo development and follicular origin, only HAS2 was downregulated in blastocysts from small compared to large follicles ($p < 0.05$). However, we also noted a downregulation of HAS2 and PTSG2 in arrested embryos from small follicles compared to those reaching blastocyst stage ($p < 0.0005$). These fluctuations reflect the complexity of translating such a basic scientific study from bench to bedside.

The results from genome expression were subjected to a principal component analysis to allow for an effective interpretation. Embryos that arrested during development showed similar gene expression patterns independent of follicle size. Embryos that developed to blastocysts showed clear differences to arrested embryos but also differences between large and small follicles. This was reflected by ANOVA analysis showing significance for differentially expressed transcripts. These results may reflect the heterogeneity of the follicular origin of human embryos.
Limitations, reasons for caution: Results were obtained with a limited number of genes studied and cannot automatically be translated to other potential candidate genes. For the second part of the study results were obtained from a small number of samples, which may not necessarily be representative for a larger cohort.
Wider implications of the findings: Cumulus gene expression studies are affected by several confounding factors that are based on follicular size and development, which may also reflect the heterogeneity of patient population undergoing IVF. Such factors should be taken into account when searching for predictive markers for IVF outcome.
Trial registration number: Not applicable.

O-190 Correlation between oocyte cumulus cells gene expression, embryo morphokinetic, blastocyst formation and euploidy

C. Scarica[1], L. Rienzi[2], G. Orlando[2], M. Stoppa[2], L. Dovere[2], D. Cimadomo[1], A. Capalbo[3], F. Ubaldi[2], R. Canipari[1]
[1]University of Rome "La Sapienza", Dipartimento di Scienze Anatomiche Istologiche, Medico Legali e dell'Apparato Locomotore, Sezione Istologia ed Embriologia Medica, Roma, Italy
[2]Clinica Valle Giulia, Reproductive Medicine Center, Rome, Italy
[3]Salus, GENETYX, Molecular Genetics Laboratory, Marostica VI, Italy

Study question: Is cumulus cells (CC) gene expression pattern of five candidate genes, combined with morphokinetic parameters a non-invasive method to predict blastocyst formation and euploidy?
Summary answer: CCs gene expression is correlated to embryo development and morphokinetic behaviour. Among blastocysts, we found PTGS2 over-expressed in CCs of euploid embryos.
What is known already: Due to the crosstalk within the follicle, CC gene expression has been proposed as a non-invasive tool to predict oocyte/embryo competence. New promises come also from time-lapse, however no clear agreements on which gene and/or morphokinetic parameter can be used to predict embryo quality. A critical aspect of embryo quality is the blastocyst chromosomal status, and this feature can be used as an outcome measure to test potential biomarkers of oocyte quality.
Study design, size, duration: Prospective longitudinal cohort study (September 2014–September 2015). A total of 58 CCs samples were individually collected from 21 consenting patients. Oocytes and belonging embryos where cultured individually in a time-lapse incubator (Embryoscope), until blastocyst stage. 29 oocytes (from 16 patients) reached blastocyst stage and underwent comprehensive chromosomal screening. Collected CCs samples were analysed for the expression of 5 candidate genes, previously found as predictive of oocyte competence: HAS2, PTGS2, CAMK1D, EFNB2, and STC1.
Participants/materials, setting, methods: Advanced maternal age patients (38.3 ± 2.5 years), underwent ICSI and pre-implantation genetic testing for aneuploidy. Severe male factor was excluded. All ovarian stimulations were performed with a fixed protocol. Retrieved cumulus-oocyte complexes were denuded individually. CCs gene expression was performed through qPCR using Taqman gene expression assays (Applied Biosystems). Twelve morphokinetic parameters were recorded during embryo culture. T-tests and Spearman's rank correlation were performed through SigmaPlot (SSI, CA, USA).
Main results and the role of chance: The 5 selected genes are known to be involved in cumulus expansion [hyaluronan acid synthase 2 (HAS2) and prostaglandin-endoperoxide synthase 2 (PTGS2)], in the mediation of developmental events [EphrinB2 (EFNB2) Ca-/calmodulin–dependent protein kinase 1 (CAMK1D)] and in autocrine and paracrine functions [Stanniocalcin-1 (STC1)]. Analysing CC gene expression of blastocysts versus arrested embryos, blastocyst formation was negatively correlated with EFNB2 expression ($p = 0.035$; 95% CI: 0.0553–1.463. Logistic regression model adjusted for female age confirmed this association, OR = 2.7, 95% CI = 1.1–7.3.

Combined analysis of morphokinetics and gene expression showed a negative correlation between timings of singamy and of second cell cycle and STC1 expression ($p < 0.004$) while timings of 4-cell divisions were related to HAS2 expression ($p = 0.032$). EFNB2, PTGS2 and CAMK1D expressions showed a positive correlation to timings of starting blastulation ($p = 0.015$).

Among obtained blastocysts we analyzed CC gene expression patterns of 18 aneuploid versus 11 euploid blastocysts, finding PTGS2 over-expression ($p = 0.026$; 95% CI: 0.180–2.515) in euploid blastocysts.
Limitations, reasons for caution: This study is limited to a specific population of patients, a relatively low number of CCs samples and a restricted number of genes. Results must be confirmed on larger scale
Wider implications of the findings: We found a correlation between CC gene expression of 5 selected genes, morphokinetics and blastocyst formation while euploidy could only be related to PTGS2 expression. We confirmed the potentiality of CC gene expression analysis in predicting embryo competence.
Trial registration number: None.

O-191 Sperm DNA integrity is associated with time-lapse parameters of early embryonic development

F. Hambiliki[1]
[1]Reproduktionsmedicinskt Centrum, Skåne University Hospital, Malmö, Sweden

Study question: Is there any interaction between DFI and fertilization method in relation to early embryo development?
Summary answer: An association between the level of impairment of sperm DNA integrity and early embryo development parameters as assessed by time-lapse are demonstrated.
What is known already: We recently demonstrated that high sperm DNA fragmentation index (DFI) is associated with a lower fertilization rate in standard IVF but not in ICSI. Therefore, by time-lapse microscopy, we studied the interaction between DFI and fertilization method in relation to early embryo development

Study design, size, duration: This is a retrospective study based on 6117 oocytes from 256 IVF and 383 ICSI treatments performed at the Reproductive Medicine Centre, Skåne University Hospital, Malmö, Sweden.
Participants/materials, setting, methods: The DFI values were categorized into 3 intervals: DFI ≤ 10% (reference group), 10% < DFI ≤ 20%, and DFI > 20%. Endpoints were meantime of formation of pronuclei (tPNa), meantime of fading of pronuclei (tPNf), meantime of early cleavage (t2) and meantime of starting blastulation (tSB). Data were analyzed using univariate analysis of variance in three ways; the interaction between DFI category and fertilization type, separately for IVF and for ICSI and also ICSI compared to standard IVF.
Main results and the role of chance: In the ICSI group the meantime of tPNa was significantly lower for 10% < DFI ≤ 20% and DFI > 20, as compared to the reference group (DFI ≤ 10%). The meantime of tPNf increased statistically significant in the standard IVF group for 10% < DFI ≤ 20% and DFI > 20 as compared to the reference group. When comparing ICSI to IVF, the mean t2 time was statistically significantly higher for the latter if DFI was above 20%. The meantime of starting blastulation was significantly longer in the ICSI group for DFI ≤ 20 as compared to the reference group, but no such association was observed within the IVF/ICSI Group.
Limitations, reasons for caution: A larger prospective randomized multistudy would be required to confirm the findings of this study.
Wider implications of the findings: Our present findings together with previous observations suggest indirectly that sperm DNA integrity takes important role not only in fertilization moment but also in early embryo development.
Trial registration number: N/A.

O-192 Influence of sperm parameters on embryonic development, morphokinetics, and ART outcomes: male factor exploration in a female factor-controlled study platform

A. Leza[1], E. Rocafort[1], I. Vilella[2], L. Medrano[1], M. Guijarro[1], B. Ramos[1], M. Enciso[2], J. Sarasa[2], M. Fernández[1], J. Aizpurua[1]
[1]*IVF Spain, Reproductive Medicine, Alicante, Spain*
[2]*iGLS, Genetics Department, Alicante, Spain*

Study question: Do sperm parameters influence embryonic development, morphokinetics, and ART outcomes in egg donation cycles?
Summary answer: High sperm apoptosis levels negatively influence good quality competent blastocyst production and ART outcomes in egg donation cycles.
What is known already: Infertility is a complex multifactorial phenotype where several elements, including male and female factors, could be involved. Accordingly, it is difficult to design controlled studies to anticipate which factors have a predominant effect on ART-outcomes. In order to investigate male factor impact on reproduction, an egg-donation program appears like the ultimate study platform. The number of studies of this kind is limited; to our knowledge none of them has focused on the effects of male parameters on embryo morphokinetics. The present study aims to shed some light into the influence of sperm quality on pre-implantation development morphokinetics and clinical outcomes.
Study design, size, duration: This unicentric and retrospective study included 282 sperm samples from patients undergoing egg-donation cycles and morphokinetic embryo selection using time-lapse imaging (Eeva™ test) at our centre between January 2014 and September 2015. The influence of sperm parameters in embryo development and ART outcomes is explored in a female factor-controlled study platform.
Participants/materials, setting, methods: Prior to fertilization, sperm concentration and motility based on WHO criteria (2010) and apoptosis levels using flow cytometry Annexin V-FITC/PI assay were determined in all samples.

All embryos were cultured until day 5 and monitored by time-lapse imaging (Eeva™) providing a prediction of embryo competency on day 3 (High/Medium/Low). Selected fresh single embryos were transferred to recipients in a hormonal substituted cycle. Reproductive outcomes were statistically compared between patients with normal and altered sperm values.
Main results and the role of chance: A significant impact on the production of good quality blastocysts with high implantation potential as predicted by Eeva test was observed in samples with altered levels of live apoptotic sperm cells (>30%). Samples with abnormal apoptotic levels showed a frequency of competent blastocysts significantly lower compared to samples with normal apoptosis values (26.54 ± 8.44 vs. 49.40 ± 2.57, $p = 0.028$). No impact of this parameter was observed on fertilization. Altered concentration or motility values were not correlated with either fertilization or embryo development rates.

In terms of clinical outcomes, the presence of apoptosis showed a dramatic negative effect on pregnancy rates. Biochemical pregnancy was significantly lower on samples with high levels of apoptosis (30.8 vs. 67.1%, $p = 0.009$). Similar results were found when clinical pregnancy rates (30.8 vs. 60.1%, $p = 0.04$) and ongoing pregnancy rates were compared (18.2 vs. 51.5%, $p = 0.036$). No such differences were detected when normal and altered sperm concentration or motility values were compared.

These results show that sperm apoptosis affects early stages of embryo development even when egg quality is good, and therefore can compromise the number of competent blastocysts obtained in egg-donation cycles. Moreover, sperm apoptosis levels negatively impact post-transfer embryo development even in cases were good quality embryos are transferred.
Limitations, reasons for caution: The retrospective and unicentric design of this study may be a reason of caution. The number of sperm samples with abnormal apoptosis levels was limited, this should be increased to confirm the results obtained. Further randomized studies are needed to validate our results.
Wider implications of the findings: Increased sperm apoptosis negatively influences blastocyst production and ART-outcomes in egg donation cycles. Reduction of apoptotic cell levels in the ejaculate by either medication or the use of MACS-selection technique may be a valuable strategy to improve embryo development and clinical outcomes in cases with high apoptotic sperm cell levels.
Trial registration number: A trial registration number was not required due to the retrospective study design.

SELECTED ORAL COMMUNICATIONS

SESSION 52: WHEN SPERM ARE THE LIMIT

Tuesday 05 July 2016 **Hall 5 CB** **17:00–18:00**

O-193 Limits for number of offspring in Danish anonymous sperm donors: what are the risks?

C.T. Ekstrøm[1], O. Schou[2], A.B. Pinborg[3]
[1]*University of Copenhagen, Biostatistics – Department of Public Health, Copenhagen, Denmark*
[2]*Cryos International, Denmark, Aarhus, Denmark*
[3]*Copenhagen University Hospital, Department of Obstetrics and Gynaecology, Hvidovre, Denmark*

Study question: How does the limit in the number of offspring from anonymous Danish sperm donors influence the risk and uncertainties of inbreeding?
Summary answer: We provide an improved statistical model that yields a recurrence time of 75 years for inbreeding with the current available Danish data.
What is known already: In 2013 the Danish limits for the number of offspring that a Danish sperm donor can father was lowered from 25 to 12. The choice for the new limit was not evidence-based, but was based on the feeling that the old limit was considered too high. The limit is set in place to reduce the risk of inbreeding and to minimize the risk that a sperm donor has an undiagnosed heritable disease that is segregated to a large number of offspring, but no-one has any good estimates of the actual risk in the Danish population.
Study design, size, duration: We used an improved version of the Hajnal–Curie–Cohen model to compute and evaluate the limits based on detailed information about the Danish population distribution drawn from Statistics Denmark.
Participants/materials, setting, methods: The Hajnal–Curie–Cohen (HCC) model is widely used to evaluate the average number of potential unwittingly consanguineous half-sibling matings among the offspring of an anonymous artificial insemination sperm donor. We extend the HCC model to accommodate detailed information about the donors and population, and improve it to make it possible to make statistical inference and evaluate different legal limits and requirements, and population restrictions.
Main results and the role of chance: We present the HCC model and our extensions and emphasize the three major improvements: (1) We can model the offspring of individual donors and not just the expected number of consanguineous

matings, which enables us to provide confidence and prediction intervals. (2) It accommodates differences in donor age distributions within and between the donor and natural offspring, and (3) the model allows us to directly evaluate the impact of legal requirements (e.g., limits based on offspring vs. families).

We find that the worst case scenario with the current limit of 12 offspring is substantially smaller ($p < 0.0001$) from the limits obtained from the improved HCC model (average recurrence time of 49 years for inbreeding in vs. 75 years), and that this difference is highly significant. In fact, our improved HCC model also provides a significant improvement in the risk estimation compared to the standard HCC model ($p < 0.01$).

We also find that a legal limit of 25 offspring per donor would still result in an average recurrence time of 21 years, which is hardly a substantial problem for the Danish society or gene pool.

Limitations, reasons for caution: This evaluation is based purely on a statistical model (albeit with detailed information from the population as input). Generally, the findings from these models is impossible to validate in the Danish (or any) population since the risk of unwittingly consanguineous half-sibling mating is extremely low.

Wider implications of the findings: The findings may influence the legal limits in Denmark, and the new statistical model may be used to make improved estimates, confidence intervals and prediction intervals of the risk of consanguineous mating among anonymous sperm donor offspring.

Trial registration number: None.

O-194 Microfluidic device based selective sorting of motile human sperm for IUI application: a preliminary study

T. Chinnasamy[1], B. Behr[2], U. Demirci[1]
[1]*Stanford University, Radiology, Stanford School of Medicine, Palo Alto, CA, USA*
[2]*Stanford University, Department of Obstetrics and Gynecology, Stanford, CA, USA*

Study question: The purpose of the study is to develop a microfluidic chip for sorting highly motile and morphologically normal sperm for IUI applications.

Summary answer: The developed microfluidic device sorted sperm shows higher percentage of motile and morphologically normal sperm as compared to conventional methods, i.e., swim-up.

What is known already: According to the American Society for Reproductive Medicine, infertility affects about 5.3 million American couples of reproductive age, among which male infertility accounts for 40–50% of cases. The leading cause of male infertility is low sperm count, which is usually associated with low sperm motility, abnormality and impaired sperm function, thus resulting in the inability to fertilize an oocyte naturally. Assisted reproductive technologies (ARTs) have offered an alternative to address challenges associated with male infertility. A major clinical challenge is, however, the selection of highly motile and morphologically viable sperm to optimize the effectiveness of the procedures

Study design, size, duration: Sperm sorting analysis was performed using de-identified discarded human semen samples from REI Laboratory, Stanford School of Medicine, Stanford University. All the sperm processing experiments were performed with in 1–3 h after the semen samples were collected. The unprocessed semen sample was injected into microfluidic device to sort highly motile sperm. Similarly, unprocessed semen sample was also subjected to traditional swim-up method to compare the sperm sorting efficiency

Participants/materials, setting, methods: A microfluidic sperm-sorting device has two chambers (top and bottom) separated by a polycarbonate filter of various pore diameters, i.e., 8, 14, and 20 μm. Followed by the injection of semen sample into bottom chamber, top chamber was filled with human tubal fluid containing 4% human serum albumin, and device was incubated in 5% CO_2 at 37°C for 30 min. The motile and morphologically normal sperm were collected from top chamber for further analysis.

Main results and the role of chance: One unprocessed semen sample was collected and split two ways, i.e., swim-up and microfluidic device, which are analyzed using CASA system (CEROS by Hamilton Throne) to measure percentage of motile sperm. All the sperm functional parameters such as motility and morphology (based on Strict criteria defined by WHO) were analyzed and compared with sperm sorted using microfluidic device and swim-up approach. The results showed that the sperm sorted using 8, 14 and 20 μm pore membrane filtered microfluidic device have higher motility of 96, 90 and 92% respectively as compared to sperm sorted in swim-up approach (50%). Similarly, higher percentage of morphologically normal sperm was observed in sperm sorted using 8, 14 and 20 μm pore membrane filtered microfluidic device such as 58, 57 and 57% respectively, as compared to swim-up (34%). The higher motility and morphology in microfluidic device sorted sperm is due to the presence of micropores between the two chambers that selectively allow the most motile and morphologically viable sperm to swim offering a functional sorting mechanism over traditional sorting methods, i.e., swim-up.

Limitations, reasons for caution: The developed microfluidic sperm sorting device is optimized with 8 mm pore sized membrane, which shows better sperm sorting efficiency as compared to other pore sized membranes. On the other hand, sperm retrieval efficiency is increased with increasing the pore size of membrane that significant to improve clinical outcomes.

Wider implications of the findings: The developed microfluidic device is easy-to-use, high-throughput, and it can be an alternative approach for routine sperm sorting analysis to potentially improve fertilization outcomes.

Trial registration number: Not applicable.

O-195 Cryopreservation of very low numbers of spermatozoa from infertile men using agarose capsules

S. Hatakeyama[1,2], S. Tokuoka[1], Y. Araki[3], Y. Araki[2,3,4]
[1]*Tokuoka Ladies Clinic, Obstetrics, Gynecology, Tokyo, Japan*
[2]*Gumma Paz College, Health Science, Takasaki, Japan*
[3]*The Institute for Advanced Reproductive Medical Technology, Cell Biology, Genetics, Maebashi, Japan*
[4]*Nippon Reprogenetics, Genetics, Mebashi, Japan*

Study question: Is it possible to cryopreserve low numbers of human spermatozoa from infertile men using agarose capsules?

Summary answer: We cryopreserved 2142 motile spermatozoa from 26 infertile male patients in 702 agarose capsules and 1356 (63%) were successfully recovered after thawing.

What is known already: Other methods for the cryopreservation of a few human spermatozoa have been reported. However, these methods are impractical due to difficulty in the preparation of materials or the time taken to search for spermatozoa after thawing. Therefore, we have devised a new method to cryopreserve a few spermatozoa using agarose capsules.

Study design, size, duration: Subjects were 26 infertile male patients at Tokuoka ladies clinic in 2015.

Participants/materials, setting, methods: We produced hollow core capsules with agarose walls. The capsules were transferred into a drop of cryoprotectant solution which contained 7% glycerol. We injected 3–4 motile spermatozoa, selected by swim up method, into agarose capsules using conventional ICSI procedure. These capsules were put on a Cryotop®, frozen in nitrogen vapor, and then submerged into liquid nitrogen and subsequently thawed and recovered. The motile spermatozoa in the capsules were counted.

Main results and the role of chance: The spermatozoa motility rates after thawing (MRAT) ranged from 20.0% (5/25) to 95.1% (58/61) among patients. The mean MRAT was 68.3%. Semen volume did not correlate with MRAT ($r = –0.075$). Spermatozoa concentration in the semen weakly correlated with MRAT ($r = 0.365$). Total number of motile spermatozoa in the semen moderately correlated with MRAT ($r = 0.493$). Total number of motile spermatozoa collected by swim up method strongly correlated with MRAT ($r = 0.746$).

Limitations, reasons for caution: None.

Wider implications of the findings: It was possible to cryopreserve infertile men's spermatozoa using agarose capsules. However, there were wide differences in MRAT among patients. It seems the oligozoospermic semen samples have a lower freezing resistance. Further studies using this method in cryptozoospermic semen samples, and spermatozoa taken from the testis or epididymis, are required.

Trial registration number: None.

O-196 Influence of the abstinence period on human sperm quality: analysis of 2,458 semen samples

A.L. Mauri[1,2], C.G. Petersen[1,2], L.D. Vagnini[2], A. Renzi[2], G.R. Oliveira-Pelegrin[2], C. Zamara[1], M. Cavagna[1,2,3], F. Dieamant[1,2], J.B.A. Oliveira[1,2], R.L.R. Baruffi[1,2], J.G. Franco Jr.[1,2]
[1]*Centre for Human Reproduction Prof Franco Jr, Research, Ribeirao Preto, Brazil*

[2]Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil
[3]Women's Health Reference Center Perola Byington Hospital, Research, Sao Paulo, Brazil

Study question: Is there a relationship between the sexual abstinence period and semen characteristics?
Summary answer: Increase in the sexual abstinence period influences sperm quality. Sperm DNA fragmentation and mitochondrial activity worsen, but chromatin packaging improves with an increased duration of abstinence.
What is known already: The duration of sexual abstinence that is needed to provide maximum sperm quality is one of the issues commonly discussed between physicians and patients. Most fertility clinics follow the World Health Organization (WHO) guidelines. However, there are few benchmark articles that have established current presumptions about the ideal duration of abstinence. The diversity regarding study designs used for assessing the influences of sexual abstinence on semen parameters and the size of the analysed population in the published reports are additional points that impair the conclusions.
Study design, size, duration: A cohort of 2,458 men undergoing infertility investigation was recruited. In the first evaluation, each man was asked to deliver a semen sample, and the abstinence period was recorded. No instruction about the abstinence period was given before semen collection for the study. Semen analyses were performed according to WHO guidelines/morphology-motile sperm organelle morphology examination/MSOME. For DNA integrity analysis, the percentages of DNA fragmentation (TUNEL), abnormal chromatin packaging/underprotamination (chromomycin A3/CMA3), abnormal mitochondrial membrane potential (MMP/MitoTracker Green), and apoptosis (annexin-V) were recorded.
Participants/materials, setting, methods: Associations between the sexual abstinence period and sperm parameters were assessed using Spearman correlation. For two-group comparisons, the subjects were categorized according to the sexual abstinence period (SAP) into three groups: SAP <2 days ($\mu = 0.8 \pm 0.3$), SAP 2–5 days ($\mu = 3.1 \pm 1.0$), and SAP >5 days ($\mu = 9.1 \pm 11.0$). At least 200 spermatozoa were examined in each evaluation. Potential confounders (age, BMI, smoking, alcohol, and varicocele) were also observed.
Main results and the role of chance: The duration of abstinence had a statistically significant positive influence on sperm concentration, volume, and the number of leukocytes and a statistically significant negative influence on sperm motility and vitality. The percentages of DNA fragmentation and MMP (mitochondrial damage) worsened with the increased duration of abstinence. The percentage of sperm protamination was statistically significantly increased with abstinence (Tables 1 and 2).

No correlation between abstinence and potential confounders was observed.

Table 1. Sexual abstinence × semen parameters: Spearman's correlation.

Outcomes	Correlation coefficient	*p*
pH	−0.01	0.52
Volume (ml)	0.10	0.0004
Concentration (ml × 10⁶)	0.12	<0.0001
Progressive motility (%)	−0.10	0.0007
Normal forms (%)	0.03	0.12
Leukocytes (×10⁶/ml)	0.10	0.0001
Vitality (%)	0.12	<0.0001
DNA fragmentation (%)	0.12	<0.0001
Apoptosis (%)	0.01	0.21
CMA3 positivity (%)	−0.12	<0.0001
Abnormal MMP (%)	0.10	0.003

Table 2. Sexual abstinence × semen parameters: group comparisons.

Outcomes	SAP: <2 days	SAP: 2–5 days	SAP >5 days	*p*
n	244	1.932	282	
pH	8.0 ± 0.6	8.0 ± 0.5	8.0 ± 0.4	0.28
Volume (ml)	2.3 ± 1.2[a,b]	2.7 ± 1.6[a]	2.8 ± 1.7[b]	0.0001[a], 0.0004[b]
Concentration (ml × 10⁶)	60.7 ± 50.0[a,b]	70.4 ± 61.1[a,c]	92.1 ± 65.8[b,c]	0.02[a], <0.0001[b,c]
Progressive motility (%)	58.3 ± 16.2[a,b]	56.1 ± 16.9[a,c]	53.8 ± 16.1[b,c]	0.03[a], 0.0004[b], 0.01[c]
Normal forms (%)	0.7 ± 1.0	0.9 ± 1.4	1.0 ± 1.8	0.77
Leukocytes (×10⁶/ml)	0.3 ± 0.6[a,b]	0.4 ± 0.9[a]	0.5 ± 1.2[b]	0.002[a], 0.0002[b]
Vitality (%)	66.8 ± 14.0[a,b]	65.0 ± 15.0[a,c]	61.3 ± 14.8[b,c]	0.03[a], <0.0001[b,c]
DNA fragmentation (%)	14.5 ± 8.2[a]	15.3 ± 8.4[b]	17.1 ± 9.0[a,b]	0.001[a], 0.002[b]
Apoptosis (%)	19.3 ± 8.5	19.1 ± 7.9	20.2 ± 7.3	0.17
CMA3 positivity (%)	59.8 ± 15.3[a,b]	56.1 ± 15.2[a,c]	53.2 ± 14.2[b,c]	0.005[a], 0.0002[b], 0.02[c]
Abnormal MMP (%)	23.3 ± 14.0[a]	25.6 ± 16.5	28.6 ± 17.5[a]	0.01[a]

Limitations, reasons for caution: The study involved samples from men attending a fertility clinic who are likely to have a lower semen quality and higher rate of pathology compared with the general population.
Wider implications of the findings: This study reinforces the importance of the duration of ejaculatory abstinence on semen parameter variation. It highlights the deleterious effect of increased abstinence on DNA damage, which is most likely associated with ROS (mitochondrial damage/number of leukocytes). The increase in chromatin packaging can represent a protective feature for DNA.
Trial registration number: Not applicable. The local ethics committee authorised this study.

SESSION 53: GENETIC FACTORS IN INFERTILITY

Tuesday 05 July 2016 **Hall 5 A** **17:00–18:00**

O-197 Identifying Clock genes and comparing their circadian expression in the endometrium of healthy fertile women and those with recurrent implantation failure (RIF)

L. Stocker[1], Y. Cheong[1]
[1]Princess Anne Hospital, Complete Fertility Centre, Southampton, UK

Study question: Are Clock genes expressed in a rhythmic manner in the endometrium of fertile women and those with RIF, and does decidualisation of the cells have an impact on this expression?
Summary answer: Clock genes are expressed in decidualised and non-decidualised endometrium. This rhythmicity may be influenced by pathology within the endometrium of women with reproductive problems.
What is known already: Many aspects of reproductive function are strongly circadian but the rhythmicity that happens within the reproductive organs themselves is less well understood. The majority of evidence from mammals suggests that female reproductive structures contain circadian clocks and Clock genes are expressed throughout the hypothalamic–pituitary–gonadal (HPG) axis.

Endometrial dysfunction may occur if regulatory endocrine stimulation fails, either centrally or peripherally, with a disruptive effect on the synchronisation of implantation. Whether this dysregulation happens at the level of the endometrium, which may be altered by the relative expression and timing of clock genes, or at the embryo-endometrial interface is not known.
Study design, size, duration: A case–control gene expression study (August 2013–2015) was performed *in vitro* to quantify the levels of Clock gene expression in human endometrial tissue. The level of expression was measured every 4 h over a 36 h period (in decidualised and non-decidualised endometrial stromal cells, total of 80 samples) to investigate how expression altered over time. The affect of adding progesterone was compared with untreated cells in healthy endometrial tissue and in those women with RIF.
Participants/materials, setting, methods: Women between 25 and 45 years were recruited and baseline demographics and fertility characteristics were collected. Women were included if they suffered RIF or were fertile controls. Endometrial biopsies were taken by suction curette, the stromal cells were isolated and cultured *in vitro* before decidualisation was commenced by the addition of

progesterone. Cells were sampled at baseline and four-hourly intervals. Total RNA extraction, cDNA synthesis and PCR of Clock-controlled genes was performed.

Main results and the role of chance: Six Clock-controlled genes (CLOCK, BMAL, PER1, PER2, CRY1, CRY2) are present and are cyclically expressed in endometrial tissues *in vivo.* This expression level varies over the period of a day. Decidualisation appears to alter the relative expression of these genes and this effect continues over time (up to 36 h) without resynchronising the peripheral "Clock" and independently of central control.

The endometrium from fertile women displays a different rhythmicity of these genes compared with those women who have suffered RIF. This suggests that any underlying pathology in RIF women may be related to dysynchrony at the level of the gene regulation within the endometrium. Whether or not this effect remains over time periods longer than 36 h is yet to be elicited.

The timing of events at the embryo-endometrial interface during the reproductive cycle is not fully understood and the expression of the Clock-controlled genes may have a role to play. Future work should be aimed at demonstrating the level of this control and whether it may be manipulated to beneficial effect.

Limitations, reasons for caution: Our results may be confounded by a small sample size; a larger scale study in this specific subgroup of women is further needed to confirm our findings.

Wider implications of the findings: Clock-controlled genes are found within the endometrium and are affected by the effects of progesterone. The manner in which these genes are expressed is also related to reproductive pathology. Cellular functions of clock genes may have a role in RIF and the process of embryo implantation.

Trial registration number: Regional ethics committee number 12/SC/0568.

O-198 Hyperandrogenism reprograms leptin *via* down-regulation of DNMT1, a novel mechanism involved in decreased pregnancy rates in PCOS patients

L. Xian-hua[1], S. Tian[2], M.E. Liu[2], J.Z. Sheng[2], H.F. Huang[1]
[1]*International Peace Maternity and Child Health Hospital of China Welfare Institute, The Reproductive Centre, Shanghai, China*
[2]*Zhejiang University, The Key Laboratory of Reproductive Genetics, Hangzhou, China*

Study question: How does hypernadrogenism affect leptin reprogramming in human granulosa cells, subsequently alter leptin levels and impact female reproductive health?

Summary answer: Dihydrotestosterone increased Leptin expression and decreased methylation level in *leptin* promoter in both *in vivo* and *in vitro* experiment, which is associated with failed pregnancy.

What is known already: Hypernadrogenism is the main pathologic characteristic of polycystic ovary syndrome (PCOS). Hyperleptinemia and high follicular fluid (FF) leptin levels are important pathologies in PCOS patients with infertility.

Study design, size, duration: A case control study was performed among 43 women with hyperandrogenism and 159 infertile women with tubal factor (control) from January to June 2015.

Participants/materials, setting, methods: The diagnosis of PCOS was made according to the Rotterdam Consensus. The subjects were divided into successful and failed subgroups according to *in vitro* fertilization outcomes. We examined testosterone and leptin levels in serum and follicular fluid using ELISA, real-time PCR. Bisulfite Sequencing PCR were performed to detect Leptin expression and methylation level in granulosa cells, also effect of dihydrotestosterone *in vitro*. Expression of DNA methyltransferase 1 was also detected *in vivo* and *in vitro*.

Main results and the role of chance: Leptin levels in serum and follicular fluid of women with hyperandrogenism were significantly higher than control, serum leptin level was positively correlated with testosterone level. *In vitro* study showed that Dihydrotestosterone (DHT) increased Leptin expression and decreased methylation level in Leptin DMR in primary granulosa cells (GCs), whereas DHT decreased the expression of DNA methyltransferase 1 (DNMT1) both *in vivo* and *in vitro*. Further analysis revealed that women from successful pregnancy group showed significantly lower Leptin and testosterone levels. Hyperandrogenism rat also showed increased Leptin expression accompanied with decreased methylation level in Leptin DMR and decreased DNMT1 expression in GCs.

Limitations, reasons for caution: Hypernadrogenism and high leptin levels were coexisted in follicular fluid. The relationship between them hasn't been proven in this study. Further study is needed.

Wider implications of the findings: Hyperandrogenism increased leptin expression *via* hypomethylation of *leptin* promoter, probably attributed to decreased DNMT1. Up-regulation of leptin was associated with failed pregnancy in patients with hyperandrogenism.

Trial registration number: ChicCTR-OCH-14004537, www.medresman.org.

O-199 Differentially methylated LINE1 patterns in sperm DNA of infertile men

C. Kostoulas[1], S. Markoula[1], L. Lazaros[1], P. Sakaloglou[1], I. Bouba[1], C. Kitsou[1], E. Hatzi[1], N. Sofikitis[2], K. Zikopoulos[3], I. Georgiou[1]
[1]*University of Ioannina, Medical School, Laboratory of Medical Genetics and Human Reproduction, Ioannina, Greece*
[2]*University of Ioannina, Medical School, Department of Urology, Ioannina, Greece*
[3]*University of Ioannina, Medical School, Department of Obstetrics and Gynecology Genetics and IVF Unit, Ioannina, Greece*

Study question: To investigate the overall methylation and the patterns of methylation of two consecutive CpGs within the LINE-1 retroelements in sperm from normospermic and oligospermic men.

Summary answer: Our data show significant differences in the overall methylation levels and in the DNA methylation patterns from spermatozoa of normospermic and oligospermic men.

What is known already: DNA methylation in mammals is a dynamic and strictly controlled process, in numerous cellular processes, cell differentiation, regulation of gene expression, genome reprogramming and silencing of repetitive elements. In mammals, epigenetic reprogramming is crucial for germ cell development. Principal epigenetic regulatory mechanism is DNA methylation during gametogenesis and early embryo preimplantation stages. Differentially methylated regions in sperm DNA involve mainly the retroelement LINE-1, which is abundant in the human genome, with 5×10^4 copies. LINE-1 is silenced during gametogenesis by DNA methylation, chromatin modifications and Piwi-interacting RNAs. Aberrant DNA methylation levels of LINE-1 have been implicated in various human disorders.

Study design, size, duration: The study included 92 men who gave a detailed medical history. Subjects were stratified in two groups: (a) normospermic (70 men) and (b) oligospermic (22 men, $<15 \times 10^6$ spermatozoa). The oligospermic group was further classified into moderate (13 men, $5–15 \times 10^6$ spermatozoa) and severe (9 men $<5 \times 10^6$ spermatozoa). LINE-1 overall methylation levels and methylation patterns of the oligospermic group were compared to the normospermic control group.

Participants/materials, setting, methods: DNA methylation levels and patterns of LINE-1 were measured by the semi-quantitative COBRA method. DNA extracted from human sperm, was treated with sodium bisulfate and amplified using primers designed to amplify the 5′UTR. Amplicons were digested with methylation sensitive enzymes, and electrophoresed in polyacrylamide-gels. Intensities of the bands were measured by a phosphoimager. COBRA assays were performed in duplicates with DNA from Hela, Jurkat and Daudi cells as controls.

Main results and the role of chance: Semi-quantitative COBRALINE-1 results were sorted as four distinct methylation patterns of the two CpG dinucleotides in the 5′UTR: hypermethylation ($^{m}C^{m}C$), hypomethylation ($^{u}C^{u}C$), partial methylation of the 5′($^{m}C^{u}C$) and partial methylation of the 3′end ($^{u}C^{m}C$).

Significant differences ($p = 0.039$) in the overall methylation levels of LINE-1 in the normospermic and severe oligospermic samples were found. In the severe oligospermic samples the overall methylation level (41.52%) was significantly higher than in the normospermic samples (40.62%).

Pattern analysis in normospermic samples found statistically significant correlation of the partially methylated $^{m}C^{u}C$ and the hypomethylated $^{u}C^{u}C$ motif ($p = 0.031$). Although we found a direct correlation ($r = 0.258$) between the two patterns in normospermics there was no such significant result in oligospermics.

Analysis in oligospermic samples found statistically significant inverse correlation ($r = -0.526$) between the partially methylated pattern $^{m}C^{u}C$ and the hypermethylated $^{m}C^{m}C$ ($p = 0.012$) in contrast to normospermics.

In addition, the partially methylated pattern $^{u}C^{m}C$ and the hypermethylated $^{m}C^{m}C$ were inversely correlated in both oligospermics and normospermics ($p = 0.003$, $r = -0.602$ and $p = 0.0001$, $r = -0.625$ respectively).

Limitations, reasons for caution: A major limitation is the small number of oligospermic subjects. The semi-quantitative COBRA method is also a limitation and a fully quantitative method would provide more accurate results.

Wider implications of the findings: Our findings indicate that normospermics have lower methylation levels and different methylation patterns of LINE-1 in comparison to oligospermics. Differences may reflect abnormalities in the initial demethylation process at Primordial Germ Cells rather than abnormalities in the reestablishment of methylation during sperm maturation.

Trial registration number: –.

O-200 Methylation of a novel FMR1 epigenetic element depends on women ovarian reserve

B. Youness[1], J. Dietrich[1], T. Strowitzki[1], P.H. Vogt[1], J. Rehnitz[1]
[1]*Women Hospital, Department of Gynecological Endocrinology and Reproductive Medicine, Women Hospital University of Heidelberg, Heidelberg, Germany*

Study question: We want to study whether FMR1 (Fragile × Mental Retardation 1) epigenetic control in human granulosa cells (GC) have an impact on women ovarian response.

Summary answer: The identification of a novel FMR1 epigenetic element (FREE3) within the promoter whose methylation pattern varies according to ovarian response

What is known already: The FMR1 gene contains in exon1 a repetitive CGG-triplet block ($n = 26$–34 in general population) which is a part of its promoter CpG island. The implication of FMR1 in human folliculogenesis is highlighted by the fact that women with increased CGG triplet numbers have increased risk of primary ovarian insufficiency/failure (POF/POI) (when: $52 \leq n \leq 200$ increase to 20%). Recent molecular studies showed that FMR1 CpG island is also under complex epigenetic control; two epigenetics elements called FREE1 and FREE2 (Fragile × epigenetic element 1 and 2) were indicated as predictors of FMR protein (FMRP) expression level in female leukocytes (CGG >52).

Study design, size, duration: Establishment of a specific CpG Methyl Specific Primers (MSP) assay to reveal allele specific CpG methylation pattern within the 5′FMR1 CpG island promoter region including its first intron in patients primary GC.

Patients seeking *In Vitro* Fertilization (IVF) treatment were divided into three groups according to their ovarian response; High (HOR), Normal (NOR) and Poor (POR) Responders (according to Bologna Criteria). CpG methylation profiles were compared between groups for statistically significance using the Mann–Whitney-*U* test.

Participants/materials, setting, methods: According to ovarian response after controlled ovarian stimulation, granulosa cells from women with different ovarian response were collected by our IVF laboratory and used for MSP assays. Human GC line COV434 was used in parallel as model system investigating the FMR1 promoter and first intron CpG methylation profile.

Main results and the role of chance: The data point to a similar complex epigenetic control in GCs as reported earlier in leukocytes. FREE1 and FREE2 were found in the COV434 cell line as well as in primary GCs from patients. Additionally, a third epigenetic element was identified in intron 1 called accordingly FREE3. Using the Mann–Whitney-*U* test significant divergent FREE3 CpG methylation patterns for specific CGs was found between HOR/NOR/POR patients groups, i.e., this pattern was dependent on ovarian response. It suggests that this CG specific methylation profile have an impact on FMRP expression level in GCs.

Limitations, reasons for caution: Our preliminary data were obtained from FREE3 sequencing results of 25 patients. Screening a higher number of patients with different ovarian reserve is going on by using a high throughput CpG methylation analysis to confirm the obtained data.

Wider implications of the findings: For the three patient groups FREE3 shows a similar divergent CG methylation profile in both leukocytes and granulosa cells. If this holds true our MSP assay for FREE3 can be used as a non-invasive prognostic tool in leukocytes to predict ovarian reserve and response in females entering the infertility clinic.

Trial registration number: This study was funded by the Deutsche Forschungsgemeinschaft (DFG) to J. Rehnitz.

O-201 Hysteroscopic intratubal Essure® device placement versus laparoscopic salpingectomy, as treatment for hydrosalpinges prior to *in vitro* fertilization (IVF)/intracytoplasmatic sperm injection (ICSI): a randomised controlled trial

K. Dreyer[1], M. Lier[2], M.H. Emanuel[3], J. Twisk[4], B.W. Mol[5], R. Schats[2], P. Hompes[2], V. Mijatovic[2]
[1]*Amsterdam, Netherlands*
[2]*VU University Medical Centre, Department of Reproductive Medicine, Amsterdam, Netherlands*
[3]*Spaarne Gasthuis, Department of Obstetrics and Gynaecology, Hoofddorp, Netherlands*
[4]*VU University Medical Centre, Department of Epidemiology and Biostatistics, Amsterdam, Netherlands*
[5]*The Robinson Research Institute, School of Paediatrics and Reproductive Health, Adelaide, SA, Australia*

Study question: Does hysteroscopic proximal tubal occlusion by Essure® devices as treatment for hydrosalpinges result in comparable ongoing pregnancy rates following IVF/ICSI as compared to laparoscopic salpingectomy?

Summary answer: Hysteroscopic proximal tubal occlusion by Essures® is inferior to laparoscopic salpingectomy in the treatment of hydrosalpinges in women undergoing IVF/ICSI with respect to ongoing pregnancy.

What is known already: It is known that women with hydrosalpinges undergoing IVF have poorer pregnancy outcomes compared to women with other forms of tubal infertility. In these women both laparoscopic salpingectomy and laparoscopic proximal tubal ligation are known to improve IVF outcomes. At present it is unclear whether a less invasive hysteroscopic treatment with Essure® leads to similar ongoing pregnancy rates following IVF as compared to laparoscopic salpingectomy which is currently considered as standard treatment.

Study design, size, duration: A two-centre, randomised controlled non-inferiority trial. Between October 2009 and December 2014 a total of 85 women were included in this study, of whom 42 were randomised to hysterocopic Essure® treatment and 43 to laparoscopic salpingectomy. Randomization was based on a computer generated randomization list. The study was unblinded. Primary outcome was ongoing pregnancy rate, defined as a fetal heartbeat on ultrasound beyond 10 weeks gestation following one IVF/ICSI treatment (fresh and frozen-thawed embryo transfers).

Participants/materials, setting, methods: We studied women between 18 and 41 years, with uni- or bilateral ultrasound visible hydrosalpinges who were scheduled for an IVF/ICSI treatment.

Main results and the role of chance: The ongoing pregnancy rates according to the intention to treat principle were 11/42 (26.2%) after Essure® (intervention group) versus 24/43 (55.8%) after laparoscopic salpingectomy (control group) (absolute difference 29.6%; 95% CI 7.1–49.1, RR 0.47 95% CI 0.27–0.83). In the per protocol analysis the ongoing pregnancy rate following Essure® treatment was 9/27 (33.3%) compared to 19/32 (59.4%) following laparoscopic salpingectomy (absolute difference 36.1%; 95% CI −1.8 to 50.0, RR 0.56; 95% CI 0.31–1.03).

Limitations, reasons for caution: Masking participants and investigators would be difficult due to the nature of both interventions and since we had objective outcome measurements we witholded sham procedures, leaving the study unblinded. Furthermore our low sample-size resulted in wide confidence intervals. A larger sample size would result in a more accurate treatment effect.

Wider implications of the findings: In the treatment of hydrosalpinges prior to IVF/ICSI, hysteroscopic proximal tubal occlusion by Essure® is

inferior to laparoscopic salpingectomy. Therefore, Essure® treatment should only be considered in women with hydrosalpinges who are laparoscopically inaccessible.

Trial registration number: The Dutch Trial Register: NTR 2073.

O-202 Laparoscopy vs. robotic surgery for endometriosis (LAROSE): a multicenter randomized controlled trial

E. Soto[1], T.H. Luu[2], X. Liu[3], J.F. Magrina[4], J.I. Einarsson[5], T. Falcone[2]
[1]*South Florida Institute for Reproductive Medicine, Reproductive Endocrinology and Infertility, Miami, FL, USA*
[2]*Cleveland Clinic, Obstetrics, Gynecology and Women's Health Institute, Cleveland, OH, USA*
[3]*Cleveland Clinic, Department of Quantitative Health Sciences, Cleveland, OH, USA*
[4]*Mayo Clinic Arizona, Gynecology, Scottsdale, AZ, USA*
[5]*Harvard/Brigham and Women's Hospital, Minimally Invasive Gynecology, Boston, MA, USA*

Study question: Is robotic surgery comparable to laparoscopy for the treatment of endometriosis?

Summary answer: There were no clinically significant differences between the laparoscopy and robotic surgery groups with regards to operative time, postoperative pain or quality of life.

What is known already: Retrospective studies in the literature suggest that robotic surgery is comparable to laparoscopy for the treatment of endometriosis but the former is associated with greater operative time. One study revealed a shorter robotics operative time for patients with advanced endometriosis (stage III and IV).

Study design, size, duration: A prospective, multicenter, randomized blinded controlled trial was performed in 73 patients between March 2012 and December 2015. Patients from Cleveland Clinic, Harvard/Brigham and Women's Hospital and Mayo Clinic Arizona were randomized at the time of surgery to laparoscopy (LSC) vs. robotic surgery (ROB) to treat presumed endometriosis. The primary outcome was operative time. Power calculation revealed that 37 patients were needed in each arm of the study ($\beta = 0.8$, $\alpha < 0.05$).

Participants/materials, setting, methods: Patients ≥18 years old that were to have minimally-invasive surgery for presumed endometriosis were randomized to laparoscopy or robotic surgery ($n = 73$). Perioperative variables recorded included operative time, estimated blood loss, perioperative complications, hospital stay and pain medication use.

Validated quality of life questionnaires -SF-12 and Endometriosis Health Profile-30 (EHP-30)-, pain medication use questionnaire and pain and activity scales were applied preoperatively and at 6 weeks and 6 months after surgery.

Main results and the role of chance: A total of 73 patients were included in the study (LSC: 35, ROB: 38). One patient from the robotic arm withdrew from the study. Mean age, body mass index, indication for surgery and other baseline characteristics were comparable in both groups. The mean operative time (SD) was similar in the laparoscopy and robotic surgery groups [101.6 (63.2) min, 106.6 (48.4) min, $P = 0.71$]. The estimated blood loss was comparable in both groups (43.8, 100.9 cc, $P = 0.136$). Intraoperative complications, length of hospital stay, postoperative complications and use of postoperative pain medication was comparable in both groups. Preoperative pain scores were similar in both groups (LSC: 51.2 ± 18.1 vs. ROB: 52.8 ± 17, $P = 0.44$). There was a progressive decrease in pain scores observed at 6 weeks and 6 months in both arms without statistically significant differences between groups [6 weeks, LSC: 22.7 (6.8, 40.9) vs. ROB: 25.0 (4.5, 43.2), $P = 0.79$; 6 months, LSC: 11.4 (0.0, 45.5) vs. ROB: 13.6 (0.0, 50.0), $P = 0.43$]. Patients in the laparoscopy arm had a higher SF-12 Physical Health Scores in comparison to patients in the robotic arm at 6 weeks [41.9 (2.8) min, 39.6 (3.6) min, $P = 0.01$]; SF-12 Physical and Mental Scores and other quality of life scores (EHP-30) were comparable in both groups at 6 months.

Limitations, reasons for caution: A limitation of the study is that the sample size may not be large enough to detect differences in the secondary outcomes. A patient from the robotic arm withdrew from the study after randomization.

Wider implications of the findings: The observations of the current study suggest that similar outcomes can be achieved with robotic or laparoscopy for the treatment of endometriosis when the surgery is performed by surgeons that are proficient in both approaches. Traditional laparoscopy should still be considered the gold standard approach for endometriosis.

Trial registration number: ClinicalTrials.gov identifier: NCT01556204.

O-203 Hysteroscopic removal of placental remnants: a randomised controlled trial comparing hysteroscopic morcellation with cold loop resection

T. Hamerlynck[1], H. van Vliet[2], A.S. Beerens[3], S. Weyers[1], B. Schoot[2]
[1]*Ghent University Hospital, Women's Clinic, Gent, Belgium*
[2]*Catharina Hospital, Department of Obstetrics and Gynaecology, Eindhoven, Netherlands*
[3]*Ghent University Hospital, Department of Pathology, Gent, Belgium*

Study question: Is hysteroscopic morcellation a better technique for hysteroscopic removal of placental remnants compared with cold loop resection?

Summary answer: Hysteroscopic morcellation is faster than cold loop resection, and both techniques show high rates of complete removal and a low risk of intrauterine adhesion formation.

What is known already: Removal of placental remnants by curettage is common practice, but it is associated with postoperative intrauterine adhesions in up to 40%. Alternatively, cold loop resection and hysteroscopic morcellation allow for mechanical, selective removal of placental remnants under direct vision, and hysteroscopic removal appears favourable to curettage in cohort studies, with more complete evacuations, less intrauterine adhesions, and similar reproductive outcomes.

Study design, size, duration: From May 2011 to July 2015 an open, randomised controlled trial was performed comparing hysteroscopic morcellation with the TRUCLEAR 8.0 Tissue Removal System with cold loop resection using a rigid 8.5 mm bipolar resectoscope for removal of placental remnants. The sample size was calculated at 34 women in each group. Randomisation was done by a computer generated random allocation sequence. Eighty-six women with placental remnants after pregnancy were included in the intention-to-treat analysis.

Participants/materials, setting, methods: Patients with placental remnants diagnosed by ultrasound and/or diagnostic hysteroscopy were randomly allocated to either removal by hysteroscopic morcellation or cold loop resection. Patients were treated in day surgery under spinal or general anaesthesia. Routine second-look ambulant hysteroscopy was performed to study postoperative adhesion formation. Both techniques were compared in terms of procedure time, adverse events, tissue availability, histology results, short-term effectiveness and postoperative adhesion formation.

Main results and the role of chance: Median operating time was significantly reduced in the hysteroscopic morcellation group compared with the cold loop resection group [6.2 min (4.0–11.2 min) vs. 10.0 min (5.8–16.4 min), $p = 0.023$]. After correction for diameter, both operating time and total procedure time were significantly less for hysteroscopic morcellation compared with cold loop resection, with a reduction of 40% (95% CI 15–58%, $p = 0.005$) and 22% (95% CI 5–37%, $p = 0.014$), respectively. No technique related adverse events occurred. However, 8 cases of perforation at dilation were seen in the hysteroscopic morcellation group, resulting in 2 procedure discontinuations and 1 incomplete removal in that group. Incomplete removal was found in, 1 uncomplicated procedure of the hysteroscopic morcellation group and 2 uncomplicated procedures of the resection group. Tissue was available for pathology analysis in 40/44 (91%) and 37/39 (95%) of cases with placental remnants present at the time of the operation in the hysteroscopic morcellation and resection group, respectively, showing positive histology in 27/40 (67.5%) and 26/37 (70%). De novo intrauterine adhesions were seen in 1/35 patients (3%) of the hysteroscopic morcellation group, and 1/30 (3%) patients of the resection group, during second-look hysteroscopy.

Limitations, reasons for caution: The study was powered for procedure time only. Patients and surgeons were not blinded for the procedure. Although the majority of patients underwent second-look ambulant hysteroscopy after removal of placental remnants, 18% of patients did not. This may have led to selection bias considering the outcome of intrauterine adhesions.

Wider implications of the findings: Hysteroscopic morcellation is a faster alternative than cold loop resection, and both techniques are effective and safe in removing placental remnants. Prospective randomised comparison between hysteroscopic treatment and curettage is needed to confirm the expected advantages of removal of placental remnants under direct vision in women with future reproductive desire.
Trial registration number: NCT01537822.

O-204 Natural pregnancy rates after fallopian tube catheterisation for proximal tubal obstruction: a systematic review and meta-analysis

P. De Silva[1], J. Chu[1], I. Gallos[1], A. Vidyasagar[1], L. Robinson[1], M. Rajkhowa, Y. Afifi[1], A. Coomarasamy[1]
[1]Birmingham Women's NHS Foundation Trust, Academic Unit, Birmingham, UK

Study question: What is the chance of natural clinical pregnancy when fallopian tube catheterisation (FTC) is used for unilateral or bilateral proximal tubal occlusion (PTO)?
Summary answer: The pooled natural clinical pregnancy rate (CPR) of FTC for PTO is 27% (95% CI 25–30%).
What is known already: Tubal disease accounts for approximately 30% of female infertility and is caused by infection, endometriosis or pelvic surgery. FTC, using a guidewire to direct a fine catheter into the fallopian tube, can be carried out under laparoscopic, hysteroscopic, fluoroscopic or ultrasonic guidance. This technique has fallen out of favour since the advent of *in vitro* fertilisation (IVF). Whilst many cohort studies have investigated the success of FTC, there have been no randomised studies comparing FTC with IVF to ascertain the optimal management of women with PTO. Our meta-analysis is the first to investigate reproductive outcome following FTC for PTO.
Study design, size, duration: Our literature search identified 26 cohort studies from 1989-2015, comprising 1530 patients who underwent FTC for PTO, all attempting natural conception. In the absence of any randomised controlled trials comparing FTC with IVF for PTO, we meta-analysed all suitable observational studies that met our inclusion criteria.
Participants/materials, setting, methods: Systematic literature searches using MEDLINE, EMBASE and Cochrane Central Register of Controlled Trials, were performed, returning a total of 2190 studies. Only studies that reported FTC outcome alone were included. Outcomes after FTC from PTO due to iatrogenic causes such as microsurgery or sterilisation were excluded. 26 cohort studies matched the strict inclusion criteria for data extraction in the meta-analysis.
Main results and the role of chance: The meta-analysis showed a pooled natural CPR of 27% (95% CI 25–30%) after the use of FTC for unilateral or bilateral PTO (26 studies, 1530 patients). In women with bilateral PTO (14 studies, 617 patients), the CPR was 27% (95% CI 23–32%).

In women undergoing FTC, meta-analysis of natural CPRs demonstrated that the cumulative CPRs were 22.3% (95% CI 17.8–27.8%) at 6 months, 25.8% (95% CI 21.1–31.5% CI) at 9 months, 26.4% (95% CI 23.0–30.2%) at 12 months, 25.8% (95% CI 22.6–29.6%) at 18 months, 26.9% (95% CI 23.9–30.4%) at 24 months, 27.8% (95% CI 24.8–31.3%) at 36 months and 28.4% (95% CI 25.4–31.7%) at 48 months.

Furthermore, the pooled live birth rate (13 studies, 525 patients) was 22% (95% CI 18–26%). The pooled miscarriage rate (15 studies, 633 patients) was 6% (95% CI 4–8%). The pooled ectopic pregnancy rate (26 studies, 1530 patients) was 4% (95% CI 3–5%).

The included studies scored satisfactorily on the Newcastle–Ottawa quality assessment scale.
Limitations, reasons for caution: The pooled natural CPR after FTC was found to be almost comparable to that after IVF (approximately 35%). However, included studies were small, non-comparative series with significant clinical heterogeneity in population characteristics, surgical technique and follow up.
Wider implications of the findings: In light of great disparity in the number of IVF cycles the National Health Service provides in the UK, these findings suggest FTC as an alternative strategy or adjunct in patients presenting with PTO. Further research is needed to identify particular patient sub-groups that would benefit the greatest from FTC.
Trial registration number: N/A.

SESSION 55: FEMALE FERTILITY. NEW AND RENEWED IDEAS

Tuesday 05 July 2016 **Hall 3 DE** **17:00–18:00**

O-205 Impact of serum vitamin D levels on ovarian reserve and ovarian response to ovarian stimulation in egg donors

C. Iglesias[1], A. Fabris[1], A. Pacheco[2], M. Cruz[1], A. Patel[3], J. Patel[3], H. Fatemi[4], J.A. Garcia-Velasco[5]
[1]IVI Madrid, Reproductive Medicine, Madrid, Spain
[2]IVI Madrid, Andrology Laboratory, Madrid, Spain
[3]Nova IVI Fertility, Reproductive Medicine, India
[4]IVI GCC Fertility Clinic, Reproductive Medicine, Abu Dhabi, United Arab Emirates
[5]IVI Madrid, Reproductive Medicine, IVI Madrid Clinic, Rey Juan Carlos University Professor, Madrid, Spain

Study question: Is there any correlation between serum vitamin D levels and the ovarian response to ovarian stimulation in healthy oocyte donors?
Summary answer: Serum vitamin D levels from oocyte donors was unrelated to their ovarian reserve or reproductive outcomes in oocyte recipients.
What is known already: Vitamin D deficiency is very common all over the world.

Some studies suggested a correlation between vit D deficiency and lower fertility; however infertility is diagnosed in around 15% of the couples, so the causative role of the vitamin D deficiency is still unclear.

A few publications demonstrated a reduction in the implantation and pregnancy rates in patients with non-replete vitamin D status after *In Vitro* Fertilization or egg donation, while others found no impact.

Only two groups have described a positive correlation between serum vitamin D and AMH levels while another group found an inverse correlation with serum FSH.
Study design, size, duration: We designed a retrospective study to investigate the association between serum vitamin D levels and ovarian reserve in oocyte donors and the reproductive outcome in the corresponding recipients.

In this study we included 994 healthy oocyte donors from June 2014 to April 2015.
Participants/materials, setting, methods: We selected 994 healthy donors between 18 and 34 years and we stimulated them using recFSH under GnRH antagonist and agonist triggered in our center.

Vitamin D binding protein measurement was performed by a commercial ELISA kit.

Vitamin D was determined by chemiluminescence by using a Advia Centaur analyzer.

Albumin determination was realized by using a Cobas Mira Plus analyzer.

Statistical analysis was performed by using SPSS program. Student's *t* test and ROCC curves were used as appropriate.
Main results and the role of chance: Among all donors, 288 were vitamin D replete (vitamin D >30 ng/ml), 524 had vitamin D insufficiency, and 182 presented deficiency (<20 ng/ml).

Days of stimulation, estradiol levels on hCG day, number of follicles, oocytes retrieved, number and rate of mature oocytes and cycle characteristics were comparable in the three groups.

Oocyte recipients that received embryos from vit D deficient donors obtained a lower number of embryos when compared to the ones who received embryos from a vitamin D replete donors ($p < 0.001$).

However, we did not find differences between the three groups of receptors in terms of implantation ($p = 0.48$), pregnancy ($p = 0.11$), ongoing pregnancy ($p = 0.6$) and miscarriage rate ($p = 0.6$).
Limitations, reasons for caution: Although this is a very large series, the retrospective nature of our study requires prospective validation.
Wider implications of the findings: Patients who receive oocytes from vitamin D deficient donors don't have a lower chance of becoming pregnant.

This highly prevalent vitamin D insufficiency does not impair ovarian reserve and/or quality in egg-donors.

Actually the recommendation of analyzing vitamin D status screening in egg-donors is not supported by our evidence
Trial registration number: 1508-MAD-055-JG.

O-206 The impact of acupuncture on IVF success rates: a randomized controlled trial

K. Gillerman[1], N. Rehman[1], M. Dilgil[1], R. Homburg[1]
[1]*Homerton University Hospital, Homerton Fertility Centre, London, UK*

Study question: To examine in a sufficiently powered prospective randomized controlled trial, whether acupuncture during IVF treatment can improve IVF success rates.
Summary answer: Acupuncture during IVF treatment significantly improves IVF success rates compared with a basically similar control group having no acupuncture.
What is known already: Clinical trials to assess the benefits of acupuncture on IVF treatment results have differed in study design, protocol, outcome measures and commercial bias. This heterogeneity has precluded any firm conclusion regarding the efficacy or otherwise of acupuncture in this field. To address this heterogeneity, 15 international acupuncturists participated in Delphi questionnaires and reached a consensus protocol to be used in future research which, so far, has not been implemented. To the best of our knowledge, this is the first study to use this newly agreed standard protocol.
Study design, size, duration: In this single-centre RCT, conducted over 1 year, according to the power calculation 160 couples were randomized into two groups using computer generated randomization numbers distributed consecutively by central telephone. One group received acupuncture treatment 4 times spread throughout the treatment cycle in addition to our standard IVF protocol. The other group went through the identical standard protocol but with no acupuncture.
Participants/materials, setting, methods: All couples in the study were undergoing their 1st or 2nd IVF cycle, age 23–43, BMI < 30 and consented to randomization before their treatment cycle. Those randomised to the study group ($n = 80$) received acupuncture based on the Delphi consensus protocol, between days 6 and 8 of ovarian stimulation, before egg retrieval and twice, before and after, embryo transfer. For both groups the IVF protocol was decided by the clinician, blinded to randomization. Primary end point was live birth.
Main results and the role of chance: To date, a total of 127 results are available and have been analysed, 67 in the acupuncture (study) group and 60 controls. So far, the total ongoing pregnancy rate in the two groups is 34.6%. This comprises an ongoing pregnancy rate of 31/67 (46.2%) in the acupuncture group and 13/60 (21.7%) in the controls ($P = 0.004$). Two couples withdrew from the control group. Live birth rates are being closely followed up and will be reported.
Limitations, reasons for caution: The additional attention paid to the acupuncture group as opposed to controls may have had a positive psychological influence.
Wider implications of the findings: The results of this study imply that acupuncture may be offered as a possible method of improving IVF outcome. This study is the first to follow a widely approved consensus protocol and therefore has settled disagreement in the literature and resolved previous disparity.
Trial registration number: 13/LO/1356.

O-207 Effectiveness of different combined oral contraceptives – final results from the "international active surveillance study – safety of contraceptives: role of estrogens" (INAS-SCORE) Study

C. Hagemann[1], J. Dinger[1], K. Heinemann[1], S. Moehner[1], C. Franke[1]
[1]*Berlin Center for Epidemiology and Health Research, Research, Berlin, Germany*

Study question: The secondary outcome focuses on unintended pregnancies and is compared between the two user cohorts: DNG/EV and established COCs in the US and Europe.
Summary answer: Combined oral contraceptives (COCs) have a high contraceptive effectiveness, nevertheless, lower contraceptive failure rates were seen in the European DNG/EV cohort compared to other COCs.
What is known already: Oral contraceptives are the most popular method of birth control and widely used in the USA and Europe. DNG/EV (Qlaira/Natazia) is a new combined oral contraceptive (COC) that contains estradiol valerate and dienogest. Up to date, there are no comparative data on the contraceptive effectiveness of DNG/EV and other COCs.
Study design, size, duration: INAS-SCORE was a large, prospective, controlled, non-interventional, long-term cohort study carried out in the US as well as in Austria, France, Germany, Italy, UK, Poland and Sweden. It was conducted as a Post-Authorization Safety Study (PASS) requested by the Medicines Evaluation Board (MEB). Overall, 50,000 women were planned to be enrolled in the study. Recruitment started in 2009 and was finished in 2012. Follow-up of complete cohorts continued until 2014.
Participants/materials, setting, methods: A network of prescribing physicians enrolled women with a new COC prescription. During the follow-up phase, the woman was contacted regularly and asked for information about unintended pregnancies. Self-reported pregnancies were validated by health care professionals. Absolute numbers, incidence rates (per 10,000 WY), rate ratios, 95% confidence intervals and Pearl Indices were calculated. Inferential statistics were based on Cox proportional hazards models. Crude and adjusted hazard ratios between cohorts were calculated.
Main results and the role of chance: The final analysis is based on 50,203 participants, contributing 105,761 women-years (WY) of observation, thereof 30,098 participants and 73,174 WY in the European arm. European regulatory authorities were concerned about the low proportion of DNG/EV users in the United States (2%) and requested that the primary analysis should be based on the European study arm only. Mean age in the DNG/EV cohort was 31.9 (SD 10.0) and 25.7 (8.0) in the COC (other) cohort. In Europe, 226 unintended pregnancies were reported, of which 28 occurred under DNG/EV use, 192 under COC (other) use and 53 under COC (LNG). The Pearl Indices for the European DNG/EV cohorts were 0.3, and for the COC (other) cohorts 0.5 and for COC (LNG) users 0.8. Adjusted HRs (for age, parity, user status, smoking) of DNG/EV vs. COC (other) and vs. COC (LNG) for Europe were: 0.7 (95% CI: 0.5–1.0) and 0.5 (95% CI: 0.3–0.9). Stratification for pregnancies by compliance yielded Pearl Indices of 0.1 ("perfect HC use") and 0.3 ("non-perfect HC use") in the European cohort.
Limitations, reasons for caution: In the INAS-SCORE study, the number of participants in the US using DNG/EV were limited. The primary analysis is therefore based on the European arm of the study. Although the European DNG/EV cohort is older, age does not seem to have a strong effect on unintended pregnancies.
Wider implications of the findings: COCs have a high contraceptive effectiveness. Overall contraceptive failure rates were lower for the European DNG/EV cohort compared to LNG containing and other COCs.
Trial registration number: N/A.

O-208 Do subfertile women with *C. trachomatis* antibodies have reduced clinical pregnancy rates, a prospective 4-year follow-up study

T. Rantsi[1], P. Joki-Korpela[1], H. Ã–hman[2], M. Puolakkainen[3], A. Bloigu[2], J. Paavonen[1], H.M. Surcel[2], A. Tiitinen[1]
[1]*University of Helsinki and Helsinki University Hospital, Department of Obstetrics and Gynecology, Helsinki, Finland*
[2]*National Institute for Health and Welfare, Oulu, Finland*
[3]*University of Helsinki and Helsinki University Hospital, Department Virology and Immunology, Helsinki, Finland*

Study question: Is the past *Chlamydia trachomatis* infection measured by IgG and IgA antibodies responsible for reduced pregnancy rates in women with unexplained infertility?
Summary answer: Past *C. trachomatis* infection is not responsible for unexplained infertility, but time to successful pregnancy is longer with serologic marker of infection.
What is known already: A number of patients suffering from subfertility have evidence of past chlamydial infection as indicated by *C. trachomatis* antibodies (CAT) in serum. The association of tubal factor infertility and chlamydial infection has been widely recognized in several studies. It has also been suggested that achieving a clinical pregnancy spontaneously is lower among patients with positive Chlamydia serology, even without visible tubal pathology. Some studies have suggested the impact of past *C. trachomatis* infection on IVF success rates, whereas others have denied this correlation. Consequently, the impact of past *C. trachomatis* infection on unexplained infertility and pregnancy rates deserves further investigation.
Study design, size, duration: Our study is a prospective study consisting of subfertile couples referred for infertility investigations to the Department of Obstetrics and Gynecology, Helsinki University Central Hospital. During July 2007–December 2010, a total 228 women were enrolled for the study. The patients were followed from July 2007 to June 2014.

Participants/materials, setting, methods: The blood specimens of the participants were collected together with routine samples and further analyzed at the Institute for Health and Welfare in Oulu. Clinical data on participants as well as the results of their examinations, treatments and pregnancy rates were collected. *C. trachomatis* immunoglobulin A (IgA) and immunoglobulin G (IgG) antibodies were studied using commercially available EIA kits (AniLabSystems, Helsinki, Finland). Chi-squared test and Mann–Whitney *U*-test were used for statistical analysis.

Main results and the role of chance: Altogether 23.7% (54/228) of the women participants had antichlamydial antibodies, 5.7% (13/228) IgA and 19.7% (45/228) IgG antibodies, respectively. Women with antichlamydial IgA antibodies had history of miscarriages before seeking to infertility investigations more often than women who were seronegative (30.8 vs. 9.3%, $p = 0.036$). Surprisingly, the number of previous ectopic pregnancies did no differ between the groups. Spontaneous pregnancies occurred more often to women negative for chlamydial serology than to patients with positive markers of infection (36.5 vs. 21.4%, p = NS). Moreover, time to successful pregnancy was longer with patients with history of chlamydial infection measured by IgG antibodies than that of patients without (1.9 vs. 1.4 years, $p = 0.011$). Women with positive *C. trachomatis* antibodies did not suffer from unexplained infertility more often than the patients with negative serology. During the follow-up period, the number of miscarriages or ectopic pregnancies did not differ between the groups. In addition, IVF treatment was not needed more often among patients with positive Chlamydia serology.

Limitations, reasons for caution: The women were followed only in the Helsinki University Central Hospital area. Thus, we do not have information of patients moved to a different locality or were later treated in private clinics. Another limitation is that some women were conceived before the actual infertility examinations took place.

Wider implications of the findings: These results are useful in counselling subfertile women on their fertility prospects. In addition, the findings of this study can help us to plan the most suitable treatment for each couple and give guidelines whether to wait spontaneous fertilization or actively proceed to infertility treatment.

Trial registration number: X.

SESSION 56: ETHICS AND LAW

Tuesday 05 July 2016 **Room 101** **17:00–18:00**

O-209 The counsellor's advice: an analysis of moral implications of providing advice about how to disclose donor conception to children

V. Provoost[1]

[1]*Bioethics Institute Ghent (BIG), Ghent University, Vakgroep Wijsbegeerte en Moraalwetenschap, Gent, Belgium*

Study question: What are the moral implications of providing professional advice about the way to disclose a child's donor conception (DC) status?

Summary answer: Professional advice about family communication risks disempowerment of patients. Advice should be based on scientific evidence and its uptake by patients should be studied.

What is known already: Counselling is mostly directed at improving the patient's empowerment. A distinction is made between process advice and substantive advice. While the first is about teaching strategies for problem solving, the latter consists of specific suggestions, for instance, advice on how to respond to a child's questions and what tools (e.g., children's books) to use as an introduction.

Given the scarcity of follow up studies of donor conception families, little is known about how patients manage such advice in their daily lives. Examples of couples who apply advice in a stringent, counterproductive way can be found in the literature.

Study design, size, duration: The literature (including both theoretical and empirical research) was studied regarding ethics of counselling and advice giving, empowerment of patients and moral responsibility. Wide Reflective Equilibrium was used as a method to integrate normative and empirical insights.

Participants/materials, setting, methods: The starting point of the analysis are examples from published qualitative interviews with DC children and parents of DC children in which perception of professional advice as well as uptake of professional advice regarding communication about the child's DC status is discussed. Morally relevant factors are identified based on the literature.

Main results and the role of chance: Ethical standards of counselling describe process advice as morally unproblematic, in contrast to substantive advice. Our analysis shows several problems. First, in the perception of patients, a distinction between the two types of advice appears to be challenging. Second, we show that substantive advice or process advice that was perceived as substantive advice can be counterproductive or even harmful to the child and the family when applied in a decontextualized way: not taking into account the specific needs and features of the child or it's family. Third, instead of improving the self-efficacy and empowerment of parents, professional advice upholds the view that the professional (and not the patient) is the person who possesses the required knowledge and skills, thereby undermining the empowerment of patients. Fourth, patients may use the advice in an attempt to abdicate their moral responsibility for family communication.

Counsellors should avoid offering (perceived) substantive advice. Moreover, any advice offered should be based on scientific evidence. For both types of advice, counsellors have the professional obligation to gather evidence and facilitate research, including a follow up of how patients implement the advice and what the implications of such implementing are for all parties involved.

Limitations, reasons for caution: Patients who build their families using donor gametes often indicate that they lack scripts for communication about the DC. In that respect, they may expect and/or request advice. Withholding substantive advice does not mean that these needs should be ignored.

Wider implications of the findings: Because offering professional advice entails risks, counsellors have a professional responsibility to facilitate follow up studies on (the implications of) the uptake of their advice. Also in the debate about directive or non-directive counselling, the patients' perception of the counsellor's intentions should be studied as a relevant factor.

Trial registration number: The author is funded by the Special Research Fund of Ghent University. There are no competing interests.

O-210 Combination-PGD: ethics of access and transfer

W.J. Dondorp[1], V. Van der Schoot[2], C. De Die[2], G. De Wert[1]

[1]*University of Maastricht, Department of Health, Ethics, and Society (HES), Faculty of Health, Medicine, and Life Sciences (FHML), Maastricht, Netherlands*

[2]*Maastricht University Medical Center, Department of Clinical Genetics, Maastricht, Netherlands*

Study question: Should accepted criteria both for access to PGD and for embryo-selection be widened in view of the growing number of requests for combination-PGD?

Summary answer: Criteria for access to PGD and for embryo-selection can be widened for secondary indications in combination-PGD.

What is known already: Professional guidelines reserve ICSI/PGD for those with a high risk of transmitting a serious disorder (or of repeated pregnancy loss due to a chromosome translocation). In several countries (NL, UK, Germany) legal instruments are in place to actually limit the scope of acceptable indications to such "high risk of serious harm" cases. With regard to transfer decisions, the corresponding rule is that only embryos without the targeted condition will be transferred. The ethical reasons behind these rules refer to societal costs, burdens & risks for the woman, the welfare of the child, and the moral sensitivity of embryo manipulation.

Study design, size, duration: Literature study, database research & ethical analysis. There is an increasing number of case reports of PGD treatments for two conditions. The focus of these publications is to emphasize the challenges and advanced technical procedures that this requires. Part of this literature refers to PGD plus aneuploidy testing (PGS), which is outside the scope of our study. Database research was done to determine the use of combination-PGD over the last 20 years in our country.

Participants/materials, setting, methods: Multidisciplinary desk research at academic PGD center. For the ethical analysis we used the method of "wide reflective equilibrium," which is an accepted approach in bioethics.

Main results and the role of chance: The literature and our data-base reveal that PGD is increasingly used for more than one genetic condition simultaneously.

As our ethical analysis shows, this has implications on several levels. First: as PGD is already done for a primary indication, there is no convincing reason for using the same strict access criteria for a secondary indication. However, the fact that a further cycle may more often be needed has proportionality implications that should be taken into account. Second: counseling for combination-PGD should address the possibility that no embryos unaffected by both conditions will be available and discuss the relevant wishes of the PGD-couple. Third, this requires transfer policy to clearly determine the conditions under which relevant options may be acceptable, including a further cycle or transferring embryos affected by a secondary condition that the procedure was initially meant to also rule out. The latter option implies a breach with the traditional rule of "never transfer an affected embryo." The primary ethical basis of this rule is the welfare of the child. However, to the extent that combination-PGD allows for less serious conditions to be accepted as secondary indications, transferring embryos affected by those conditions may well be acceptable.

Limitations, reasons for caution: The ethical implications of combination-PGD have not yet been systematically discussed in the literature. Our study is a first systematic contribution to this urgent debate.

Wider implications of the findings: Our conclusions are relevant for PGD policy making on all relevant levels (center policy, professional guidelines, health policy rules and regulations). For instance, in many countries access to PGD is bound to rules specifying strict access criteria that do not take account of the ethically relevant aspects of combination-PGD.

Trial registration number: N/A.

O-211 Preimplantation genetic screening (PGS): a blessing or a curse for patient centred fertility treatment?

H. Mertes[1]
[1]*Bioethics Institute Ghent (BIG), Ghent University, Department of Philosophy and Moral Sciences, Gent, Belgium*

Study question: Under which circumstances would PGS (preimplantation genetic screening) benefit, rather than threaten patient centred fertility treatment?

Summary answer: As the (potential) utility of PGS varies according to one's definition of successful treatment, patient education and joint decision making will be of utmost importance.

What is known already: There is currently much controversy over whether or not PGS should (already) be introduced into the clinic and if so, for which patient population. Scientific evidence is currently being gathered in order to establish the benefits and drawbacks of this new technology. Important outcome measures will be cumulative pregnancy rate per cycle started, time to pregnancy, miscarriage rate (all three for different age ranges), health outcomes for the offspring and cost-effectiveness of the treatment. Expectations are that PGS will lower the cumulative pregnancy rate, but also shorten the time to pregnancy and reduce miscarriage rates.

Study design, size, duration: A philosophical assessment was made about the most ethical way of introducing PGS into the clinic, starting from the premise that it will deliver on its promise of predicting the implantation potential of the *in vitro* embryo. The method that is used to bring empirical data (as found in literature research) and normative ethics together is the "Wide Reflective Equilibrium," the most commonly used method in bioethics.

Participants/materials, setting, methods: Claims about the benefits and drawbacks of PGS (Anno, 2015) as found in scientific literature, position statements of professional societies and commercial marketing were gathered and assessed for validity against current evidence. In light of patient-centred care, the relevance of these claims on burden, effectiveness, safety and financial cost was assessed. This information was then coupled with the treatment outcome measures that patients deem important (as found in the literature) and scanned for possible misconceptions.

Main results and the role of chance: Currently, most of the controversy over PGS is focussing on whether or not (or to what extent) this technology is successful at predicting which embryos will lead to a healthy live birth. However, proving that PGS "works" does not prove that it will benefit the individual patient.

PGS is often marketed as a technology that increases IVF success rates. This success rate certainly does not refer to the "singleton, term gestation, live birth rate per cycle initiated" as PGS can never increase this rate. Rather, it refers to a reduction in miscarriage rate and time to pregnancy and/or to an increase in implantation rate in the first transfer cycle. If and when this treatment option is offered to patients, it is therefore of utmost importance to know what the patient's definition of success is. For example, if the psychological burden of repeated miscarriages is unbearable for patient 1, while the thought of risking the loss of a viable embryo in the last stimulation cycle she can afford is unbearable for patient 2, PGS might benefit patient 1, but not patient 2. More attention should go to cost-benefit analysis and to managing misconceptions and unrealistic expectations.

Limitations, reasons for caution: An assessment of *how* PGS should be introduced into the clinic does not imply that the debate about *whether* we need PGS or whether it can fairly accurately predict which embryo will lead to a live birth is settled.

Wider implications of the findings: Fertility clinics need to be aware that whether or not a certain new technology is beneficial to a patient cannot be decided based on scientific evidence alone, as it depends on the patient's personal values and personal definition of success.

Trial registration number: N/A.

O-212 Genetic conditions in gamete donors and the handling of genetic risk

L. Bruhn Madsen[1], O. Schou[1]
[1]*Cryos International, Denmark, Aarhus, Denmark*

Study question: All humans carry several genetic diseases and are predisposed for various genetic conditions. How should this issue be addressed without excluding all gamete donors from donor programs?

Summary answer: A platform has been developed considering the "right not to know" which simultaneously reveals genetic conditions allowing for the use of donors with genetic conditions.

What is known already: Genetic screening of sperm donors is an important component in the selection of gamete donors. It is a fact that every human is a carrier of several recessive genetic diseases, but guidelines presenting a uniform recommendation on how to address this issue in a donor perspective are still lacking. Current recommendations for genetic screening of gamete donors mainly consist of a medical history of the donor's family and testing for a limited number of frequent recessive disorders. Although this decreases the risk for transmitting certain genetic diseases through donor conception, the likelihood for transmitting genetic disorders can not be avoided.

Study design, size, duration: During the last decades there has been an increase in the number of reported conditions on gamete donors even though donor screening programs are more thorough than ever. This means, that currently approximately 20% of all donors at the sperm bank Cryos International, who have passed initial screening procedures, have subsequently been associated with a genetic condition mainly of multifactorial or recessive nature. This figure will continue to increase since all donors carry genetic diseases.

Participants/materials, setting, methods: Donors with known genetic conditions identified through adverse reaction reports are made available in a transparent system hosted by Cryos International allowing for the recipients to make an informed choice with respect to the usage of specific donors.

Main results and the role of chance: To accommodate for the fact that everyone carries recessive diseases and genetic variants predisposing for multifactorial diseases a platform has been developed where knowledge on donors with registered genetic conditions are made available. This serves the purpose of transparency and also that sperm from donors with registered genetic conditions are made available for distribution. However, not everyone wants to know, and therefore the platform has been developed to acknowledge the "right not to know," which also means that several steps have to be actively accomplished before specific knowledge is made available.

Despite web-based efforts, and subsequent e-mails to make sure that recipients actually understand that their chosen gamete donor has been registered with a genetic condition, assessment of the distribution of sperm from the donors reveals that it is still employed beyond the usage for siblings, although to a lesser extent than sperm from donors with no registered conditions. Still, this indicates that there might be a movement away from the illusion of preventative perfectionism towards an acceptance of the fact that avoiding all risk is impossible, which might even form the basis for expanded genetic screening programs allowing for inclusion of donors, where initial genetic screening has revealed heterozygosity.

Limitations, reasons for caution: Although individuals are explicitly informed when using the system, and have to give consent before genetic information is

disclosed, there is still a possibility that the achieved information is not cognized, which is why professional guidance is recommended prior to the use of gamete donors with known genetic conditions.

Wider implications of the findings: This abstract contributes to the discussion about the range of genetic screening of gamete donors and the need for harmonization of guidelines for genetic screening and how to assess genetic risk in gamete donors.

INVITED SESSION

SESSION 57: MOLECULAR ELEMENTS IN MALE INFERTILITY

Wednesday 06 July 2016 **Hall 1** **08:30–09:30**

O-213 Male infertility as a monogenic pathology

S. Viville[1]

[1]*Nouvel hôpital civil, Laboratoire de diagnostic génétique, UF3472 Infertilité, Strasbourg, France*

Despite 38 years of IVF practice, human gametogenesis remains a black box and many of the molecular mechanisms underlying this process remain to be discovered. This lack of knowledge is mainly due to the absence of an *in vitro* model for human gametogenesis. The direct clinical consequence is the large number of patients for whom no diagnosis is available. Indeed, the cause of infertility in about half of the couples seeking reproductive assistance remains idiopathic. For many of them infertility has a genetic origin. During the last decade, a large effort was undertaken to identify genes that are solely involved in human infertility. Following this effort the number of "infertility genes" grew very quickly. Such research has many rewards. In terms of basic science, it is a powerful strategy to identify gametogenic molecular pathways and to study them with the help of appropriate models. A better understanding of human gametogenesis will bring new tools not only at the diagnostic level but also for the development of new reproductive technologies. At the clinical level, it opens the possibility to offer proper diagnosis and to determine the prognosis and the best management of such couples, therefore providing the most adapted therapeutics and counselling strategies to them.

During my presentation, I shall give a quick overview of the genetic causes of human infertility. These include numerical or structural chromosomal anomalies, syndromic and non-syndromic genetic pathologies. In addition, I shall mention the few studies, so called "whole genome association studies," which have been performed to try to establish correlations between genetic makers and human infertility. These try, not so successfully, to correlate infertility phenotypes with genetic markers. The major limitation of these studies resides in the phenotypic heterogeneity and the limited number of patients and controls analyzed.

Chromosomal anomalies have been well known for a long time and karyotype analyses have been well established in the reproductive field. Most of the syndromic pathologies are too severe to allow patients enough time and/or energy to set up a reproductive project. For non-syndromic genetic infertility, during the last decade, studying family cases of infertility or groups of infertile patients, the list of human genes has grown very quickly. So far, there are nearly 20 genes for which data are firm enough to consider them as responsible for a non-syndromic infertility phenotype in humans when mutated. The fact that over 200 infertile or subfertile genetic mouse models have been described gives an idea of the long pathway still to go in human studies to identify genes that could be involved in male and female reproduction. It also pinpoints the high degree of complexity of the gametogenesis process. I shall describe the strategies used to identify these genes, which should give you an understanding of how you could participate in this research effort. I shall also give some examples to underline the importance of studying these genes in order to better understand the human gametogenic process.

Last, I shall share some recommendations of what to offer your patients and some perspectives.

O-214 Transposable elements and male gametogenesis

P. Fauque[1], D. Bourc'his[2]

[1]*Hôpital Dijon, Laboratoire de Biologie de la Reproduction, Dijon, France*

[2]*Institut Curie, CNRS UMR3215/INSERM U934, Paris, France*

The epigenetic setting of the germline is known to be important for the acquisition of genomic imprinting, through the deposition of sex-specific methylation marks that will lead to the differential expression of paternally and maternally inherited alleles of a handset of genes after fertilization. Perturbation in imprinting acquisition in gametes has well-recognized consequences on the occurrence of epigenetic disorders, such as Beckwith–Wiedemann syndrome (Robertson, 2005).

Other targets of the germline-specific epigenetic reprogramming are transposable elements (TEs). TEs make up the majority of the genetic material. Indeed, the release of the human genome sequence has revealed that TEs represent more than half of genomic mass. This transposon landscape reflects an evolutionary tug-of-war between integration and propagation events orchestrated by these elements, and counteracting defense mechanisms exerted by the host. For genetic innovation and diversification, transposons have participated to genome shaping and speciation during evolution. However, on a short-term basis, transposons can adversely modify the function and the architecture of the genome (Ostertag and Kazazian, 2001). Spurious relaxation of transposon control can allow mobilization of these elements, which can disrupt genes by insertional mutagenesis. When occurring in somatic cells, cancer can ensue; when occurring in gametes, heritable mutations can be generated and lead to congenital disorders (Cordaux and Batzer, 2009).

Recent studies have highlighted the existence of specialized pathways acting in the germline for the life-long repression of transposons and the protection of the hereditary material (Zamudio and Bourc'his, 2010). Genetic impairment of this system in mice invariably leads to massive transposon reactivation and complete failure to produce spermatozoa in males (Bourc'his and Bestor, 2004). Transposon control therefore appears as a major safe guarder of male fertility in mouse, but also in other animal species. Such a role is highly likely to be conserved in human. The purpose of this lecture is to shed light onto these newly appreciated determinants of male reproductive fitness, the transposons. Improper control of these elements, of genetic or environmental origin, could be revealed as a major cause of male infertility (Fauque and Bourc'his, 2014).

INVITED SESSION

SESSION 58: ENDOMETRIAL INJURY PRIOR TO EMBRYO TRANSFER IN IVF

Wednesday 06 July 2016 **Hall 5 CB** **08:30–09:30**

O-215 Does it make scientific sense?

H. Critchley[1]

[1]*University of Edinburgh, The Queen's Medical Research Institute, MRC Centre for Reproductive Health, Edinburgh, UK*

Successful implantation is a multi-step process that requires synchronous development of both the endometrium and embryo. Implantation is a rate-limiting step in assisted reproduction and a mismatch between endometrial and embryo development may play a role in implantation failure. When a pregnancy fails to occur there is an equally exquisitely, spatial and temporally, regulated physiological breakdown, shedding and repair of an "injured/wounded" endometrium (menstruation and endometrial repair). Underpinning this physiological event of injury and repair are hormone withdrawal, local tissue hypoxia, cyto/chemokine production and leukocyte traffic.

Endometrial "scratching"/"injury" is intended local damage to the endometrium that has been reported to have impact on subsequent receptivity. To

date there is however no consistent mode of "injury": biopsy or curette; depth or number of injury events; cycle phase for imposing injury event; interval between injury and treatment cycle. Furthermore there is an endometrial breakdown and repair event between the act of injury/trauma and the subsequent cycle which prepares to be receptive for a potential implantation.

The endometrium is a complex, steroid-dependent tissue. Its form and function reflect exposure of component stromal, epithelial, vascular and immune cells, in both the superficial and basal layers, to endocrine and intracrine steroid signals (oestrogen, progesterone, androgen, glucocorticoids). Endometrial receptivity involves a transformation of the stromal compartment and tightly co-ordinated stromal-epithelial cross-talk. The peri-implantation milieu also involves immune cells and cytokine production, in turn regulated by the prevailing hormone environment.

It has been suggested that a local "mechanical" endometrial injury may provoke decidualisation; an inflammatory response, and/or a vascular reaction; and delay endometrial maturation and thereby, in some way, enhance preparation of the endometrium for implantation in the next menstrual cycle. The molecular/cellular mechanisms by which "endometrial scratch"/local endometrial injury may potentially lead to improvement in IVF outcome in women still remains unclear. The molecular and cellular mechanisms that underpin injury-induced events in the endometrium (physiological and mechanical) will be considered.

O-216 Does it make clinical sense?

C. Blockeel[1]
[1]*UZ Brussel, Centre for Reproductive Medicine, Jette, Brussels, Belgium*

Despite the vast development in assisted reproductive technologies (ART) during the last 30 years, live birth rates have remained low and, since the year 2000, rather stagnant. Researchers have postulated that endometrial non-receptivity may now be the main reason why even morphologically top quality embryos still frequently fail to implant.

The intricate dialogue between the embryo and endometrium is generally only possible during a specific timeframe of the secretory phase – the window of implantation. Previous studies have shown that there is a disruption of the natural endocrine function during ART caused by exogenous ovarian simulation, potentially hindering endometrial decidualization, function and receptivity.

Intentional endometrial injury, also referred to as "endometrial scratching," is one among many adjuvant methods designed to enhance implantation during ART. This technique, first described in the animal model by Loeb in 1907, seems to potentially improve receptivity, albeit by unknown mechanisms.

Evidence deriving from randomized controlled trials, systematic reviews and meta-analyses moderately favour inducing local injury in women with recurrent implantation failure. However, these results have been a subject of much debate, with detractors pointing out methodological weaknesses in the presented data and a general lack of basic scientific evidence to prove a definite beneficial effect of endometrial scratching. Furthermore, the heterogeneity within the clinical trials performed thus far have further increased the controversy, since the method and timing of the endometrial scratching have varied greatly. Nonetheless, owing to the fact that endometrial scratching is so easy to use in daily clinical practice, many physicians have hastily applied this technique unselectively to their patients in all fields of reproductive medicine, including intrauterine insemination and frozen embryo transfers. This widespread use has generated the perfect storm which has pitted the proponents and the detractors of this technique even further from each other and from the current scientific knowledge all-together.

In this presentation, a review of the current evidence, gaps of knowledge and future prospects regarding the potential benefit of endometrial scratching will be provided.

INVITED SESSION

SESSION 59: PARAMEDICAL INVITED SESSION - CONTROVERSIES - "EMBRYO TRANSFER EXCLUSIVELY IN THE FROZEN CYCLE?"

Wednesday 06 July 2016 **Room 101** **08:30–09:30**

O-217 Does it increase the probability of pregnancy?

B. Shapiro[1]
[1]*Fertility Center of Las Vegas, Las Vegas, NV, USA*

Fresh embryo transfer was the default treatment for women undergoing *in vitro* fertilization (IVF) for almost 40 years. Recently, however, there has been increased use of embryo banking cycles, in which all embryos are cryopreserved for subsequent thaw and transfer in a later cycle. The increasing use of embryo banking may be for any of several purposes. These include reducing the risk of ovarian hyperstimulation syndrome (OHSS), suspending embryo development while genetic test results are obtained, and postponing embryo transfer to obtain a better uterine environment in the absence of uterine exposure to controlled ovarian stimulation (COS). It has been shown that the implantation rate, clinical pregnancy rate per transfer, and ongoing pregnancy rate per transfer are increased with frozen-thawed embryo transfer (FET) into an artificially prepared endometrium when compared to fresh embryo transfer following exposure to COS. This was shown in a randomized trial in a population of normal responders undergoing their first IVF cycle.

Endometrial receptivity can be impaired following COS, primarily through an effect of embryo-endometrium asynchrony. Numerous clinical and basic science studies have revealed advanced endometrial histology and advanced down-regulation of the progesterone receptor following COS exposure. It has been shown that slowly developing embryos (day 6 blastocysts) are less likely to implant that their faster counterparts (day 5 blastocysts) if transferred in fresh cycles following COS exposure. This relationship diminishes or vanishes in cycles lacking COS exposure, such as oocyte donation and transfers of frozen-thawed embryos after artificial endometrial preparation. Despite the potential for cryo-damage, thawed day 6 blastocysts have been repeatedly shown to implant more readily than fresh day 6 blastocysts.

The evidence for impaired endometrial receptivity is much less clear in high responders. Two reports have concluded no significant evidence of impaired receptivity in high responders, although one was halted early for safety reasons. It seems high responders are more likely to have at least one rapidly developing embryo and therefore are more likely to have good embryo-endometrium synchrony.

However, the benefits of cryopreservation have a price. Some embryos do not survive thaw, and some transfers are therefore cancelled. The risk of embryo loss must be balanced against the improved endometrial receptivity. This balance might vary depending on methodology and patient characteristics.

Also, the benefits described above are per transfer, not per retrieval. This is a particular concern if post-thaw non-survival is a significant cause of cancellations. A meta-analysis of three randomized trials comparing FET and fresh transfer concluded the ongoing pregnancy rate per retrieval (through the first transfer) was greater in patients randomized to FET than in those randomized to fresh transfer. However, the largest study in that meta-analysis was subsequently withdrawn.

Another important measure is the cumulative success rate per retrieval, considering all transfers from each embryo cohort. Our own results, not previously published, reveal no significant difference in cumulative live birth rate per retrieval between patients randomly assigned to either fresh transfer or FET, after subsequent transfers of frozen-thawed supernumerary embryos were considered in both groups. In this follow-on analysis of the combined results following two randomized trials, the cumulative live birth rate is now final, because no patient who failed to have a live birth still has any remaining frozen supernumerary embryos. However, both studies employed only conventional slow-freezing, potentially reducing cumulative success rates when compared to current vitrification techniques.

Fresh autologous transfers can achieve excellent success rates in selected circumstances, specifically when embryo development is rapid (day 5 blastocyst expansion) and pre-ovulatory progesterone levels are low.

Future research should compare success rates per retrieval in patients randomized to fresh or vitrified blastocyst transfer using the most current techniques.

O-218 Does it affect the mother and the offspring?

S. Bhattacharya[1]
[1]*University of Aberdeen, Obstetrics and Gynaecology, Aberdeen, UK*

In vitro fertilisation (IVF) has traditionally tended to rely on a strategy of transferring the best quality fresh embryo or embryos within the endometrial cavity during the treatment cycle. Increasing success rates associated with embryo cryopreservation have allowed spare embryos are now usually frozen and replaced later – either in natural or hormonally manipulated cycles. High levels of

estrogen and progesterone produced during ovarian stimulation could result in a relatively hostile intrauterine environment whilst increasing the risk of ovarian hyperstimulation. Electively freezing embryos with the intention of thawing and replacing them within the uterus at a later stage when the influence of supra-physiological levels of ovarian steroids have abated, could increase pregnancy rates and reduce complications.

Data from two small randomised trials suggest potentially better pregnancy rates following elective frozen embryo transfer but have not been able to provide robust data on perinatal outcomes. Analyses of large observational datasets suggest that the risks of preterm birth, small for gestational age, antepartum haemorrhage are reduced in pregnancies following frozen embryo transfer but these results are not free from serious bias and confounding. Some women have contributed more than one pregnancy to the dataset and it is not always been possible to adjust for key variable such as parity, body mass index and smoking. Thus, the existing evidence base is insufficient in terms of quality to warrant a major change in clinical practice towards a strategy of elective embryo freezing in all couples. In addition some recent studies have demonstrated an enhanced risk of large for gestation al age associated with frozen embryo transfer, which needs further evaluation. Large adequately powered pragmatic randomised trials are urgently needed. Follow up of offspring conceived by women randomised to frozen embryo transfer is the best way of evaluating perinatal outcomes.

SELECTED ORAL COMMUNICATIONS

SESSION 60: EMBRYO TIME-LAPSE MICROSCOPY

Wednesday 06 July 2016 **Hall 1** **10:00–11:45**

O-219 Time lapse technology allows us to study the effect of sperm quality in the embryonic development

D. Agudo[1], G. Pirastu[1], D. Cernuda[1], F. Bronet[1]
[1]IVI Madrid, FIV, Madrid, Spain

Study question: Is embryo kinetics affected by sperm quality?
Summary answer: Our data show a direct cleavages increase and a cell division synchrony decrease in microinjected embryos with oligoasthenoteratozoospermics spermatozoa.
What is known already: Time lapse technology is offering a multitude data about kinetics of embryonic development. In addition, some studies have tested whether embryonic kinetics is affected by culture medium, ovarian stimulation, oxygen tension, origin of the eggs, the age of the patient, but few have studied influence of the male gamete in embryonic kinetics.
Study design, size, duration: Retrospective study of 118 oocyte donation cycles. Two groups of patients were compared. 80 cycles (863 oocytes, 719 embryos) were good prognosis patients sperm samples (more than 15 million/ml, more than 30% of motility, more than 4% of normal forms) (group A) and 38 cycles (427 oocytes, 303 embryos) coming from poor prognosis sperm samples (less than 5 million/ml, less than 5% of motility and less than 1% of normal forms) (group B).
Participants/materials, setting, methods: This cycles were incubated in embryoscope. We studied Cellular events described by Meseguer et al. (2011), including all cellular divisions until blastocyst stage, appearance and fading of some cellular structures, and two cellular events described as cc2 (difference in hours between first and second cellular cleavage) and S2 (difference in hours between second and third cellular cleavage). Data were exported from the embryo viewer data base. SPSS software was used on data analysis.
Main results and the role of chance: No significant differences between two groups under study (A and B) were found respecting the time of cell division (T2, T3, T4...). However when percentage of embryos, that had synchrony in the range S2, were analyzed (less than 5 h) we found statistically significant differences ($p = 0.0087$), when comparing both groups (46.94% in A group and 37.42% in group B).

Moreover, we subdivided groups A and B into two subgroups respectively. The first subgroup consists of transferred and frozen embryos, and the second consists of discarded embryos. We found statistically significant association in every time of cell division, when we compared the two subgroups of the group A, observing a development delay in discarded embryos. However no differences were found between the group B two subgroups in T3, T5, T9 and s2 times, concurring with second, third and fourth cell cycle starting times, which might reflect a delay in cellular interphase.
Limitations, reasons for caution: This study has been performed in oocyte donors, which form a fairly homogeneous group in terms of age and ovarian response, so these results may not be extrapolated to other groups of women undergoing an assisted reproductive treatment. However, more data are needed to draw firm conclusions.
Wider implications of the findings: The sperm sample quality may affect the synchrony in second cell cycle (S2) and may induce a delay in second, third and fourth cell cycle in embryos transferred and frozen coming from poor quality sperm samples if we compare to embryos discarded.
Trial registration number: 1406-MAD-047-DA/NCT02155179 Clinical trials/COI: MAD-DA-09-2014-05.

O-220 Cinematographic analysis of embryo vacuoles and their impact on reproductive outcome

R. Herrer[1], P. Valero[1], B. Monge[1], V. Ramirez[1], E. Gil[2], J. Serna[2], J.A. Garcia-velasco[3], M. Meseguer[4]
[1]IVI Zaragoza, IVF Laboratory, Zaragoza, Spain
[2]IVI Zaragoza, Medical, Zaragoza, Spain
[3]IVI Madrid, Medical, Madrid, Spain
[4]IVI Valencia, IVF Laboratory, Valencia, Spain

Study question: To evaluate the dynamics of the impact of spontaneous appearance of vacuoles in embryo quality and clinical outcome after time-lapse evaluation with donor oocytes.
Summary answer: No significant, although relevant differences, were found in the number of good quality embryos, pregnancy and implantation rates between non-vacuolated (NVE) and vacuolated embryos (VE).
What is known already: In animal cells, vacuoles are implicated in transport and cellular digestion processes. The spontaneous appearance of vacuoles in oocytes and embryos in IVF cycles is relatively frequent. Although this morphological aspect is considered detrimental for embryo outcome, the conclusions derived from bibliography are controversial and are based in single point morphological observations. It is accepted that little vacuoles (≤5 µm) in less than a half of the embryo are better than bigger ones in many cells. However, the use of video-time lapse has shown that vacuoles are a very dynamic process in terms of time of appearance, number and size.
Study design, size, duration: Retrospective study of 340 embryo transfer (either fresh or cryopreserved) at blastocyst stage, from our oocyte donation program, performed between October 2011 and December 2014. A total of 1354 embryos were analyzed, from which 499 blastocyst were transferred. 54.3% of the embryos presented at least a vacuole along the development. For implantation analysis, only embryos with Known Implantation Data (KID) where considered ($n = 376$). 223 of the 376 KID embryos were vacuolated (59.3%).
Participants/materials, setting, methods: Ovarian stimulation was performed with rFSH and GnRH antagonist. Ovulation was triggered with GrRH agonist.

After ICSI, oocytes and embryos were cultured in continuous medium (Global, Life-Global) at 37°C, 5% CO_2, 5% O_2, in Embryoscope™.

Morphological and kinetics events of embryo development were recorded and analyzed in the EmbryoViewer™. Appearance of vacuoles was matched in each stage, from oocyte to blastocyst.

Embryo quality, pregnancy and implantation were compared between NVE and VE.
Main results and the role of chance: The first spontaneous appearance of vacuoles was more frequent: between the extrusion of de 2° Polar Body and 2 cells (31% in all studied embryos and 29% in the transferred blastocyst), and especially from 8 cells to Morula stage (M) (54.3% in all studied embryos and 58.1% in the transferred blastocyst).

There were no differences in terms of good quality blastocysts between NVE [72.4%, (95% CI 68.2–76.5)] and VE [74.2% (95% CI 70.8–77.6)] ($p = 0.49$).

There were significantly fewer arrested VE than NVE [18.8%, (95% CI 15.9–21.6) vs. 37.2% (95% CI 33.4–41), $p < 0.0001$].

There were no significant differences in terms of clinical pregnancy [60.2% (95% CI 50.7–69.6) vs. 49.7% (95% CI 42.3–57.1), $p = 0.09$], and implantation rate [49.7% (95% CI 41.7–57.6) vs. 39.9% (95% CI 33.5–46.3), $p = 0.06$]

between NVE and VE, although clinical outcome decreases in 10 points approximately.
Regarding to KID VE, the better the embryo quality is, the better implants: There are significantly more high quality embryos in the group of implanted VE (48.3 vs. 37.6%, $p = 0.002$) than in the non-implanted one.
Limitations, reasons for caution: Spontaneous vacuolization may be modified by oocyte and embryo characteristics and culture conditions. Taking into account the dynamic behavior of this event, the annotation of vacuoles were made just before the next embryo cleavage.
Wider implications of the findings: Appearance of vacuoles does not affect embryo quality or arrest. We found a relevant, although not significant, decrease in pregnancy and implantation when VE are transferred, due to the sample size. Good quality VE implant better than low quality ones. VE should be a second alternative for embryo transfer.
Trial registration number: None.

O-221 Morphokinetic analysis of early fertilization and embryo cleavage dynamics based on the mode of insemination technique used on human embryos: a prospective sibling oocyte study

T. Aksoy[1], N. Findikli[1], G. Karlikaya[2], I.O. Olcay[1], B. Ozturk[1], F.K. Boynukalin[2], M. Bahceci[2]
[1]*Bahceci Fulya IVF Centre, Embryology Laboratory, Istanbul, Turkey*
[2]*Bahceci Fulya IVF Centre, Istanbul, Turkey*

Study question: Does the mode of insemination create disturbances in embryo developmental timings in couples undergoing assisted reproductive treatment (ART) with their own gamete cells?
Summary answer: Both insemination method showed similar morhokinetic patterns for all the other timepoints compared, except that IVF embryos reached expanded blastocyst-stage (tEB) significantly faster.
What is known already: ART registry data in many countries as well as international societies state that the use of ICSI for other than severe male infertility is on the rise. Since it bypasses many biological events in the course of fertilization, there always exist a debate regarding whether the use of ICSI *per se* can increase the risk of chromosomal or congenital abnormalities or not. Recent introduction of time lapse analyses start to bring valuable information regarding embryo dynamics and the studies using this technology in order to delineate the contribution of the fertilization method in the laboratory & clinical outcome is scarce.
Study design, size, duration: This prospective sibling oocyte study was performed in Bahçeci Fulya IVF Centre between April 2014 and October 2015. It includes cycles having female age less than 38, with sperm concentration >15 million/ml, motility >50% and morphology >4%.
Participants/materials, setting, methods: A total of 37 cycles were included. For each cycle, retrieved oocytes were randomly and equally assigned into IVF and ICSI during ART treatment and simultaneously processed for IVF (Group IVF) or ICSI (Group ICSI). Fertilized oocytes were cultured in a time lapse incubator and scored for morphokinetic check points (time points from tPNf through tHB) until embryo transfer or cryopreservation.
Main results and the role of chance: Overall, 780 oocytes were found to be at M2 stage and inseminated according to study protocol. Fertilization rates for IVF and ICSI groups were 75.8 and 80.8% respectively. Based on the capacity of the time lapse incubator, 406 of these fertilized oocytes (195 by IVF and 211 by ICSI) were simultaneously cultured and scored for morphokinetic parameters from pronuclear fading until blastocyst stage. When tPNf is taken as t_0 for comparative analysis, embryos on both arms of the study showed similar embryo cleavage dynamics as well as quality. The only significant difference between the study groups was found to be the time to reach expanded blastocyst-stage (tEB). Embryos generated after IVF were found to reach to the expanded blastocyst stage significantly earlier than that of ICSI-fertilized embryos ($p < 0.02$).
Limitations, reasons for caution: This study includes an isolated group of infertile cases in which both oocyte and sperm quality are devoid of any known morphological abnormalities. Our results should therefore be taken as preliminary when they are extrapolated for cases with lower oocyte & sperm yield/quality.
Wider implications of the findings: Our results can show that the insemination technique *per se* does not create significant distortions on the morphokinetic behavior of the *in vitro* fertilized embryos. The differences observed in the literature can therefore be due to the intrinsic characteristics of the gamete cells from which they were produced.
Trial registration number: None.

O-222 Euploid blastocysts that experience more collapses are less likely to result in live birth: a quantitative and automated analysis of time-lapse cinematography

G. Harton[1], L. Tan[1], M. Chian[1], V. Suraj[1], S. Shen[1], M.G. Larman[1]
[1]*Progyny Inc., Medical and Scientific Affairs, Menlo Park, CA, USA*

Study question: What are the dynamic blastocyst collapse patterns between euploid blastocysts that do or do not result in a live birth?
Summary answer: Euploid blastocysts that experienced higher number of collapses and more frequent collapses were less likely to achieve live birth.
What is known already**:** Pre-implantation genetic screening (PGS) improves IVF success by selecting against aneuploid embryos. Morphology has been shown to correlate with blastocyst aneuploidy, but not with implantation of euploid blastocysts. Currently effective embryo assessment methods that help selection among euploid blastocysts are highly desired to further enhance the success rates of euploid embryo transfer. Blastocyst collapses have been found to associate with lower likelihood to hatch and/or implant in animal and human studies. This study examined the relationship between blastocyst collapse patterns and euploid embryos resulting in live birth.
Study design, size, duration: Prospective observational study. Of 102 patients enrolled (August 2012–November 2013), 32 had Day 3 laser-assisted hatching and were excluded. Of the remaining 70 patients, 11 had no transfer and 4 had unavailable image analysis. Therefore 55 patients with 85 transferred euploid blastocysts from fresh/frozen cycles were analyzed. Four transferred embryos were further excluded as they expanded <10% on Day 5 (one led to live birth), and the final dataset was comprised of eighty-one embryos (forty-three led to live birth).
Participants/materials, setting, methods: Entire cohorts of embryos from patients were imaged using the Eeva System. Time-lapse images were automatically processed to extract dynamic parameters including number, frequency, time, degree and rates of collapses. Median values for the parameters were reported, and Mann–Whitney–Wilcoxon Test was performed to calculate *p*-values. Following qPCR-based comprehensive chromosome screening, euploid blastocysts were selected for transfer and patients were followed until delivery, with DNA finger printing performed when necessary to determine outcome of individual embryos.
Main results and the role of chance: A fully automatic image analysis routine was developed to calculate the size of the embryo for each frame of the video (one frame every 5 min). The computer automated embryo size calculation was validated for its accuracy by comparing to manual measurements (96%). Dynamic profiles of blastocyst size vs. time were then automatically analyzed by MatLab programs to identify each collapse event and output the timing and embryo size at the start and end of each collapse event. Euploid blastocysts that resulted in live birth experienced a 62% relative decrease in collapse events compared to those that resulted in no live birth (median 4 vs. 6.5, $p = 0.008$). Euploid blastocysts selected for transfer had an average collapse frequency of 0.37 ± 0.27 collapse events per hour. Euploid blastocysts that resulted in live birth had statistically significantly lower frequency of collapse events (median 0.30 vs. 0.43 collapse events per hour, $p = 0.004$). Consistent with the findings above, euploid blastocysts that resulted in live birth spent significantly less time during the collapse phase (11 vs. 15%, $p = 0.002$).
Limitations, reasons for caution: This is an observational study performed in a single centre, and therefore the clinical significance of the finding needs to be validated in a multi-centered study with a larger sample size.
Wider implications of the findings: This study is the first to examine the relationship of automatically-measured human blastocyst collapse dynamics with live-birth. Euploid blastocysts with more frequent collapses appear to have a lower live-birth rate, suggesting that frequent collapses may compromise embryo viability. Our findings may assist embryo selection for PGS-patients with multiple euploid embryos.
Trial registration number: Clinicaltrials.gov, NCT01635049.

O-223 Pregnancy outcomes of single cleavage-stage embryo transfer by using Time-lapse imaging do not differ from single blastocyst transfer

S. Wang[1], X. Zhao[1], X. Ni[1], G. Yan[1], H. Sun[1]
[1]*The Affiliated Drum Tower Hospital, Reproductive Medicine Center, Nanjing, Jiangsu, China*

Study question: By using time-lapse imaging (TLI), whether single cleavage-stage embryo transfer (SCT) on Day 3 can achieve the same pregnancy outcomes as single blastocyst transfer (SBT) on Day 5?
Summary answer: SCT achieved the same pregnancy outcomes as SBT by TLI. No significant differences were found in implantation rate and early abortion rate between two groups.
What is known already: TLI is a powerful tool for selecting competent embryos, which enables embryo development to be monitored continuously. SBT has been advocated to eliminate multiple births while a high pregnancy rate is guaranteed. However, SBT increases the risk of cancelled cycles, epigenetic disorders and preterm delivery due to a long culture time.
Study design, size, duration: A retrospective study was performed from January 2014 to December 2014 for establishing the embryo selection criteria using TLI. A prospective randomized study of the SET on Day 3/5 was conducted by using the established criteria during January 2015 to November 2015. When the optimal embryos ≥3 per cycle on Day 3, women were randomly assigned to SCT Group or SBT Group (If the patient refused to SBT, this cycle would not be included).
Participants/materials, setting, methods: A total of 1355 embryos were used for blastocyst culture in the reprospective study. The time of pronuclear fading (PNf) was defined as the starting point. During 104 SET cycles, SCT was conducted in 65 women and SBT was conducted in 39 women. Logistic regression analysis was used to evaluate the association of embryo cleavage patterns, timing parameters and blastocyst quality. Pregnancy outcomes were analyzed using the Chi-square test.
Main results and the role of chance: A new criteria was established for selecting the optimal embryo for SET in which embryos with normal cleavage, uneven cleavage or non-axial cleavage patterns simultaneously had optimal time intervals [*s*2 (synchrony of the second cell cycle) ≤ 0.5 h and *t*5 (five cells time point) ≤ 26.67 h)]. No significant difference was found in terms of the implantation rate (64.62 vs. 66.70%) and early abortion rate (4.44 vs. 3.85%) between SCT group and SBT group.
Limitations, reasons for caution: Large-scale clinical trials of SET on Day 3/5 with take-home infant rates as the endpoint were required to further prove the effectiveness and safety of SCT.
Wider implications of the findings: The use of the new criteria would improve the selection of embryo with better development potential. This process can improve the implantation rate of SCT, thus to further promote SET, in order to reduce multiple pregnancy rate and culture time.
Trial registration number: The study was registered at ClinicalTrial.gov with accession number NCT02313311.

O-224 Time-lapse algorithms and morphological selection of blastocysts for transfer: a pre-clinical validation study

A. Storr[1], C. Venetis[2], S. Cooke[1], S. Kilani[2], W. Ledger[2]
[1]IVF Australia, Embryology, Sydney, NSW, Australia
[2]University of New South Wales, School of Women and Children's Health, Sydney, NSW, Australia

Study question: What is the agreement between published time-lapse algorithms in selecting a day-5 embryo for transfer and what is the agreement between these algorithms and embryologists?
Summary answer: The agreement between published time-lapse algorithms was surprisingly variable while it was only fair between these algorithms and embryologists.
What is known already: The introduction of time-lapse incubators has allowed for the provision of more information regarding embryo growth and development. The timing and duration of embryo developmental events has been correlated with pregnancy, and allowed the developed time-lapse algorithms to select an embryo for transfer with presumably the highest implantation potential. However, the generalizability of these algorithms still remains highly questionable, and given that randomized controlled trials (RCTs) are costly and demanding in resources, it might be useful to firstly assess the pre-clinical validity of these algorithms in a different setting before conducting a RCT.
Study design, size, duration: This was a prospective study (n = 100 cases with ≥2 day-5 embryos cultured in the EmbryoScope) comparing the agreement in selecting the best day 5 embryo for transfer between published time-lapse algorithms aiming to improve implantation or pregnancy rates. Furthermore, the agreement between these algorithms and 10 embryologists at five different clinics was assessed. The cases included were from a pre-clinical phase prior to EmbryoScope use, where embryologists did not apply any algorithm during embryo selection.
Participants/materials, setting, methods: Three published algorithms were identified and analyzed in this study. (A) Meseguer et al. (2011), (B) Basile et al. (2015) and (C) Goodman et al. (2015). Embryologists were also asked to choose an embryo for transfer using 2D images. For each case, day-5 images were provided, followed by a day-3 and day-5 image of the same embryo. Agreement between the algorithms as well as the algorithms and the embryologists was assessed using the kappa coefficient.
Main results and the role of chance: The mean number of day-5 embryos available was 4.28 (standard deviation-SD: 1.99). Application of algorithm A, B and C resulted in 63, 53 and 53% of cases having only one embryo selected for transfer, respectively. The mean reduction in day-5 embryos suitable for transfer was (A) 2.55 embryos (SD: 1.87), (B) 2.31 embryos (SD: 1.83) and (C) 2.67 embryos (SD: 2.07).

The agreement for the classification of embryos as suitable for transfer was found to be good between algorithm A and B (kappa = 0.725, 95% CI 0.659–0.790). These algorithms showed no agreement with algorithm C (kappa = 0.072, 95% CI – 0.023–0.167; 0.040, 95% CI – 0.053–0.123, respectively). Fair kappa scores were seen for assessment of agreement between the embryo(s) selected by the algorithms and the embryo that was chosen by the majority (>5) of embryologists when day-5 images, as well as when day-3 and day-5 images were provided. The agreement between the embryos identified as selectable for transfer by the algorithms and the ones that were deemed selectable in the laboratory (i.e., transferred or cryopreserved) on the day of each transfer was poor or non-existent (algorithm A: – 0.007, 95% CI – 0.092–0.078; algorithm B: 0.019, 95% CI – 0.069–0.107; algorithm C: 0.068, 95% CI – 0.012–0.149).
Limitations, reasons for caution: Only three algorithms were identified for analysis, two of which (A and B) were designed by the same group of authors.
Wider implications of the findings: If the tested algorithms were indeed selecting the embryo with the highest implantation potential, then high agreement would be expected. The results of this study raise concerns as to whether these algorithms are applicable in a different setting, emphasizing the need for proper external validation before any large-scale clinical use.
Trial registration number: N/A.

O-225 A meta-analysis of the benefit using time-lapse imaging in assisted reproduction to improve pregnancy rate and reduce early pregnancy loss

M. Montag[1], C. Pribenszky[2]
[1]ilabcomm GmbH, Sankt Augustin, Germany
[2]Istvan University Faculty of Veterinary Science, Animal Breeding and Genetics, Budapest, Hungary

Study question: Does a meta-analysis of existing RCTs on human embryo assessment favor time-lapse imaging or conventional morphology assessment for ongoing clinical pregnancy and early pregnancy loss.
Summary answer: The results favor time-lapse compared to conventional embryo assessment for pregnancy. This is strengthened by the use of algorithms, which also reduce early pregnancy loss.
What is known already: The introduction of time-lapse imaging systems in human IVF has caused discussions about how new technologies shall be implemented in daily clinical routines. It has been suggested that the clinical benefits of applying new technologies shall be verified and documented by randomized controlled trials (RCTs) before routine implementation into clinical IVF. A Cochrane review based on three randomized trials concluded that there was insufficient evidence for the benefit of time-lapse imaging, although the authors of this study questioned this review. However, in the meanwhile three further RCTs were published, justifying another meta-analysis on this subject.
Study design, size, duration: A comprehensive search of major databases was undertaken for trials that randomized patients to time-lapse based embryo culture and assessment, with or without using an algorithm, or to conventional embryo assessment. Eligible studies were screened for number of patients treated. For ongoing pregnancy rate and early pregnancy loss absolute numbers of positive βhCG and clinical pregnancies with fetal heartbeat were evaluated. Missing data were requested from authors of the respective RCTs.
Participants/materials, setting, methods: A meta-analysis was performed on the selected studies and subsequently on the subset of studies that used an

algorithm. For the meta-analysis, the fixed or random effect model was applied when appropriate. For the statistical analysis, proportions were presented as percentages and compared using a 2 × 2 Chi-square test. The analysis were performed using MedCalc® 16.1 with *p*-values <0.05 considered statistically significant.

Main results and the role of chance: Six studies based on randomization of 1893 patients were included. The meta-analysis showed an increase of the ongoing pregnancy rate from 40.9 to 46.8% by using time-lapse for continuous embryo assessment compared to the conventional approach at fixed time points (odds ratio 1.366; 95% CI: 1.130–1.652; $p = 0.001$). Early pregnancy loss did not reach significance in these six studies ($p = 0.051$). Four of the studies applied, in addition to time-lapse imaging, an algorithm for selecting embryos for transfer and randomized 1465 patients. In these studies the results for ongoing pregnancy were further strengthened (41.9 versus 53.2%; odds ratio 1.525; 95% CI: 1.235–1.884; $p < 0.001$) and the early pregnancy loss was significantly lowered (21.0–15.2%; odds ratio 0.664; 95% CI: 0.465–0.947; $p = 0.024$) by time-lapse assessment. Repeating the evaluations by using the absolute numbers for positive/negative results and comparing with Chi-square test supported the results of the meta-analysis and showed a significant improvement in ongoing pregnancy and a significant decrease in early pregnancy loss for all study groups compared to controls.

Limitations, reasons for caution: This meta-analysis was based on the currently available RCTs. The design of these studies differs from one to another and further studies that use similar protocols may be valuable. Algorithms in the RCTs were based on clinics own data. It is not advisable using these algorithms directly.

Wider implications of the findings: This meta-analysis underscores the growing evidence for the clinical benefit of using time-lapse imaging systems in human IVF. Reduced early pregnancy loss and higher ongoing pregnancy after embryo assessment by time-lapse does result in a shorter time to pregnancy and is further strengthened by the use of an algorithm.

Trial registration number: Not applicable.

O-226 Activin A production and actions during three-dimensional culture of macaque ovarian follicles – a potential noninvasive biomarker for follicle and oocyte growth *in vitro*

J. Xu[1], C. Bishop[1], M. Lawson[1], F. Xu[1]
[1]*Oregon National Primate Research Center, Oregon Health and Science University, Division of Reproductive and Developmental Sciences, Beaverton, OR, USA*

Study question: What are the production patterns and direct actions of activin A during *in vitro* follicle maturation in primates?

Summary answer: While activin A production levels correlated positively with follicle and oocyte growth rates, supraphysiologic levels of activin A suppressed follicular development and function *in vitro*.

What is known already: Activin A is expressed in the adult ovary, particularly in developing follicles. Studies in rodents and domestic animals investigated activin A actions *in vitro* using cell and follicle culture, and results varied in terms of activin A effects on follicle growth and steroid hormone production.

Study design, size, duration: *In vitro* follicle maturation was performed using rhesus macaques ($n = 4$; 4–7 years old). Secondary follicles (diameter = 125–225 µm) were mechanically isolated from ovaries obtained at days 2–4 of the menstrual cycle, encapsulated into alginate (0.25% w/v), and cultured for 5 weeks with or without activin A treatment. Data were analyzed using a two-way ANOVA with repeated measures. A Student's *t* test was used to compare between two groups at each time point.

Participants/materials, setting, methods: Individual follicles (36–48 follicles/monkey) were cultured in a 5% O_2 environment, in alpha minimum essential medium supplemented with recombinant human follicle-stimulating hormone and insulin. Follicles were randomly assigned to two groups: (a) media-only control and (b) 50 ng/ml recombinant human activin A during week 3–5 (after antrum formation). Follicle survival, growth, and oocyte size were assessed. Culture media were analyzed weekly for estradiol, progesterone (immunochemiluminescence), and total activin A (control media only; ELISA).

Main results and the role of chance: In the control group, macaque follicles that survived to grow formed an antrum at week 3. The *in vitro*-developed small antral follicles (diameter = 0.5–1.5 µm) were divided into distinct cohorts based on production of activin A. While media activin A remained undetectable (<40 pg/ml) for 72% follicles throughout 5 weeks of culture, 28% follicles started to produce activin A at week 3 with media concentrations increased at week 5 (113 vs. 264 pg/ml; $P < 0.05$). Diameters of follicles and their enclosed oocytes were greater at week 5 in follicles producing activin A relative to those without activin A production (847 vs. 736 µm; 112 vs. 108 µm; $P < 0.05$). While exogenous activin A during week 3–5 did not alter follicle survival, activin A exposure decreased diameters of *in vitro*-developed small antral follicles and their enclosed oocytes at week 5 compared with controls (672 vs. 777 m; 87 vs. 109 µm; $P < 0.05$). Steroid hormone production by growing follicles increased after antrum formation. Follicles cultured with activin A during week 3–5 had lower media concentrations of estradiol and progesterone compared with controls at week 5 (2377 vs. 3324 pg/ml; 9 vs. 80 ng/ml; $P < 0.05$).

Limitations, reasons for caution: This study reports activin A production and actions during *in vitro* maturation of individual macaque follicles limited to the interval from the secondary to small antral stage.

Wider implications of the findings: Active activin A production by small antral follicles may serve as noninvasive biomarker indicating the potential of follicle and oocyte growth in primates. The findings may be applied to human *in vitro* follicle maturation, by selecting follicles for further culture or oocyte maturation, to offer fertility preservation options to women.

Trial registration number: Not applicable.

O-227 Lessons learnt from a dedicated, tertiary, multidisciplinary clinic for Mayer Rokitansky Küster Hauser Syndrome

N. Liou[1], R. Ali[1], V. Evans[1], S. Creighton[1], E. Yasmin[1]
[1]*University College London Hospital, Women's Health, London, UK*

Study question: We present the lessons learnt from our experience of a dedicated clinic for Mayer Rokitansky Küster Hauser Syndrome (MRKH).

Summary answer**:** There is considerable variation in the approach to the management of these patients and this study highlights that referral to tertiary services is timely.

What is known already: MRKH is a condition that affects 1 in 4500 females. It is characterised by the absence of a functioning uterus, an absent or short vagina, normal secondary sexual characteristics, normal external genitalia and a normal female karyotype. The medical care of these patients in a multidisciplinary setting involves gynaecologists, nurse specialists, psychologists and radiologists.

Study design, size, duration: A retrospective analysis of 213 MRKH patients was carried out between 2010 and 2015. Out of 213 case notes, 152 cases where data was complete were selected for final analysis.

Participants/materials, setting, methods: Participants were selected from a dedicated, multidisciplinary clinic for the care and management of MRKH patients at a tertiary care centre in London, UK. A dataset was completed and analysed for age of presentation, diagnostic tests, patient desires for treatment, MRI features of the Müllerian and Wolffian duct structures, other co-existing conditions and management outcomes. Statistical analysis was carried out using SPSS.

Main results and the role of chance: The average age at presentation to secondary care was 16 years old (23.3%, IQR 16–18 years) and the average age at presentation to tertiary care was 17 years old (21%, IQR 16–19 years). Although primary amenorrhoea was present in all, 6% of patients presented with inability to have penetrative sexual intercourse and 4.6% presented with cyclical pelvic pain. In MRI imaging, rudimentary uteri were found in 90%, out of which 40.5% had bilateral uterine buds. Adenomyosis and endometriosis were seen in 11.7% and four patients had functional endometrium requiring removal of the rudimentary uteri. 16.6% of patients had examinations under anesthesia and diagnostic laparoscopies before referral. Polycystic ovary syndrome (PCOS) diagnosed by hyperandrogenism and polycystic ovaries was noted in 4.6% and two patients had premature ovarian insufficiency. 22% of patients had renal abnormalities, 3.3% had skeletal abnormalities. 63.2% of patients

embarked on a vaginal dilation programme, 34% did not require dilation and 12% deferred any treatment. 67% of patients completed vaginal dilation programme. Vecchietti procedure was performed in nine patients who did not have success with dilator therapy. Of these, four patients were unable to have sexual intercourse despite vaginas of adequate length and capacity.

Limitations, reasons for caution: We have not analysed psychological outcomes and fertility as a part of this study.

Wider implications of the findings: Rudimentary uteri are typically present and a small proportion contain functional endometrium. Some patients undergo unnecessarily invasive tests in secondary care due to diagnostic uncertainty. Failure rates in Vecchietti procedure highlight that women who are unsuccessful with dilator therapy may not be successful due to non-compliance with dilation after surgery.

Trial registration number: N/A.

O-228 Gonadotrophin secretion is a useful adjunct in the assessment of patients with hyperprolactinaemia

A. Abbara[1], S. Clarke[1], A. Nesbitt[1], S. Ali[1], A. Comninos[1], E. Hatfield[2], N. Martin[2], A. Sam[2], K. Meeran[2], W. Dhillo[1]
[1]*Imperial College London, Endocrinology, London, UK*
[2]*Imperial College NHS Trust, Endocrinology, London, UK*

Study question: Can evaluation of gonadotrophin secretion assist in the diagnosis of patients with hyperprolactinaemia?

Summary answer: Gonadotrophin secretion aids the diagnosis of patients with hyperprolactinaemia. Patients with PCOS have LH-predominant secretion, whereas patients with Microprolactinomas/Drug-Induced Hyperprolactinaemia have FSH-predominant secretion.

What is known already: Hyperprolactinaemia accounts for one in seven patients presenting with amenorrhoea and infertility.

Recent data suggests that prolactin acts at the level of kisspeptin-neurons in the hypothalamus to reduce GnRH-pulsatility.

Conditions in which GnRH-pulsatility is reduced, favour FSH-predominant secretion from the pituitary gland. However conditions in which GnRH-pulsatility is increased, such as PCOS, favour LH-predominant secretion.

Thus, causes of hyperprolactinaemia such as Drug-Induced Hyperprolactinaemia (DIH) or Microprolactinoma, would be expected to have reduced GnRH-pulsatility and FSH-predominant gonadotrophin secretion.

Patients with hyperprolactinaemic conditions in which pituitary gonadotroph function is directly impaired, such as Macroprolactinoma, would be expected to have attenuated gonadotrophin secretion.

Study design, size, duration: A retrospective analysis of gonadotrophin secretion in patients presenting with hyperprolactinaemia during June 2012–October 2015 was performed. 302 patient records were reviewed and 262 patients with monomeric hyperprolactinaemia and gonadotrophin evaluation were identified (166 female, 96 male). The most frequently encountered diagnoses were Microprolactinoma (n = 86), Macroprolactinoma (n = 45), Non-Functioning Microadenoma (NFMI) (n = 15), Non-Functioning Macroadenoma (NFMA) (n = 90), Drug-Induced Hyperprolactinaemia (DIH) (n = 12) and Polycystic Ovarian Syndrome (PCOS) (n = 14).

Participants/materials, setting, methods: Concomitant serum FSH and LH levels in patients with a raised serum monomeric prolactin level over the gender-specific reference range were recorded at Imperial College Healthcare NHS Trust, London, UK.

The cause of hyperprolactinaemia was diagnosed by an experienced reproductive endocrinologist at a tertiary centre, unless pituitary surgery yielded a histologically confirmed diagnosis. Groups were compared by one-way ANOVA with post hoc Tukey's. Mean gonadotrophin values are presented. P-value 0.05 was regarded as statistically significant.

Main results and the role of chance: Gonadotrophin secretion in Drug-Induced Hyperprolactinaemia (DIH) (FSH 4.5 IU/L, LH 3.1 IU/L, FSH-LH +1.4 IU/L) was similar to that observed in Microprolactinomas (FSH 4.6 IU/L, LH 3.8 IU/L, FSH-LH +0.8 IU/L). As expected, patients with DIH or Microprolactinoma have FSH-predominant gonadotrophin secretion consistent with reduced GnRH pulsatility, due to the action of prolactin at the level of the hypothalamus.

However, in patients with PCOS and hyperprolactinaemia, LH-predominant secretion was observed, consistent with increased GnRH pulsatility (FSH 3.5 IU/L, LH 5.1 IU/L, FSH-LH −1.6 IU/L).

In patients with Macroprolactinoma, serum gonadotrophin secretion was reduced when compared with Microprolactinoma consistent with direct pituitary gonadotroph infiltration and hypo-function in patients with Macroprolactinoma (FSH 3.0 IU/L, LH 2.4 IU/L, FSH-LH +0.5 IU/L) (serum LH $P < 0.05$ vs. Microprolactinoma).

In patients with Macroadenomas, those with "Non-Functioning Macroadenomas" (NFMA) had greater FSH secretion than those with Macroprolactinoma (NFMA: FSH 5.9 IU/L, LH 2.4 IU/L, FSH-LH +3.8 IU/L (FSH $P <$ 0.05 vs. Macroprolactinoma; FSH-LH $P < 0.05$ vs. Macroprolactinoma). This suggests that whilst nominally "Non-Functioning," many NFMA's secrete FSH at subclinical levels. This observation may assist in the assessment of patients with macroadenoma, differentiating patients with Macroprolactinoma from those with NFMA and disconnection hyperprolactinaemia (Area Under Curve of ROC analysis for FSH-LH is 0.67, 95% CI 0.57–0.76).

Limitations, reasons for caution: Causes of hyperprolactinaemia were diagnosed by experienced clinicians in reproductive endocrinology at a tertiary centre, however not all patients required pituitary surgery and thus not all diagnoses were histologically confirmed.

Wider implications of the findings: Reproductive specialists may use these data in the diagnosis of patients with hyperprolactinaemia. These data may assist physicians in the identification of patients with PCOS with mildly elevated prolactin levels. Patients on drugs causing hyperprolactinaemia, but with reduced gonadotrophin secretion, may require urgent assessment to exclude causes of hypopituitarism.

Trial registration number: This retrospective analysis was not a registered clinical trial.

O-229 TOP001, a novel orally active allosteric agonist of follicle stimulating hormone (FSH) receptor, stimulates similar maturation of high quality oocytes in preclinical models as hFSH

S. Palmer[1], H. Yu[1], S. Nataraja[1]
[1]*TocopheRx Inc., Research, Burlington, VT, USA*

Study question: Can orally administered TOP001 stimulate increases in follicular growth, plasma estradiol, oocyte fertilization and blastocyst development in animal models comparable to injected recombinant hFSH (rec-hFSH)?

Summary answer: TOP001 and rec-hFSH stimulated similar dose-dependent increases in follicular growth and estradiol production in rats, and blastocyst development rates in mice.

What is known already: Last year, we presented the development of orally active FSHR allosteric agonists through a rational drug discovery effort. TOP001, the lead compound, stimulated cAMP in CHO cells expressing hFSHR with an EC50 of 9.8 nM, while it had 6 & 50 fold less activity in hLHR and hTSHR expressed cells, respectively. TOP001 dose dependently stimulated estradiol production in rat and human granulosa cell cultures, and it has been shown to stimulate follicular development *in vivo*. TOP001 has been shown to have remarkable safety profile in *in vitro* safety and selectivity assays, and in *in vivo* toxicology assessments in rats and dogs.

Study design, size, duration: Immature rats were treated for 2 days with low (0.29 IU) or high dose FSH (1.16 IU), while TOP001 was administered orally (1–100 mg/kg) to evaluate follicular growth either in presence or absence of FSH. Serum estradiol was measured to monitor follicular growth. Immature mice received TOP001, rec-hFSH or PMSG, and oocytes were isolated, fertilized, and embryo development to blastocysts was measured. Each experiment was repeated at least twice with n = 5 animals/group.

Participants/materials, setting, methods: This study was performed in a preclinical drug discovery setting. Animals were maintained and treated with injectable FSH, PMSG or orally active TOP001 according to approved animal care protocols.

Main results and the role of chance: In immature rats, oral administration of TOP001 at 5, 10 & 25 mg/kg along with injection of low dose FSH (0.29 IU), significantly increased the number of oocytes (22.1 + 1.9; 50.5 + 3.4 & 56.8 + 3.4 respectively, $p < 0.05$; ANOVA) compared to low dose FSH alone (6.8 + 0.9). Significant increases in serum estradiol were observed at the doses of 10 & 25 mg/kg (94.5 + 13.2; 94 + 9.6 pg/ml respectively) over low FSH alone (35 + 7.3 pg/ml). Similar increases in oocyte and serum estradiol were observed when animals were treated orally with TOP001 alone. Maximal serum estradiol (87.3 + 10.2 pg/ml) and number of oocytes in oviduct (42.5 + 3.3) were similar for rec-hFSH and TOP001. The ovarian stimulation

protocol was adopted to immature mice with similar increases in follicular growth for TOP001 (1–100 mg/kg), rec-hFSH and PMSG. The percent of MI & MII oocytes retrieved following oral administration TOP001 at 30 mg/kg (68.6 & 31.4) & 100 mg/kg (84.8 & 15.2) was similar to the high dose rec-hFSH (71.3 & 28.7). The fertilization rate of oocytes from TOP001 treated animals (30 mg/kg–76.5 + 8.9%; 100 mg/kg–77 + 6.2%) was not different from those obtained from rec-hFSH (73.2 + 6.1%) or PMSG treated groups (87.2 + 5.7%). Furthermore, development of blastocysts among TOP001, rec-hFSH and PMSG groups were similar.

Limitations, reasons for caution: The compound is in early evaluation of safety and toxicology prior to initiating GLP studies for IND filing. The safety and efficacy of the compound in humans will be determined in 2017.

Wider implications of the findings: TOP001 shows promise to be a novel and convenient therapy for controlled ovarian stimulation, as demonstrated by significant increases in follicular growth, and plasma estradiol. Similarly, TOP001-derived oocytes is shown to lead to comparable blastocyst development rates as rec-hFSH and PMSG, reflecting the overall safety of this compound on oocytes.

Trial registration number: Only preclinical animal models have been used in this research.

O-230 Cell-free DNA level in serum, as a new biomarker for prognostic prediction of ovarian response to stimulation

E. Scalici[1], A. Gala[2], S. Belloc[3], F. Lamazou[4], C. Vincens[2], S. Hamamah[1]
[1]*CHU Montpellier, ART-PGD Department, INSERM U1203, Montpellier, France*
[2]*CHU Montpellier, ART-PGD Department, Montpellier, France*
[3]*Laboratory Eylau, Unilabs, Paris, France*
[4]*Clinique Pierre Cherest, IVF Department, Neuilly-sur-seine, France*

Study question: Could cell-free DNA (cfDNA) level in serum at day 3 of menstrual cycle be clinically useful for prediction of patient's ovarian response to stimulation during *in vitro* fertilization (IVF) procedure?

Summary answer: Cell-free DNA levels in serum at day 3 of menstrual cycle can predict significantly the number of retrieved oocyte, independently of Anti-Müllerian hormone (AMH) concentrations.

What is known already: DNA fragments, detected in blood and in other biological fluids, are released from apoptotic and/or necrotic events. Cell-free DNA level in serum is increased in some cancers or gynecological and obstetrics disorders and currently used as a non-invasive biomarker for their early detection and/or prognosis. Sometimes, AMH concentration, classically measured in patient's serum at day 3 of menstrual cycle can be inconsistent to predict ovarian response to stimulation. The potential cfDNA level in serum for the prediction of ovarian response remains to be investigated in order to identify a supplemental prognostic tool for improving the management of ovarian stimulation treatment.

Study design, size, duration: This prospective study included 32 serum samples collected at day 3 of menstrual cycle from patients undergoing IVF/ICSI procedure. AMH and cfDNA levels were measured in each serum sample in order to compare their predictive value for patient's ovarian response to stimulation.

Participants/materials, setting, methods: Serum samples were prepared in Proteinase K buffer and the total cfDNA was quantified by qPCR, using ALU 115 primers. CfDNA concentration was determined based on a standard curve obtained by successive dilution of genomic DNA. The *p*-values were calculated by using the unpaired *t*-test, Spearman correlation, multiple and logistic regressions and ROC curve analysis on GraphPad and Medcalc softwares.

Main results and the role of chance: Cell-free DNA concentrations (mean ± SD = 152.02 ± 160.48 ng/m, median = 92 ng/ml) were significantly and positively correlated with patient's age ($r = 0.18$; $p = 0.02$). Indeed, cfDNA levels were significantly higher in serum from older women (≥38 years) than those from young patients (<38 years) ($p = 0.035$). Very interestingly, cell-free DNA level was significantly related to the number of oocyte collected at oocyte retrieval ($p = 0.031$). Furthermore, cfDNA levels predicted significantly a low ovarian response (<6 retrieved oocytes), independently of AMH concentrations [Adjusted Odd Ratio = 1.01 (1.0–1.02); $p = 0.02$]. The area under the ROC curve (AUC), which quantifies the low ovarian response prediction of cfDNA level was 0.79 (0.61–0.91) with higher sensitivity (73.33%) and specificity (82.35%) ($p = 0.001$) than AMH level [AUC = 0.72 (0.54–0.87); sensitivity = 60%; specificity = 88.2%, $p = 0.02$].

Limitations, reasons for caution: Further investigations with large number of patients and their attempt outcomes will be conducted to confirm the clinical utility of cfDNA for ovarian response prediction.

Wider implications of the findings: High cfDNA levels in serum could be significantly related to a low ovarian response. Cell-free DNA quantification at day 3 could be used as a supplemental tool to identify more accurately women with a risk of poor ovarian response, in order to develop a personalized care program for these patients.

Trial registration number: N/A.

O-231 New insight into the pathogenesis of ovarian hyperstimulation syndrome (OHSS): pigment epithelium-derived factor (PEDF) targets both angiogenic and inflammatory pathways

I. Miller[1], D. Chuderland[1], R. Ron-El[2], R. Shalgi[1], I. Ben-Ami[2]
[1]*Sackler Faculty of Medicine, Tel-Aviv University, Department of Cell and Developmental Biology, Tel-Aviv, Israel*
[2]*Sackler Faculty of Medicine, Tel-Aviv University, IVF and Infertility Unit, Department of Obstetrics and Gynecology, Assaf Harofeh Medical Center, Zerifin, Israel*

Study question: Could pigment epithelium-derived factor (PEDF) function as a physiological negative modulator of both angiogenic and inflammatory pathways in ovarian hyperstimulation syndrome (OHSS)?

Summary answer: Recombinant PEDF (rPEDF) possesses potent therapeutic properties in OHSS, manifested by independent dual negative regulation of the angiogenic and inflammatory pathways, which govern OHSS.

What is known already: OHSS is a potentially life-threatening complication of ART, induced by an ovarian release of vasoactive, angiogenic substances; resulting in vascular leakage. The consequent ascites is attributed to hCG-induced VEGF increase, as well as to lysophosphatidic acid (LPA)-induced increase of angiogenic cytokines interleukin (IL)-6 and IL-8.

Recently, we have shown that PEDF, a potent anti-angiogenic factor that counteracts VEGF, plays a fundamental role in the pathogenesis and treatment of OHSS. Our aim was to elucidate the putative role of the anti-angiogenic and anti-inflammatory mediator, PEDF, as a physiological negative regulator of both VEGF and angiogenic cytokines networks.

Study design, size, duration: OHSS was induced in 5-weeks old ICR female mice by three consecutive daily injections of 20 IU PMSG, followed 24 h later by 7 IU hCG. Control mice were given a single dose of 5 IU PMSG, followed 48 h later by 7 IU hCG (six mice per experimental group). To test PEDF therapeutic abilities we injected rPEDF together with hCG and recorded changes in body weight and in peritoneal vascular leakage, as quantified by the modified Miles vascular permeability assay.

Participants/materials, setting, methods: We used a mouse OHSS model and cultured granulosa cells (primary – human; cell line – rat). Changes in the levels of PEDF, VEGF and IL-6/IL-8 were measured by qPCR, western blot and enzyme-linked immunosorbent (ELISA). OHSS symptoms were recorded by changes in body weight, ovarian weight and by peritoneal vascular leakage.

Main results and the role of chance: We found that stimulation by LPA resulted in a significant increase of IL-6/8 mRNA and protein levels in granulosa cells, inversely to PEDF level ($P < 0.01$). In addition, we found that OHSS was correlated with hCG-induced impaired PEDF/VEGF ratio. Interestingly, triggering with GnRH-agonist, which is known to prevent OHSS, modulated PEDF/VEGF ratio inversely to that induced by hCG-triggering, both *in vitro* and *in vivo*. Stimulation with rPEDF reduced the LPA-induced increase of IL-6\8 levels in human granulosa cells ($P < 0.01$). Moreover, *in vivo* treatment with rPEDF (0.5 mg/kg) alleviated OHSS signs including edema ($P < 0.05$), vascular leakage ($P < 0.01$) and reduced ovarian IL-6 mRNA and protein levels ($P < 0.01$).

Limitations, reasons for caution: The *in vivo* experiments were performed in a mouse model.

Wider implications of the **findings:** Our findings provide new perspectives into the role of PEDF in OHSS pathophysiology: low level of PEDF expression enables high levels of VEGF and IL-6/8 expression. Exploring the anti-angiogenic and anti-inflammatory properties of PEDF in the female reproductive system could open new therapeutic avenues for other fertility and gynecological pathologies.

Trial registration number: Not relevant.

O-232 Vitamin D deficiency and pregnancy rates following frozen-thawed embryo transfer: a prospective cohort study

A. Van de Vijver[1], P. Drakopoulos[1], L. Van Landuyt[1], A. Vaiarelli[1], C. Blockeel[1], S. Santos-Ribeiro[1], H. Tournaye[1], N.P. Polyzos[1]
[1]*UZ Brussel CRG, CRG, Jette, Belgium*

Study question: What is the effect of vitamin D deficiency on the pregnancy rates in frozen-thawed embryo transfer cycles?
Summary answer: Vitamin D deficiency does not affect pregnancy rates in frozen-thawed embryo transfer cycles.
What is known already: Although there is evidence that the potential impact of vitamin D deficiency on reproductive outcome may be mediated through a detrimental effect on oocyte or embryo quality, the rationale of our design was based on evidence derived from basic science suggesting that vitamin D may have a key role in endometrial receptivity and implantation. Only few retrospective clinical studies have been published up to date with conflicting results.
Study design, size, duration: This study is a prospective cohort study from the Centre for Reproductive Medicine at the University Hospital of Brussels. The duration of the study was 1 year.
Participants/materials, setting, methods: A total of 280 consecutive patients who had at least 1 blastocyst frozen and were planned for a frozen-thawed embryo transfer, were enrolled in the study following detailed information and signing of a written informed consent. Serum analysis of 25-OH vitamin D was measured on the day of embryo transfer and the impact of vitamin deficiency was investigated on reproductive outcomes.
Main results and the role of chance: Among all patients, 45.3% ($n = 127$) had vitamin D deficiency (<20 ng/ml), and 54.6% ($n = 153$) had normal vitamin D levels (>20 ng/ml). Positive hCG rates were similar among patients with vitamin D deficiency and women with normal total serum 25-OH vitamin D levels (40.9 versus 48.3%, $p = 0.2$). Similarly, no difference was found in clinical pregnancy rates in women with vitamin D deficiency [32.2% (41/127)] compared to those with higher vitamin D levels [37.9% (58/153)]; $p = 0.3$. When analyzing the results according to different thresholds, as proposed by the Endocrine Society, clinical pregnancy rates were comparable between vitamin D deficient (<20 ng/ml), vitamin D insufficient (20–30 ng/ml) and vitamin D replete women (≥30 ng/ml) [32.3% (41/127) versus 39.5% (36/91) versus 35.5% (22/62), respectively, $p = 0.54$]. Multivariate logistic regression analysis showed that vitamin D status is not an independent predictive factor of clinical pregnancy.
Limitations, reasons for caution: Ethnicity was not assessed, given that the vast majority of patients were Caucasian. Furthermore, although we failed to find a difference between vitamin D deficient and non-deficient women, we need to underscore that our study was powered to detect a difference of 15% in clinical pregnancy rates.
Wider implications of the findings: Vitamin D deficiency does not significantly impair pregnancy rates among infertile women undergoing frozen-thawed embryo transfer cycles. The measurement of vitamin D levels in this population should not be routinely recommended.
Trial registration number: The trial was prospectively registered in clinicaltrials.gov as NCT01985672.

O-233 A new device for warming embryo during the transfer improves clinical outcomes. Preliminary results in a RCT

R. Bernabeu-Perez[1], A. Rodríguez-Arnedo[2], B. Moliner[1], J. Ten[2], J.C. Castillo[1], F. Sellers[1], J. Llácer[1]
[1]*Instituto Bernabeu, Reproductive Medicine, Alicante, Spain*
[2]*Instituto Bernabeu, Reproductive Biology, Alicante, Spain*

Study question: To determine whether protecting embryos from thermal stress with the use of a new device can improve clinical outcomes.
Summary answer: By maintaining the temperature at 37°C during the embryo transfer procedure, we increase success rates in IVF.
What is known already: The human embryo is very sensitive to adverse conditions. *In vivo* fertilization and cleavage preserve it from changes in the temperature. During the embryo transfer procedure, the embryo is transported from the incubator to the maternal uterus inside a soft catheter. Despite the lab temperature being around 24°C, we have determined a temperature drop in the catheter, in which it falls from 37 to 29°C in just 40 s. Keeping embryos in these suboptimal conditions could negatively affect their development.
Study design, size, duration: After the Ethics Committee approval, we carried out a randomized control trial study. Patients were assigned to group A (control: conventional embryo transfer procedure) or group B (study: catheter carried in the device). The objective is to observe if a 15% increase in success rate is achieved in group B. The number of data collected must be 176 cases in each group. The period of time has not been established. The results were analyzed periodically.
Participants/materials, setting, methods: Only cryotransfers of embryos from donated oocytes were included. Exclusion criteria are: patients suffering from repeat implantation failure, recurrent pregnancy losses or anatomic abnormalities in uterine cavity.

After being informed and signing a consent form, patients were randomly assigned to group A (control group) or group B (study group).
Main results and the role of chance: Before launching this study, we confirmed the accuracy of maintaining the temperature in this new device. We warmed up the device inside the incubator at 37°C overnight. We then tested the temperature drop inside the device at room temperature during a long period of time. We observed a slow temperature fall, registering 36.5°C inside the device 10 min after exposure to room temperature.

We analyzed our preliminary data with a χ-test to evaluate differences. 66 treatments were included [27 control group (A), 39 study group (B)]. An improvement in positive pregnancy tests in the study group was observed, 44.4 vs. 51.3% ($p = 0.624$). No statistical significance was obtained with high probability due to the low number of cases, considering that we need 176 treatments in each group. Despite the low number of reported cases, from the very beginning there was a trend of higher success rates in transfers using the thermal device.
Limitations, reasons for caution: These are preliminary results and we need a higher number of cases to confirm our hypothesis. However, we hope to confirm them briefly since the results are encouraging.
Wider implications of the findings: Taking care of the embryo during the whole IVF procedure including the embryo transfer should be mandatory. Maintaining the optimal temperature until the embryo arrives in the maternal uterus using this new device could improve the success rates.
Trial registration number: NCT02650310.

O-234 Hydroxypropyl cellulose is an effective surfactant agent for vitrification solutions: a prospective study on donor oocytes

M. Gallardo Molina[1], M. Hebles[2], B. Migueles[2], M. Dorado[3], L. Aguilera[2], M. Gonzalez[2], P. Piqueras[2], L. Montero[1], S. Pascual[2], S.M. Fernando[2], R. Risco[4]
[1]*Malo Clinic – Ginemed, IVF Laboratory, Lisbon, Portugal*
[2]*Clinicas Ginemed, IVF Laboratory, Sevilla, Spain*
[3]*Fundacion Ginemed, IVF Laboratory, Sevilla, Spain*
[4]*National Accelerator Centre, Seville Engineering School, Applied Physics, Seville, Spain*

Study question: Test the effectiveness of a protein-free vitrification solution supplemented with the synthetic macromolecule hydroxypropyl cellulose (HPC) as surfactant agent for the vitrification of human donor oocytes.
Summary answer: Vitrification of human donor oocytes with a protein-free vitrification solution yields excellent laboratory outcomes, comparable to fresh sibling oocytes.
What is known already: Protein supplementation with human serum albumin has traditionally been employed as surfactant agent for the vitrification and rewarming solutions. However, it presents risks of contamination and production variability so a replacement synthetic component has been sought for long. A fully synthetic formulation is desirable: the international regulatory policies are also encouraging the use of medias with these synthetic substitutes. The synthetic macromolecule HPC is a variable length polysaccharide that forms a viscous gel under low temperatures. HPC based vitrification solutions have shown promissory results on murine and human embryos.
Study design, size, duration: A prospective study including 219 donor MII oocytes. Depending on the availability, each recipient was assigned 6–9 fresh

MII oocytes (control group) and 2–5 vitrified/re-warmed MII oocytes (experimental group) from the same donor of a previous donation cycle. Both groups of oocytes underwent ICSI and were cultured in parallel. Primary performance end-point was the fertilization rate. Secondary parameters assessed were embryo quality in day 2 and day 3.

Participants/materials, setting, methods: Oocytes underwent a 8–12 min equilibration step (ES: 7.5% ethylene glycol EG, 7.5% DMSO), rinsed in vitrification solution for 60 s (VS: 15% EG, 15% DMSO), and loaded in a kitazato open carrier (Kitazato, Japan). Occytes were warmed in 1.5 mL of thawing solution for 60 s (TS, 1M sucrose), placed for 3 min in dilution solution (DS: 0.5M sucrose) 5 min in washing solution (WS: cryoprotectant free solution). Vitrification solutions by SafePreservation, Spain.

Main results and the role of chance: Out of 73 vitrified MII oocytes, 70 (95.9%) presented morphologic survival 2 h post warming, and 49 of them (70.0%) presented normal fertilization, compared to 105 (71.9%) of 141 MII fresh oocytes ($p > 0.05$) (Table 2). In day 2, 82.2% of embryos from vitrified oocytes were of good quality, against a 71.7% from fresh oocytes, and 69.2% against a 70.0% of good quality embryos on day 3, respectively ($p > 0.05$). 15 embryos were transferred in total from both fresh and vitrified oocytes, with an implantation rate of 53.3%.

Limitations, reasons for caution: Only the extended use of HPC based vitrification solutions over time and in a wide variety of patients will provide good quality evidence of these findings.

Wider implications **of the findings:** The satisfactory results of this direct comparison with fresh controls is a strong indicator of the safety and effectivity of HPC supplementation of vitrification solutions, confirming its role as a substitute of protein supplementation.

Trial registration number: N/A.

O-235 Oxidative markers in cryopreservation medium of frozen- thawed embryos in *In Vitro* Fertilization: a possible tool for improved embryo selection?

Z. Wiener-Megnazi[1], S. Lahav-Baratz[1], S. Matarasso[1], M. Koifman[1], S. Shnizer[1], D. Ishai[1], G. Peer[1], G. Younes[1], R. Auslander[1], M. Dirnfeld[1], I. Blais[1]
[1]*Carmel Medical Hospital, IVF Unit, Obstetrics and Gynecology, Haifa, Israel*

Study question: Is there an association between oxidative parameters in embryo cryopreservation medium measured by the Thermochemiluminescence (TCL) assay and laboratory and clinical outcome parameters?

Summary answer: Thawed embryos may express oxidative processes in the cryopreservation medium. Higher oxidative levels are associated with lower implantation rates.

What is known already: Cryopreservation of surplus embryos has been routine practice in IVF laboratories. Both cryopreservation and thawing have been associated with post-thaw damage *via* several mechanisms, including oxidative stress. Embryos chosen for transfer following a freeze-thaw cycle are assessed on the basis of a subjective morphological grading and scoring system. The TCL assay has been used to investigate oxidative stress in biological fluids and been validated in several studies using various biological samples. In a previous study, we found that TCL oxidative parameters in the embryo culture media may serve as quick, simple, and accurate tools for embryo selection in IVF.

Study design, size, duration: A Prospective, cohort clinical and laboratory study. Study population included ninety one IVF patients undergoing frozen-thawed embryo transfer cycle during 2013.

Participants/materials, setting, methods: The Study was held in an IVF unit in a university-affiliated hospital were included. Following thawing, 50 microliters of embryo cryopreservation medium were retrieved from each cryotube and tested in the TCL Analyzer. Recorded parameters were: TCL amplitudes after 50 (H1), 150 (H2) and 280 s (H3) in counts per seconds (CPS) and TCL ratio (%). These were compared with clinical and laboratory parameters including implantation and pregnancy rates. Data underwent statistical analysis.

Main results and the role of chance: Altogether 194 embryos were transferred in 85 frozen-thaw cycles. Twenty-one pregnancies (24.7%) occurred. In the ROC analysis, the median TCL H1 amplitude of 32 CPS was the best cut-off value for discriminating between conception and non-conception cycles. Implantation, overall and clinical pregnancy rates were higher when TCL H1 amplitude was <32 CPS (median) compared with TCL H1 ≥ 32 CPS (14.6 vs. 5.3, 37.5 vs. 17, 28.1 vs. 9.4%, respectively). In addition, higher pregnancy rates were associated with the transfer of embryos at 2 days, a greater number of transferred embryos, and the transfer of embryos with a lower TCL H1 amplitude, or a TCL H2 amplitude <35 CPS. No pregnancies occurred when H1 amplitude was ≥40 CPS. Logistic regression multivariate analysis found that only TCL H1 median amplitude was associated with the occurrence of pregnancy (OR = 2.93, 95% CI = 1.065–8.08). TCL ratio inversely correlated the duration of embryo cryopreservation ($r = -0.37$). The median TCL H3 amplitude was higher among smokers than non-smokers.

Limitations, reasons for caution: As a TCL H1 amplitude >40 CPS was found in only five cases, it is premature to recommend that embryos be discarded from transfer if this specific value is measured. This small- scale preliminary study warrants a larger, prospective, randomized, controlled study, before clinical recommendations may be made.

Wider implications of the findings: Results warrant a large-scale prospective study using cryopreservation medium from vitrified embryos, (cleavage stage and single blastocysts). As cryopreservation of embryos becomes more common, we believe that application of the TCL assay may provide an additional quick, non-invasive, simple, accurate, and objective tool for better embryo selection after thawing.

Trial registration number: Since this study was not an interventional study, it was not registered.

O-236 Different thawed cleaved embryo transfer strategy for cryopreserved embryos according to mode of cryopreservation?: a prospective randomized study comparing 2 culture medium duration

A. Benammar[1], X. Ferraretto[1], E. Galati[1], M.A. Llabador De Royer[1], S. Gricourt[2], S. Epelboin[2], C. Yazbeck[2], C. Patrat[1]
[1]*Hopital Bichat Claude Bernard, Biologie de la Reproduction, Paris, France*
[2]*Hopital Bichat Claude Bernard, Gynecology, Paris, France*

Study question: Impact of post-thaw embryo culture duration on implantation and pregnancy rates according to the freezing techniques: vitrification vs. slow freezing.

Summary answer: While the time of embryo-culture post thawing shows no impact after slow freezing, it seems to be decisive on implantation and pregnancy rates after vitrification.

What is known already: The two most common procedures to select cleaved embryos for frozen embryo transfer (FET) are the observation of blastomere survival and proliferation after thawing, requiring a longer culture (overnight) (El-Toukhy et al., 2003). A study pointed out a potential harmful effect of the *in vitro* embryo culture of slowly frozen embryos after thawing, because of their sensibility to sub-optimal environmental conditions (Rato et al., 2012). The vitrification induces fewer traumas to cells and is, therefore, most efficient (Loutradi et al., 2008), but it requires an increase of cryoprotectant concentration.

Study design, size, duration: Prospective cohort study at Bichat-Claude Bernard Hospital (AP-HP, Paris) including 701 frozen thawed embryo cycles between March 2013 and December 2015. Day 2 embryos with 3 <6 blastomeres and ≤30% fragmentation were cryopreserved using slow controlled freezing [Embryo Freezing Pack, Origio, France] or closed vitrification [Vit KitR – Freeze, Irvine Scientific, France]. Only embryos with ≥50% of cells intact after thawing were transferred either after 2 h (group A) or overnight of culture (group B).

Participants/materials, setting, methods: A total of 449 thawed day 2 cleaved embryo cycles were included. 88 and 116 cycles after slow freezing and vitrification respectively were included in group A 125 and 120 cycles after slow freezing and vitrification respectively were included in group B Chi 2 tests were performed to assess survival, clinical pregnancy (CPR) and implantation rates (IR) according to the group and the mode of cryopreservation.

Main results and the role of chance: The number of transferred embryos was 316 and 356 after slow freezing and vitrification respectively. The survival rate was 79.9 and 85.5% after slow freezing and vitrification respectively. No significant difference was evidenced between groups A and B in terms of CPR and IR in case of slow frozen embryos (20.5 vs. 20.0, and 15.7 vs. 14.3%). However, C PR and IR were significantly higher in the group B (overnight culture) than in group A when frozen embryos were vitrified (28.3 vs. 16.4 and 22.0 vs. 11.5% respectively; $P < 0.01$).

Interestingly, to confirm the importance of culture duration on vitrified embryo outcomes, we compared results of 184 day 3 frozen embryos (132 cycles) where thawing and transfer occurred the same day. Despite a significant higher

survival rate after vitrification than slow freezing (89.3 vs. 59.0% $P < 0.01$), PR and IR were significantly better after slow freezing (27.3 and 21.2%) than after vitrification (20.0 and 17.0%, $P < 0.05$), suggesting the potential role of culture duration on thawed vitrified embryos.

Vitrified embryos need longer time of *in vitro* culture before transfer, probably to reject the main quantity of cryoprotectants.

Limitations, reasons for caution: Need to compare other stages of frozen embryo (day 1, day 5 and 6) to confirm the effect of time culture duration after vitrification.

Wider implications of the findings: With all the enthusiasm that has occurred in recent years around vitrification, mainly of blastocyst, and earnings on cell preservation, this study suggests that the effect of cryoprotectants at high concentration could be harmful, and new recommendations on frozen cleaved embryo transfer strategies could be depicted.

Trial registration number: Not applied.

O-237 Morphology dynamics of warmed blastocyst are strong predictors of clinical outcome

A. Galán Rivas[1], A. Coello[1], A. Cobo[1], M. Nohales[1], L. Alegre[1], M. Meseguer[1]
[1]*Instituto Universitario IVI Valencia, IVF Laboratory, Valencia, Spain*

Study question: Can time-lapse imaging be used to define morphology dynamics of frozen blastocysts and become indicators of embryo outcome?

Summary answer: The analysis of warmed blastocysts by cinematography is providing new insights on embryo outcome and defines new markers for blastocyst implantation potential.

What is known already: Blastocyst re-expansion has shown to have predictive properties for the implantation of warmed blastocysts. However, no quantitative values have been defined to be used as a predictor of viability.

Study design, size, duration: A retrospective study including 414 frozen embryo transfer cycles from November 2014 to December 2015.

Participants/materials, setting, methods: The study includes 435 thawed blastocysts with known implantation data, evaluated using time lapse. Blastocysts were placed in Embryoscope® (Unisense-FertiliTech) from immediately after warming until transfer (>3.5 h). Embryos were vitrified and warmed with Cryotop method (Kitazato Biopharma). Variables studied included initial and final thickness of zona pellucida (ZP) (µm), initial and final area (µm^2), area of inner cell mass (µm^2) and presence of collapse after warming procedure. Variables analyzed were compared by ANOVA test or chi-square.

Main results and the role of chance: Implantation rate (IR) was increased (33.6 vs. 20.2%) in blastocysts with initial ZP thickness <18 µm. Blastocysts with initial area >9900 µm^2 obtained higher implantation rate (33.3 vs. 22.5%). IR was higher (35.7 vs. 24.4%) when the final ZP were <12 µm and it was also significantly increased (41 vs. 26%) when the final blastocyst area reached more than 19136 µm^2. No differences were found in area of inner cell mass between blastocysts which implanted and those which failed. In 32 cases, one or more contractions of the blastocyst were observed but no relation with implantation was confirmed.

Limitations, reasons for caution: The retrospective nature of this study may be a limitation, although the magnitude of the sample size would overcome it. In addition, the time period in which embryos were analyzed may vary depending on transfer schedule.

Wider implications of the findings: These results show that the analysis of warmed blastocysts by time-lapse imaging provides new markers for implantation, establishing quantitative values linked with clinical outcome. In those cases in which the warmed blastocyst does not reach the optimal ZP thickness and full area, a double embryo transfer strategy must be considered.

Trial registration number: None.

O-238 Higher cumulative ongoing pregnancy rate after IVF cycles including a fresh embryo transfer than after freeze-all cycles

V. Barraud-Lange[1,2], A. Rouquette[3,4], N. Le Foll[1], N. Celton[1], P. Santulli[2,5], K. Pocate-Cheriet[1], J.P. Wolf[1,2]

[5]*Cochin-Port Royal Hospital, Gynecology Obstetrics II and Reproductive Medicine Department, Paris, France*

Study question: Is there a benefit in term of ongoing pregnancy rate to perform fresh embryo transfers in IVF cycles compared to "freeze all" strategy?

Summary answer: The cumulative ongoing pregnancy rate is significantly higher in IVF cycles including a fresh embryo transfer compared to "freeze all" cycles.

What is known already: Currently, there is a trend toward the elective freezing of all embryos and subsequent replacements, so-called the "freeze all" policy. If this option is not debatable to prevent the risk of ovarian hyperstimulation syndrome (patient risk-based approach), the universal approach (cryopreservation of all embryos for all cycles) still needs to be proven.

Study design, size, duration: This cohort study includes all IVF and ICSI attempts carried out between December 2012 and April 2015 and giving rise to a pregnancy or for which all embryos were used. Women for whom the "freeze all" strategy was used (unexposed) were matched to women exposed to a first fresh embryo transfer using the propensity score, in order to reduce the recruitment bias of observational studies.

Participants/materials, setting, methods: For women who had more than one IVF attempt during the study period, only the most recent was considered. The propensity score was based on 16 individual characteristics. The main outcome was the occurrence of an ongoing pregnancy. The odds ratio (OR) was computed to quantify the association between the fresh embryo strategy and the main outcome using a logistic regression fitted by generalized estimating equations to account for paired data.

Main results and the role of chance: A total of 1624 women were included: 1068 in the fresh embryo transfer exposed group and 556 in the "freeze all" group. The propensity score matching strategy led to 398 matched exposed and unexposed women. The mean number of transfers performed in each group was 1.36 ± 0.72 and 1.29 ± 0.67 ($p = 0.139$), respectively. The cumulative ongoing pregnancy rate was 57.5% in the fresh embryo transfer exposed group vs. 40.0% in the "freeze-all" group ($p = 0.001$, OR = 2.04, 95% confidence interval: 1.54–2.69). The mean number of transfers necessary to achieved a pregnancy was 1.33 ± 0.62 and 1.37 ± 0.78 ($p = 0.581$), respectively.

Limitations, reasons for caution: Propensity score matching process could have decreased the generalizability of the results but it is a powerful tool to reduce recruitment bias. The sample size did not allow analysis of subgroups with enough power (risk of hyperstimulation syndrome, 2 prior implantation failures, premature luteinization, hydrosalpinx, endometrial polyp, endometriosis).

Wider implications of the findings: Performing a fresh transfer in the management of an IVF treatment keeps a beneficial effect on ongoing pregnancy rate compared to the freezing of all embryos, without maximizing the time to pregnancy. This emphasizes that the universal "freeze-all" approach still needs prospective randomized clinical trials to be evidence based.

Trial registration number: None.

O-239 Multi-center study demonstrates freeze-all IVF protocols are correlated with higher ongoing pregnancy rates in women of advanced maternal age.

Study question: Questions remain about whether utilization of freeze-all protocols would improve IVF outcomes for the majority of patients.
Summary answer: Freeze-all protocols were found to result in equivalent ongoing pregnancy rates in younger patients and significantly improved outcomes in patients over 35 years old.
What is known already: As IVF with frozen embryo transfer has become more common, protocols in which all embryos are frozen and transferred in a later cycle have emerged to reduce the risk for OHSS and address concerns about endometrial receptivity (ER) in women undergoing controlled ovarian stimulation and/or experiencing a premature elevation of progesterone (P). To date, randomized control studies comparing freeze-all to fresh protocols have focused on good prognosis patients, leaving open questions about which patients might benefit most from a freeze-all protocol.
Study design, size, duration: We performed a retrospective cohort study on patients at 12 fertility treatment centers in the United States who had undergone IVF cycles in 2009–2015. We included cycles in which fresh embryos were transferred (Fresh) and cycles in which all embryos were frozen, followed by a frozen embryo transfer (Freeze-all). We excluded frozen transfers of supernumerary embryos, cancelled cycles, and cycles for which patient age, height, weight, or progesterone level at surge (hCG administration) were missing.
Participants/materials, setting, methods: 16,206 cycles were available for analysis, including 2,100 Freeze-all cycles. A matching algorithm was used to select 2,100 fresh cycles with similar distributions of measured covariates (age, diagnoses, embryos transferred, use of pre-implantation genetic screening (PGS), P at surge, bAFC, Day 3 LH, Day 3 FSH, Day 3 E2, parity, gravidity, BMI) to the Freeze-all cycles. Logistic regression was used to compare the odds of ongoing pregnancy in Freeze-all compared to matched Fresh control cycles.
Main results and the role of chance: In a matched cohort, ongoing pregnancy rates were 40.3% for Fresh and 50.2% for Freeze-all cycles. We controlled for hormone levels, number of embryos transferred, diagnosis, age, and PGS utilization and found that ongoing pregnancy rates were significantly higher in Freeze-all cycles for patients between age 35–38 [OR = 1.48 (1.14, 1.92), $p = 0.006$], 38–41 [OR = 2.59 (1.90, 3.52), $p < 0.001$], and older than 41 [OR = 8.16 (4.89, 13.59), $p < 0.001$] compared to Fresh controls. Cycles for patients younger than 35 did not have significantly different odds of ongoing pregnancy in Freeze-all compared to Fresh [OR = 1.02, (0.86, 1.22), $p = 0.83$]. Additionally, we found that a diagnosis of DOR, PCOS, endometriosis, tubal disease, uterine factor, ovulatory dysfunction, or idiopathic infertility had no significant impact on the effect of Freeze-all (all $p > 0.05$). We also observed the effect of Freeze-all versus Fresh in cycles where P at surge was greater than 1.5 ng/mL, found no significant difference in outcomes between these two protocols for these patient ($p = 0.16$). In addition, when comparing the patients that had P at surge less than 1.5 ng/mL, we again saw no significant difference in Fresh versus Freeze-all ($p = 0.57$).
Limitations, reasons for caution: Variability in reported values of P due to laboratory assay variation and cycle timing could be a confounding factor in grouping patients with elevated P. Our study was performed on retrospective data from the United States. Future studies could expand to European practice patterns and involve randomized controls trials.
Wider implications of the findings: Freeze-all cycles provide advantages for patients over fresh embryo transfer cycles. We found that not only are pregnancy outcomes equivalent from fresh cycles in younger patients, but that freeze-all protocols provide benefit for older patients. Interestingly, we did not see this in patients with a premature rise in progesterone levels.
Trial registration number: None.

O-240 Isolation and characterization of exosome nanovesicles secreted by pre-pubertal Sertoli cells

G. Luca[1], G. Falabella[1], M. Calvitti[1], S. Giovagnoli[2], F. Mancuso[1], I. Arato[1], C. Lilli[1], C. Bellucci[1], A. Becchetti[3], C. Antognelli[1], M. Bodo[1], T. Baroni[1], R. Calafiore[4]
[1]University of Perugia, Department of Experimental Medicine, Perugia, Italy
[2]University of Perugia, Department of Pharmaceutical Sciences, Perugia, Italy
[3]Hospital Universitario de la Ribera de Alzira, Department of Plastic and Reconstructive Surgery, Valencia, Spain
[4]Saint Mary Hospital, Division of Medical Andrology and Endocrinology of Reproduction, Terni, Italy

Study question: The aim of our work was to verify if pre-pubertal Sertoli cells (SC) release exosome nanovesicle (Nv) and analyse their mRNA content.
Summary answer: For the first time in the Literature, our work showed the presence of Nv secreted by SC including their mRNA content.
What is known already: Recent studies have shown that extra-cellular secretion of Nv is an important mechanism of intercellular communication. In fact, Nv may contain proteins, DNA and mRNA. In particular, the latter play an important role in various biological processes including regulation and cell differentiation. SC, once described as a mere "sustentacular cell," were re-evaluated in their functions and elevated to the rank of a "sentinel" in spermatogenesis due to production of trophic, differentiation and immune-modulators factors.
Study design, size, duration: Pure porcine pre-pubertal SC were isolated according to previously established methods. Briefly, the testes underwent enzymatic digestion and were cultured in specific SC medium.
Upon 48 h culture, SC were stimulated with FSH or FSH + testosterone (T) and: (a) the presence in the medium of SC-derived exosome nanovesicle (SC-Nv) and (b) SC-Nv content, in terms of Anti-Müllerian hormone (AMH), inhibin B, Androgen Binding Protein (ABP) and FSH-receptor (FSH-r), by Real Time PC, were assessed.
Participants/materials, setting, methods: After 48 h of SC stimulation, culture media were centrifuged at 2000 g (to remove cell debris) and the obtained supernatant underwent further centrifugation with Vivaspin 300 kD at 4000 g for 30 min. Upon washing, the obtained cell pellet was resuspended in both PBS, for scanning electron microscope (SEM) and Dynamic Light Scattering (DLS) analysis, and Trizol, for total mRNA extraction.
Main results and the role of chance: SEM analysis highlighted the presence of SC-Nv in culture medium with 3 different mean diameters (1388, 838 and 149 nm). We have also demonstrated, within the SC-Nv, significant increase in mRNA for AMH, ABP and FSH-r after both FSH and FSH + T stimulation, as compared to unstimulated SC-Nv. Differently from unstimulated SC-Nv, mRNA inhibin B levels were unchanged in FSH-stimulated SC-Nv, and increased after FSH + T stimulation. Interestingly, an opposite trend was shown in mRNA secretion, in control SC monolayer where, we demonstrated a decrease of AMH and FSH-r mRNA (after both stimulation with FSH or FSH + T) and an increase of inhibin B mRNA. On the contrary, mRNA ABP levels, in SC monolayer, decreased after stimulation with FSH but were unchanged in the presence of FSH + T.
Limitations, reasons for caution: These preliminary data will be confirmed in future experiments.
Wider implications **of the findings:** For the first time in the Literature, our work has shown the presence of SC-Nv containing AMH, inhibin B, ABP and FSH-r mRNA. This result may suggest that other testicular cells could produce factors that, until now, were considered an exclusive SC secretory product.
Trial registration number: Not required.

O-241 Decoding mammalian fertility: characterising the genetic loci implicated in male fertility potential

D.E. Parfitt[1], A. Oromendia[1], A. Conover[1], I. Hirschmann[1], B. Burnett[1], S. Globus[1], T. Hu Seliger[1], P. Yurttas Beim[1]
[1]Celmatix Inc., Science, New York, NY, USA

Study question: The aim of this study was to compile and collate data implicating genes in male fertility, including data demonstrating how particular genes contribute to mechanisms of male reproductive physiology.
Summary answer: We outline the incorporation of comparative genomic data into a systems-level knowledgebase of fertility-centric data to comprehensively understand the molecular drivers of male reproductive physiology.
What is known already: It is estimated that for around a third of couples unable to conceive a child, subfertility of the male partner is the sole explanation. This subfertility remains unexplained for almost half of these men, even after extensive clinical evaluation. Genetic mutation likely accounts for the majority of these patients. However, identification and characterization of the genetic elements collectively contributing to male subfertility is only possible with a fully comprehensive understanding of the genes involved in male-specific reproductive processes.
Study design, size, duration: We collected and cross-referenced human- and animal-model specific expression data, phenotypic and genotypic data for more than 5,000 genetic loci.
Participants/materials, setting, methods: Data were iteratively cross-referenced and analyzed using meta-analyses and bioinformatics tools to characterize roles in particular reproductive processes.
Main results and the role of chance: From >55,000 mammalian phenotypes described on the international database for the laboratory mouse (MGI), a series of algorithmic searches identified 2,493 directly or indirectly linked to reproduction. A second set of algorithms was then used to group and cross-reference genetic loci according to their inferred and/or reported male-specific reproductive function(s). Our algorithmic approach led to the inclusion of more than 1,100 genetic loci in our knowledgebase whose associated phenotypes linked them to at least one aspect of male-specific reproductive biology. For example, the phenotypes of 254 genes demonstrated their role in spermiogenesis, the spermatogenic process involving the morphological differentiation of spermatozoa. Perhaps understandably, 33 of these genes were also reported to result in phenotypes related to sperm count, such as "oligozoospermia." However, our dataset also allowed us to make non-obvious associations between subsets of these 33 genes with endocrinological and immunological phenotypes, thus highlighting potentially important genes and physiological pathways contributing to the etiology of abnormal sperm metrics. Our results contribute to a powerful data set with which to identify candidate genetic biomarkers of human fertility potential, and thus novel targets for drug development and therapeutics.
Limitations, reasons for caution: Data relating particular genes and variants to reproductive processes in mammalian models or humans may have yet to be identified.
Wider implications of the findings: Our classification of genetic loci according to their role in reproductive mechanisms helps clarify how genetic mutations contribute to the pathophysiology of male subfertility. Identifying genetic loci for which little existing information links them mechanistically to infertility, provides a route for hypothesis-driven research into novel, clinically actionable molecular targets.
Trial registration number: None.

O-242 Fingerprinting of tubulin post-translational modifications (PTM) identifies the spermatozoa tail tip as a cluster area of candidate sperm fitness biomarkers

F. Amargant[1], M. Barragan[1], M. Rodriguez de la Vega[2], I. Vernos[2], R. Vassena[1]
[1]*Clínica Eugin, Barcelona, Spain*
[2]*Center for Genomic Regulation CRG, Cell and Developmental Biology, Barcelona, Spain*

Study question: What is the make-up and distribution of sperm flagella tubulin PTMs, and their relationship with sperm fitness in the human species?
Summary answer: Human sperm flagella have several PTMs with specific distributions in the last 10% of the tail, which differ between motile and unselected semen fractions.
What is known already: The microtubules in the sperm flagella are composed of tubulin, and are necessary for sperm movement. Tubulin can be modified post translationally by the addition or removal of different amino acids; defining the flagellum functionality. Several tubulin PTMs have been described in *Drosophila* and sea urchin spermatozoa, where blocking tubulin polyglutamylation decreases sperm motility. Tubulin monoglycylation and acetylation are associated with axoneme stability, while preventing tubulin glycylation causes sperm defects and infertility in *Drosophila*. Despite the reported effect of PTMs on sperm fitness, very little is known about PTMs presence and role in human sperm functionality.
Study design, size, duration: This is a basic research study. Fresh ejaculate from normozoospermic and teratozoospermic patients was processed by swim-up. The presence and distribution of the following tubulin PTM were analyzed by western blot (WB) and immunofluorescence (IF) using specific antibodies both in the motile fraction and the unselected one: acetylation, polyglutamylation, branching glutamylation, monoglycylation, lack of the two last amino acids, lack of tyrosine, and tyrosination.
Participants/materials, setting, methods: WBs were carried out on 1.5×10^6 spermatozoa while IF was performed on 100,000 spermatozoa for each condition. A double IF for tubulin and each PTM was performed. The localization pattern of 20 spermatozoa per condition was further analyzed by calculating the tail intensity for every 0.1 micron to then normalize the tail length to 1, and interpolar lineation was applied to calculate the relative intensities across each tail for each 0.001 relative length units.
Main results and the role of chance: We found that the microtubules in the human sperm flagella are highly modified overall; in fact, we detected acetylation, polyglutamylation, branching glutamylation, monoglycylation, lack of the two last amino acids, lack of tyrosine, and tyrosination both by WB and IF. Interestingly, although some of them (lack of the two last amino acids, lack of tyrosine, tyrosination and polyglutamylation) show a similar distribution pattern along the flagella of all normozoospermic and teratozoospermic samples, other (acetylation, monoglycylation and branching glutamylation) are especially reduced in the last 10% of the flagella. Moreover, the specific reduction pattern is different for motile normozoospermic and either unselected normozoospermic and any teratozoospermic sample (motile or unselected), indicating that the motile fraction selected by swim-up of pathological semen, although morphologically normal, could retain some ultrastructural alterations when compared to normozoospermic samples. Overall, our results suggest that tubulin modifications are important for flagellum stability and tail motility, overall affecting sperm functionality.
Limitations, reasons for caution: No attempts to correlate tubulin PTMs and reproductive outcomes were made yet. A degree of phenotype overlap between sperm from the selected and the unselected fractions makes the interpretation of molecular data difficult; samples with close to no motility will be necessary to strongly correlate PTMs fingerprinting with sperm motility.
Wider implications of the findings: This is the first study that describes the presence of most known tubulin PTMs in human sperm. Our results identify the last 10% of the sperm flagellum length as a region of high PTM plasticity. PTM fingerprinting of this area could provide important marker for sperm diagnosis and prognosis.
Trial registration number: N/A.

O-243 Dutasteride mediated morphological changes in genitourinary tract was associated with altered expression patterns of androgen receptor and estrogen receptor in male rat

N. Enatsu[1], K. Chiba[1], K. Sumii[1], T. Fukuda[1], M. Fujisawa[1]
[1]*Kobe University, Urology, Kobe City, Japan*

Study question: Does dutasteride affect the histological and hormonal status in genitourinary tract other than prostate?
Summary answer: Dutasteride caused the fibrotic changes in penis associated with the altered expression of androgen receptor and estrogen receptor.
What is known already: 5-alpha reductase inhibitors are known to cause adverse effects on sexual function, and some clinical evidences suggest that these adverse effects are persistent or irreversible in some patients. These facts indicate that 5α-RIs may cause the structural degeneration in penis. In fact, Traish et al. reported that finasteride treatment decreased autophagy and produced deterioration in the ultrastracture of the corpus cavernosum, including mitochondria injury and increased trabecular smooth muscle cell death. It is inferred that these changes were caused by altered hormonal environment in the tissue. However the actual hormone dynamics in genitourinary tract related to 5α-RI is still unknown.
Study design, size, duration: Fifteen 8-week-old male Sprague-Dawley rats were used. The animals were divided into 3 groups comprising 5 animals each

and treated as follows. Group A as control group, members of Group B received oral administration of dutasteride 0.1 mg/kg/day from the age of 8 weeks to 12 weeks, and members of Group C were castrated at 8 weeks. All rats were sacrificed at the age of 12 weeks.
Participants/materials, setting, methods: After the measurement of size, bladder, prostate, seminal vesicle, and penis were removed for pathological examination. Smooth muscle/collagen ratio was evaluated by azan staining and measured using color assisted quantitative image analysis to evaluate tissue fibrosis. We also evaluated the expression of androgen receptor and estrogen receptor by immunofluorescent staining.
Main results and the role of chance: The results showed the mean size of prostate and seminal vesicle was smaller in castrated group and dutasteride group than that of control group. Moreover, in castration group, the bladder volume and penile length was also smaller than that of control group. Castration group showed statistically significant histological changes such as increase in fibrotic tissue in bladder, prostate and penis. Similarly, dutasteride group showed fibrotic changes in prostate and penis compared to the control group. Immunofluorescent staining revealed that androgen receptor was more strongly expressed than that of estrogen receptor in control group. On the other hand, in castration group, week expression of androgen receptor and strong expression of estrogen receptor was noted. In dutasteride group, these changes were also noted in prostate and penis. These findings suggest that dutasteride cause morphological changes not only in prostate, but also in penis. These changes are associated with altered expression patterns of androgen receptor and estrogen receptor.
Limitations, reasons for caution: This study only included adolescent rat, therefore, it would be difficult to apply present findings to the entire cohort of male.
Wider implications of the findings: Dutasteride induced changes of hormonal receptor expressions and tissue fibrosis may explain the mechanisms of persistent or irreversible adverse effects of dutasteride in some patients with benign prostate hyperplasia or alopecia.
Trial registration number: None.

O-244 Quantitative proteomic analysis of human sperm tail in asthenozoospermic patients

T. Rezaei-Topraggaleh[1,2], M. Mirzaei[3], S. Mirshahvaladi[4], M. Alikhani[4], V. Esmaeili[1], G. Hosseini Salekdeh[4], A. Shahverdi[1]
[1]Royan Institute for Reproductive Biomedicine ACECR, Department of Embryology, Reproductive Biomedicine Research Center, Tehran, Iran
[2]Tarbiat Modares University, Department of Anatomy, School of Medical Sciences, Tehran, Iran
[3]Macquarie University, Department of Chemistry and Biomolecular Sciences, Sydney, NSW, Australia
[4]Royan Institute for Stem Cell Biology and Technology ACECR, Department of Molecular Systems Biology, Cell Science Research Center, Tehran, Iran

Study question: Are there quantitative variations in the sperm tail proteome of asthenozoospermic patients compared to normozoospermic donors?
Summary answer: Compared with normozoospermic donors, 479 proteins were altered in sperm tail proteome of asthenozoospermic patients.
What is known already: The sperm tail is an important structure for the elucidation of the molecular dynamics of sperm motion, as it is the only means of motility and contains mitochondria as the power plants of the sperm. Subcellular proteomics with combining high-throughput techniques allows us to identify low-abundance proteins which would otherwise be undetectable by conventional methods.
Study design, size, duration: This was a case-control study comprising 80 men who attended Royan infertility center for assisted reproduction between October 2014 and July 2015.
Participants/materials, setting, methods: Semen samples were evaluated by computer assessed analyzer and divided into asthenozoospermic group (progressive motility <32%, $N = 40$) and normozoospermic group (progressive motility >32%, $N = 40$). Samples of four individuals were pooled and the tail fractions isolated by sonication and successive sucrose gradient. After confirming tail fraction purity, extracted proteins were labeled with tandem mass tags (TMTs) followed by shotgun proteomics. Bioinformatic analyses were performed using DAVID. Candidate proteins were further validated by Western blot analysis.
Main results and the role of chance: We detected 2145 proteins in the tail fraction of human sperm where 189 and 280 proteins were respectively up and down regulated in asthenozoospermic patients compared to normozoospermic donors. The main down-regulated proteins were structural proteins as well as those involved in energy production pathways. Furthermore, we identified DDX3Y (ATP-dependent RNA helicase), a Y chromosome encoded protein, being over expressed in the sperm of asthenozoospermic patients.
Limitations, reasons for caution: Due to difficulties in isolation of the tail fraction as well as the lack of an adequate amount of protein for shutgun proteomics, samples from four individuals were pooled.
Wider implications of the findings: While it is known that Y chromosome encoded proteins play a critical role in male gonad development and spermatogenesis, our data highlight their significance in the function of mature spermatozoa.
Trial registration number: 0000.

O-245 Signaling pathways in human spermatozoa to screen for idiopathic infertility

A. Clement[1], T. Cozzubbo[1], N. Pereira[1], S. Cheung[1], Q.V. Neri[1], Z. Rosenwaks[1], G.D. Palermo[1]
[1]Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, Reproductive Medicine, New York, NY, USA

Study question: We question whether the gene products compartmentalized in the human spermatozoon influence semen parameter characteristics and if the specific genes involved effect embryo developmental competence.
Summary answer: Expressivity of the genes whose protein is localized in various components of the sperm cell provides inherent information on male gamete competence.
What is known already: The limitation of evaluating human semen characteristics, even according to the most stringent criteria, is known to provide limited information on the performance of spermatozoa even when used for assisted reproductive technologies (ART). Standard semen analysis is ill-defined in predicting reproductive outcome in men with idiopathic infertility. For this purpose, attempts have been made to detect ploidy, chromatinic integrity, highly detailed morphology and maturational status of the spermatozoon. Epigenetic assessment by profiling RNA transcripts in the sperm cell has been proposed as an alternative method to screen the male partner for infertility.
Study design, size, duration: In a 12-month period, we assessed the eventual impact of gene products specific to the sperm cell on semen characteristics and reproductive outcome. RNA extraction was carried out on 26 semen specimens of consenting men undergoing infertility screening. The specific proteins that were allocated among key structural components of the spermatozoon, such as the acrosomal vesicle, nucleus & flagellum were compared to sperm concentration, motility, morphology, as well as embryonic development and implantation.
Participants/materials, setting, methods: An average of 25×10^6 human spermatozoa was used to isolate total RNA using a spin column commercial kit. The nucleic acid quality and spermatozoal RNA concentration was assessed. The RNA samples were then made into paired-end libraries. Pilot paired-end 76 bp RNA-Sequencing (RNA-Seq) using an Illumina platform (NextSeq 500) was carried out and expanded to 60M reads. Expression values were calculated in Fragments Per Kilobase Of Exon Per Million Fragments Mapped (FPKM) and normalized read counts.
Main results and the role of chance: From a total of 26 men that provided sperm for RNA extraction, 8 were chosen for their adequate nucleic acid quality and concentration. Total RNA extraction from an average of 25×10^6 spermatozoa (range 4×10^6–30×10^6) was utilized. These men had an average age of 26 ± 5 years and presented with a sperm concentration of 27.3 ± 27, a motility of 46.6 ± 24, and a morphology of 3.0 ± 2. After grouping gene expression to their respective spermatozoon compartment, *ATP6V1E2* localized to the acrosomal vesicle, *TSSK6 & H1FNT* localized to the nucleus, *AKAP4 & CATSPER1* localized to the flagellum, *AGPAT2* localized to the endoplasmic reticulum, and *PLK4* localized to the centrosome. After plotting the expression in FPKM of all the above mentioned genes against the semen parameters *AKAP4,* a gene that encodes a protein localized to the sperm flagellum, had a strong inverse correlation with motility ($P = 0.01$). When ART outcome was evaluated, *ATP6V1E2* (acrosomal vesicle) had an inverse correlation to fertilization rates ($P = 0.03$). All gene products localized in the head and midpiece (centriole) were strongly expressed in men that established pregnancy that resulted in delivery ($P = 0.01$).

Limitations, reasons for caution: This study investigates the ability to profile men with idiopathic infertility and must be confirmed in a larger cohort. While the contribution of the female partner cannot be excluded, gene expression profiling of infertile men may serve as an assay to measure the reproductive potential of the male gamete.
Wider implications of the findings: Deep sequencing of sperm RNA is a reliable and reproducible technique that may aid in the diagnosis and screening of infertile men. Gene products specific of the diverse compartments of the sperm cell may supplement standard semen parameters and provide a pivotal tool in the diagnosis of idiopathic infertility.
Trial registration number: N/A.

O-246 The impact of sperm protamination on embryo development and ART result

M. Benchaib[2,3,4], C. Fournier[1], G. Soignon[2], E. Labrune[2,3,4], S. Giscard d'Estaing[2,3,5], J. Lornage[2,3,5], J.F. Guérin[2,3,4]

[3]*INSERM U1208, SBRI, Bron Cedex, France*
[4]*Université Lyon 1, Faculté de Médecine Lyon-Est, Lyon Cedex, France*
[5]*Université Lyon I, Faculté de Médecine Lyon-Sud, Oullins Cedex, France*

Study question: The percentage of histone protein remaining in spermatozoa chromatin could be calculated and used as a prognostic factor of fertilizing capacity and a prognostic factor for ART success?
Summary answer: The HRI is partially correlated to sperm DNA fragmentation. A relationship with embryo development has been found. HRI indirectly influences the ART success.
What is known already: The Histone Protamine Ratio (HRI) is the spermatozoa protamination reflect. The protamine ratio (P1/P2) is known to be associated with male factor infertility. However, persistent histones play an important role in the sperm epigenome. So an abnormal percentage of remaining histones could impact on embryo development and decrease the rate of ART success.
Study design, size, duration: A prospective study was performed at the HFME Hospital (Bron, France). A total of 291 ART cycles were included. ART procedure occurred between October 2013 and July 2015. The exclusion factors were: less than 6 oocytes punctured, cryopreserved sperm used and a total number of spermatozoa below 40 million.
Participants/materials, setting, methods: In order to calculate the HRI, a modified method described by Wikes (2003) was used. Modifications were done in order to obtain a reproducible procedure. DFI was measured with TUNEL technique. The measurement were performed on sperm used for ART procedure. A hierarchical analysis was performed to calculate the HRI cut-of value that allows obtaining the higher pregnancy rate (PR).
Main results and the role of chance: 42 c-IVF and 249 ICSI procedures were performed. 3870 oocytes were punctured, 2211 embryos were obtained: 307 embryos with c-FIV procedure and 1904 embryos with ICSI procedure. Among those embryos, 507 were transferred and 336 were frozen. The mean HRI was equal to 18.9%. The mean HRI find in this study corresponds to the remaining histone as usually described in human sperm. A significant negative correlation coefficient was fount between HRI and DFI ($r = -0.12$, $p < 0.05$). When the HRI was within the range (6–26%), the probability to obtain a blastocyst was higher: 87.8%, against 71.2% for HRI below 6 and 75.7% for HRI above 26% ($p < 0.01$). The highest PR: 27.8%, was obtained for HRI within the range (6–26%), the PR was equal to 25.0% for HRI below 6%, equal to 20.9%, when HRI was 26%; however the differences were not statistically significant.
Limitations, reasons for caution: The size of the sample should be increased in order to confirm the relationship between HRI and pregnancy. The method to quantitate HRI should be adapted to low number of spermatozoa, as actually only cycles with good sperm could be studied.
Wider implications of the findings: This procedure allows a reliable evaluation of the sperm protamination. There is a relationship between HRI, embryo development and ART success. Another proof of the implication of male factor on embryo development was found. The HRI seems to be more predictive than DFI and could be included in sperm investigation.

SESSION 64: SAFETY AND QUALITY IN ART 2

Wednesday 06 July 2016 **Hall 3 DE** **10:00–11:45**

O-247 Which patient and treatment factors contribute to the risk of congenital heart defects after art?

M. Davies[1], A. Rumbold[1], R. Fernandez[1], K. Willson[2], W. Scheil[3], V. Moore[4]
[1]*The University of Adelaide, The Robinson Institute, Adelaide, SA, Australia*
[2]*University of Adelaide, Public Health, Adelaide, SA, Australia*
[3]*South Australian Department of Health, Pregnancy Outcomes Unit, Adelaide, SA, Australia*
[4]*The University of Adelaide, Public Health, Adelaide, SA, Australia*

Study question: Do congenital heart (CH) defects occur with elevated frequency after ART, and how are patient factors and treatment modality associated with the risk?
Summary answer: Maternal factors contributed to all 3 major ICD-9 classes of CH defect. Specific ART treatments were associated with 2 of the 3 classes, after adjustment.
What is known already: CH defects occur in around 8 per 1,000 births and are a leading cause of death in the first year of life. Approximately half of children diagnosed will require surgery, with more complex conditions often requiring lifelong medical care. We and others have reported previously that ART is associated with an increased risk of birth defects. There is a need to consider specific defect types by mode of treatment, together with a range of patient characteristics, in a representative sample.
Study design, size, duration: Cohort study of all deliveries ($n = 302,811$) and terminations of pregnancy in South Australia for the period Jan 1986–Dec 2002 that were linked to all cycles of ART (6,163 births) for the same time period. These data were linked to a State-wide birth defect registry.
Participants/materials, setting, methods: The South Australian Birth Cohort is based on all registrations of birth and terminations of pregnancy, linked to all cycles of ART, and to all congenital anomalies notified to the 5th birthday (ICD-9 British Paediatric Association codes). Logistic regression was used to investigate associations between parental factors, treatment modality and the presence of CH defects.
Main results and the role of chance: Compared to women aged 25–29 years, those aged 35–39 and 40–45 years had greater risk of having a child with CH defect (an increase of 18 and 48%, respectively). Nulliparous women had an elevated risk of CH defect in the child of 9%. Diabetes and hypertension each increased the risk of CH defect by approximately 30%, and a history of miscarriage increased risk by approximately 10%. Over time, CH defects have been trending down, by around 5% per year. Female babies had a higher risk of defect overall compared to males, an increase of 7%. Twin pregnancy increases the risk of CH defect, by around 40%. ART singletons carried the same risk as twins.
Compared to the fertile population: (a) Cardiac Septal Closure anomalies (BPA 74500–74599) did not vary by ART treatment, but were increased amongst "natural" conceptions to ART patients, and after infertility consultations conducted outside an ART clinic.

(b) Other Congenital Heart anomalies (BPA 74600–74699) were increased for fresh IVF (OR = 1.9), IUI (OR = 2.3) and "natural" conceptions to ART patient (OR = 2.2) (c) Other Congenital Circulatory System anomalies (BPA 74700–74799) were increased for IVF fresh (OR = 2.0) ICSI frozen (OR = 4.7) IUI (OR = 2.4) and fertility consultation outside an ART clinic (OR = 2.5).
Limitations, reasons for caution: The decline in CH defects over time mean that more recent data are needed. We are also limited in power, with a likelihood of having false negative findings in some comparisons. We do not have access to specific treatments received outside ART clinics where ovulation induction is common.
Wider implications of the findings: Cardiac septal closure defects were related to maternal factors and non-ART infertility care.

Other anomalies of the heart and circulatory system varied significantly by ART treatment. Neither singleton pregnancy nor use of embryo cryopreservation reduced the excess risk of cardiac defects. Further basic research is therefore indicated.
Trial registration number: Not applicable.

O-248 Trends over time in congenital malformations among children conceived after assisted reproductive technology (ART)

[8]*University of Copenhagen, Department of Biostatistics, Copenhagen, Denmark*
[9]*University of Copenhagen, Department of Obstetrics and Gynecology, Hvidovre Hospital, Copenhagen, Denmark*

Study question: Has there been a change in the risk of congenital malformations for children conceived after ART during latest decades?
Summary answer: In contrast to the declining rates of poor neonatal outcomes, the incidence of major congenital malformations among ART children has remained stable over time.
What is known already: Recently, it has been demonstrated that the risk of several adverse perinatal outcomes, has decreased over time for both singletons and twins. Children conceived after ART have a well-known increased risk of congenital malformations compared to spontaneously conceived (SC) children, but whether the rate is declining over time as other neonatal risks has not yet been explored. Some studies have found a particularly increased risk of congenital malformations for children conceived after intracytoplasmic sperm injection (ICSI), which still needs further investigation.
Study design, size, duration: Population-based cohort study including 90 201 ART children and 482 552 SC children. Both singletons and twins born after IVF, ICSI and frozen embryo transfer were included. The ART singletons were matched 1:4 on with a control group of SC children from their own country. The matching criteria were parity (0 versus 1) and year of birth. To allow stratified analyses for twins, all SC twins born within the study period were included.
Participants/materials, setting, methods: Multiple logistic regression analyses were used to estimate the risks and adjusted odds ratios for congenital malformations in four time periods: 1988–1992; 1993–1997; 1998–2002 and 2003–2007. To assess whether the risk patterns between the conception groups changed over time we tested group-time interaction terms. All malformations were classified and grouped according to the EUROCAT classification of malformations. Only major malformations were included. We used nationwide health registers from Denmark, Finland, Norway and Sweden.
Main results and the role of chance: A major congenital malformation was observed among 2304 (3.76%) ART versus 11 110 (3.17%) SC singletons, adjusted odds ratio (AOR) 1.15 [95% confidence interval (CI), 1.10–1.21]. Among twins, $n = 1785$ (6.17%) ART versus $n = 6970$ (5.29%) SC twin children had a major congenital malformation, AOR 0.93 (95% CI, 0.88–0.99). For all ART children the total risk of any major congenital malformation was AOR 1.14 (95% CI, 1.10–1.18). The difference in risk of major malformations between children conceived after ART and SC did not change significantly during the four time periods, neither for singletons, $p = 0.46$; nor twins, $p = 0.30$. The risk of any major congenital malformation was the same for all children conceived after IVF versus ICSI, AOR 1.00 (95% CI, 0.92–1.08). This was also the case regarding the risk of urinary malformations, AOR 0.97 (95% CI, 0.71–1.33) and genital malformations, AOR 0.76 (95% CI, 0.57–1.00). When comparing children born after replacement of a fresh embryo with children born after replacement of a frozen-thawed embryo, no difference in risk of any major malformation could be detected, AOR 1.06 (95% CI, 0.95–1.19).
Limitations, reasons for caution: Many factors potentially affect the development of the early embryo. Residual confounding by parental factors is possible and the Nordic ART population has changed over time. Although no clear differences in risk of any major malformation were found between specific ART procedures, a contribution from treatment factors cannot be excluded.
Wider implications of the findings: Since the incidence of major congenital malformations remained stable over time, this may indicate that an increased risk for ART children persists in spite developments in both clinical programs and laboratory techniques over time. Still, the total risk of congenital malformations in ART children remains slightly elevated.
Trial registration number: 0.

O-249 The influence of specific infertility treatments on long-term cognitive abilities in children: a systematic review

V. Moore[1], A. Rumbold[2], M. Whitrow[2], T. Oswald[2], L. Moran[3], R. Fernandez[2], M. Davies[2]
[1]*University of Adelaide, Public Health, Adelaide, SA, Australia*
[2]*University of Adelaide, The Robinson Research Institute, Adelaide, SA, Australia*
[3]*Monash University, Health Sciences, Melbourne, VIC, Australia*

Study question: Are children conceived with infertility treatment at increased risk of impaired cognitive development in the long-term, and does the type of treatment alter the risk?
Summary answer: Although a substantial literature on longer-term cognitive outcomes exists, most studies have methodological limitations. Population-based studies are required to clarify the impact of specific treatments.
What is known already: There have been longstanding concerns about the extent to which infertility treatment alters programming of early development, and whether this has enduring consequences for children's cognitive function. Previous reviews of this literature have generally concluded that overall, cognitive outcomes are "comparable" between children conceived with infertility treatment and those conceived naturally. However, in the existing reviews there has been varying assessment of the quality of available studies. In addition, none have separately reviewed the range of components involved in infertility treatment, to determine whether specific aspects (mode of conception, cryopreservation, donor gametes etc.) have different effects on neurodevelopment.
Study design, size, duration: We undertook a systematic review of studies published in English before 5th January 2016. Studies were eligible if they assessed cognitive development from age 5 years or more, among children conceived with infertility treatment compared with either children conceived naturally or children born from a different type of infertility treatment. A meta-analysis was not performed as the included studies used a wide range of cognitive assessments.
Participants/materials, setting, methods: We searched the databases PubMed, PsycINFO, and ERIC, as well as the reference lists of included studies. Two authors independently reviewed papers for eligibility, extracted data and assessed study quality. Where available, data were extracted and reported separately according to the mode of conception, exposure to cryopreservation, use of donor gametes, and the type of comparison group used. Risk of bias was assessed using the Newcastle–Ottowa Scale, with a score ≥7/9 indicative of high quality.
Main results and the role of chance: Of 845 publications identified, 33 were eligible. Seven studies were high quality. Among moderate/poor quality studies the main limitation was selection bias, resulting from exclusion of children at increased risk of intellectual impairment (23 studies) or use of discrete clinic populations (26 studies). Among high quality studies, there were no differences in cognitive abilities between IVF children compared with natural conceptions (Table 1). In contrast, findings among ICSI children were inconsistent. Studies assessing exposure to cryopreservation were scant.

Table 1. Number of included studies and findings of high quality studies.

Comparison	No. of studies (No. high quality)	Findings of high quality studies
Any treatment vs. NC	27 (7)	4 studies: ↑ risk of cognitive impairment in treated group; 3 studies: #
IVF vs. NC	11 (3)	#
ICSI vs. NC	13 (3)	1 study: ↓ IQ among ICSI children; 2 studies: #
Cryopreservation vs. NC	1 (1)	#
OI alone vs. NC	2 (1)	↑ risk of mental disorders with OI

Comparison	No. of studies (No. high quality)	Findings of high quality studies
Donor gametes vs. NC	3 (1)	#
IVF vs. ICSI	9 (3)	2 studies: ↓ IQ among ICSI children; 1 study: #
IVF/ICSI vs. NC in subfertile couples	8 (1)	#

NC, natural conceptions; #, no difference.

Limitations, reasons for caution: We undertook a systematic search across a range of databases to identify relevant studies, and two authors independently made decisions about study eligibility as well as study quality. Nevertheless, it is possible that relevant studies may have been missed.
Wider implications of the findings: There are gaps in knowledge about the longer-term impact of certain aspects of treatment including ICSI and cryopreservation. Further studies are indicated, that include the complete group of children exposed to treatment, and utilise appropriate comparison groups to discern the effects of treatment and parental health characteristics.
Trial registration number: Not applicable.

O-250 Long-term prognosis of live birth after ART, intrauterine insemination and spontaneous conceptions in women initiating treatment with homologous gametes – a Danish national cohort study

S. Malchau[1], A. Loft[2], A.A. Henningsen[2], A. Nyboe Andersen[2], A. Pinborg[1]
[1]*Copenhagen University Hospital Hvidovre, Obstetrics and Gynecology, Hvidovre, Denmark*
[2]*Copenhagen University Hospital Rigshospitalet, Fertility Clinic, Copenhagen, Denmark*

Study question: What is the prognosis of live birth 2, 3 and 5 years after first treatment, and how many deliver after assisted reproductive technology (ART), intrauterine insemination (IUI) and spontaneous conception?
Summary answer: Overall, 71% of the women had a live birth within 5 years from the first treatment, of which 57% conceived after treatment and 14% conceived spontaneously.
What is known already: Cumulative birthrates have been reported as birthrates after a number of complete ART-cycles, where one cycle refers to all fresh and frozen-thawed transfers, generated from one oocyte pick-up. Although reflecting the efficiency of ART, it may not be the optimal measure when advising couples, since the time-frame of one cycle can vary considerably. Couples may shift between ART and intrauterine insemination, but few studies include IUI-treatments. Choice of statistical method influences the estimated birthrates substantially. Survival analyses assume that subjects who discontinue treatment have the same prognosis as subjects who continue, whereas conservative rates reflect the proportion who actually delivers.
Study design, size, duration: This cohort study includes all women initiating fertility treatments with homologous gametes in public and private clinics in Denmark 1997–2010, $N = 19\,884$. Subjects were identified in the Danish ART Registry and treatment-cycles were cross-linked with the Medical Birth Registry to identify live birth after treatment and spontaneous conception. Subjects were followed 2, 3 and 5 years or until the first live birth. Women were censored after the first live birth and if they shifted to donor semen.
Participants/materials, setting, methods: Cumulative live birthrates were calculated as the number of women with at least one live birth 2, 3 and 5 years after the first ART or IUI-cycle, divided by the total number of women entering treatment, including also spontaneous conceptions (SC). Birthrates were subdivided according to mode of conception (ART/IUI/SC), and stratified according to type of first treatment (ART/IUI). Birthrates were also stratified according to female age at time of first treatment.
Main results and the role of chance: Complete 2, 3 and 5 years follow-up was available for 19,884 women, 14,445 women and 5165 women, respectively. The total live birthrates 2, 3 and 5 years after treatment were: 57.0% (95% CI 56.3–57.7), 65.0% (95% CI 64.2–65.8) and 71.0% (95% CI 69.8–72.2).

In women where ART was the first treatment, 46.1% (95% CI 45.0–47.2), 51.1% (95% CI 49.8–52.4) and 52.9% (95% CI 50.8–55.0) delivered after ART-conception within 2, 3, and 5 years. In this group, the birthrates for spontaneous and IUI-conceptions after 5 years were 11.2% (95% CI 9.9–12.5) and 0.6% (95% CI 0.3–0.9), respectively.

When the first treatment was IUI, 34.2% (95% CI 33.4–35.0) delivered after IUI-conceptions within 2 years, and the birthrate did not increase significantly after 3 and 5 years. Shift to ART-treatment resulted in birthrates for ART-conceptions of 15.1% (95% CI 14.5–15.7), 21.1% (95% CI 20.3–22.0) and 23.7% (95% CI 22.2–25.2), after 2, 3, and 5 years respectively. After 5 years, 16.6% (95% CI 15.3–17.9) of women starting treatments with IUI had delivered after spontaneous conception.

Age-stratified analysis at 5 years follow-up in women <35 years, 35–40 years and ≥40 years: the total birthrates were 80.0% (95% CI 78.9–81.1), 60.5% (95% CI 59.2–61.8) and 26.2% (95% CI 25.0–27.4), respectively.
Limitations, reasons for caution: The national ART register is compulsory and clinics should report all initiated treatment-cycles, but underreporting of cycles not resulting in a pregnancy may occur. Since the register is cycle-based and most women have repeated treatments, it is less likely that we have underestimated the number of women with no birth.
Wider implications of the findings: Based on these results, we are now able to provide couples with a comprehensible, age stratified long-term prognosis at start of treatment. Birthrates after IUI did not increase after 2 years, which reflect the Danish treatment strategy: 3–6 cycles of IUI followed by ART.
Trial registration number: The study was approved by the Danish Data Protection Agency (J. nr. 2012-41-1330).

O-251 Perinatal outcomes following preimplantation genetic diagnosis versus IVF or ICSI: analysis of 99,498 singleton live births

S.K. Sunkara[1], M.S. Kamat[2], B. Antonisamy[3]
[1]*Barking Havering Redbridge University Hospitals, Reproductive Medicine Unit, Essex, UK*
[2]*Chistian Medical College, Reproductive Medicine Unit, Vellore, India*
[3]*Christian Medical College, Department of Biostatistics, Vellore, India*

Study question: Does embryo biopsy for preimplantation genetic diagnosis (PGD) affect perinatal outcomes such as preterm birth (PTB) and low birth weight (LBW).
Summary answer**:** There was no increased risk of PTB, early PTB, LBW and very LBW following PGD suggesting that embryo biopsy did not influence these perinatal outcomes.
What is known already: Pregnancies resulting from assisted reproductive treatments (ART) are associated with a higher risk of pregnancy complications compared to spontaneously conceived pregnancies. The possible reason of adverse obstetric outcomes following ART has been attributed to the underlying infertility itself and embryo specific epigenetic modifications due to the *in vitro* fertilisation techniques. It is of interest whether interventions such as embryo biopsy as performed in PGD affects perinatal outcomes.
Study design, size, duration: Anonymous data were obtained from the Human Fertilization and Embryology Authority (HFEA), the statutory regulator of assisted reproduction treatment (ART) in the UK. The HFEA has collected data prospectively on all ART performed in the UK since 1991. Data from 1991 to 2011 involving a total of 99,498 singleton live births (452 following PGD cycles and 99,046 following stimulated fresh IVF ± ICSI cycles) were analysed.
Participants/materials, setting, methods: Data on all women undergoing stimulated fresh IVF ± ICSI or PGD treatment were analysed to compare PTB, early PTB, LBW and very LBW. Occurrence of a live birth at <37 weeks gestation is defined as PTB and <32 weeks gestation as early PTB. Birth weight <2500 g is defined as LBW and <1500 g as very LBW. Logistic regression analysis was performed adjusting for female age, previous IVF cycles, infertility diagnosis, oocyte number, IVF or ICSI.
Main results and the role of chance: The unadjusted odds were OR 0.66, 95% CI 0.46–0.97 for PTB, OR 0.58, 95% CI 0.24–1.40 for early PTB, OR 0.58, 95% CI 0.38–0.86 for LBW and OR 0.61, 95% CI 0.25–1.48 very LBW. After adjusting for potential confounders such as female age, previous IVF cycles, diagnosis of infertility, number of oocytes retrieved and IVF or ICSI, there was no significant increase in the risk of adverse perinatal outcomes following PGD: PTB [adjusted odds ratio (a OR) 0.70, 95% CI 0.48–1.03], early PTB (a OR 0.52, 95% CI 0.19–1.38), LBW (a OR 0.59, 95% CI 0.44–1.05) and very LBW (a OR 0.51, 95% CI 0.91–1.39).
Limitations, reasons for caution: Although the analysis was adjusted for a number of important confounders, the dataset had no information on confounders such as smoking, body mass index and medical history of women during pregnancy to allow adjustment. It should also be noted that majority of PGD cycles in the dataset involved blastomere biopsy.

Wider implications of the findings: Analysis of this large dataset of singletons following PGD and IVF ± ICSI suggests that there is no increased risk of adverse perinatal outcomes following PGD. Embryo biopsy for PGD did not introduce extra perinatal risks. This information is useful for counselling patients.
Trial registration number: Not applicable.

O-252 Follow-up of children born after new technologies: testicular sperm extraction (TESE), *in vitro* maturation (IVM), and artificial oocyte activation (AOA)

Y. Nakajo[1], S. Shibasaki[1], N. Matsukawa[1], N. Aono[1], M. Toya[1], M. Doshida[1], T. Hashimoto[1], K. Kyono[1]
[1]*Kyono ART Clinic, Department of Obstetrics and Gynecology, Sendai, Japan*

Study question: We evaluated the outcome of infants using relatively new technologies –TESE, IVM, and artificial oocyte activation (AOA) – compared with those achieved with conventional IVF.
Summary answer: There were no significant differences between conventional IVF (C-IVF), ejaculated sperm ICSI (ej-ICSI) and advanced technology such as TESE, IVM and AOA.
What is known already: Assisted reproductive technology (ART) has been performed widely and its treatment methods have become complex. In order to verify the safety of new technology, an ongoing follow-up of children is needed.

Some reports have been published about the safety of IVF, ICSI and frozen embryo transfer. However, there are few reports about advanced technologies.
Study design, size, duration: The subjects were 2977 children who were born after fresh or frozen embryo transfer, from October 1995 to October 2014. The subjects were separated into 5 groups: Group 1, conventional IVF; Group 2, ej-ICSI; Group 3, TESE; Group 4, IVM; and Group 5, AOA (using Ca ionophore or $SrCl_2$).
Participants/materials, setting, methods: Among 2977 children [Group 1 (587 singletons, 108 twins, 18 triplets), Group 2 (1614 singletons, 302 twins, 30 triplets), Group 3 (178 singletons, 46 twins), Group 4 (26 singletons, 6 twins), and Group 5 (51 singletons, 8 twins, 3 triplets)], we evaluated perinatal outcomes and their development.
Main results and the role of chance: From Groups 1–5, premature birth rates of singletons were 7.8, 7.0, 4.5, 13.7 and 24.0%. Low birth weight rates of singletons were 10.8, 10.7, 8.5, 11.8 and 12.0%. Abnormality rates were 3.6, 3.8, 1.8, 3.2 and 3.1%, respectively. There were no significant differences between standard IVF and the other groups for perinatal outcomes. In each group, the most commonly recognized congenital abnormality was inguinal hernia due to low birth weight, and the majority of children have recovered naturally. Chromosomal abnormalities – 13 (1, 0), 18 (2, 0) and 21 (5, 1) trisomy were observed in group 2 and group 5, respectively.

Moreover, there were no significant differences in physical or cognitive development up to the age of 6, including weight and height, between standard IVF and the other groups.
Limitations, reasons for caution: None.
Wider implications of the findings: We concluded that advanced technology such as TESE, IVM, and AOA does not increase perinatal risk or affect the growth of children. However, we need to continue long-term follow-up to evaluate more cases.
Trial registration number: None.

O-253 Cumulative live birth rate and perinatal outcomes comparing women with freeze-all embryo transfers and women with fresh and subsequent frozen embryo transfers

Y.A. Wang[1], Z. Li[1], L. Johnson[2], K. Hammarberg[2], M. Bowman[3], C. Farquhar[4], N. Safi[1], E. Sullivan[1]
[1]*University of Technology Sydney, Faculty of Health, Ultimo, NSW, Australia*
[2]*Victorian Assisted Reproductive Treatment Authority, Melbourne, VIC, Australia*
[3]*Genea, Sydney, NSW, Australia*
[4]*University of Auckland, Department of Obstetrics and Gynaecology and National Women's Health, Auckland, New Zealand*

Study question: Are cumulative treatment outcomes better for women who have all embryos frozen before transfer than for women with both fresh and frozen embryo transfers?
Summary answer: Treatment outcomes are similar for women who have all embryos frozen before transfer and those who have both fresh and frozen embryos transfers.
What is known already: Cycle-based assisted reproductive technology (ART) data consistently report that fresh embryo transfers have a higher live birth rate than frozen/thawed embryo transfers. This may be explained by the selective transfer of good embryos in the fresh cycles. However, births following frozen embryo transfers have better perinatal outcomes than those following fresh embryo transfers. It is unknown whether freezing all embryos adversely affects the cumulative live birth rate.
Study design, size, duration: A population-based retrospective cohort study used ART data collected by the Victorian Assisted Reproductive Treatment Authority (VARTA). This study included 10,553 women undergoing their first autologous oocyte pick-up during 1 July 2009 and 30 June 2013 in Victoria Australia. Treatment and pregnancy/birth outcomes were recorded from the start of the first oocyte pick-up through associated thaw cycles until 30 June 2014, or until all embryos used or a live birth achieved.
Participants/materials, setting, methods: Women who had all embryos frozen and subsequently transferred (freeze-all group, $n = 701$) and those with fresh and frozen embryo transfers (fresh group, $n = 9852$) were identified. Groups' treatment characteristics, cumulative live birth rate and rates of adverse perinatal outcomes (preterm birth, low birth weight) were compared. Life-table method was used to calculate the cumulative live birth rate per number of transfer cycles. A generalised estimating equation model was used to assess each adverse perinatal outcome.
Main results and the role of chance: The mean age of women was lower (33.4 years) in the freeze-all than in the fresh group (34.9 years) ($p < 0.01$). About 60% of women in the freeze-all group had >15 oocytes collected compared with 18.5% in the fresh group ($p < 0.01$). In the freeze-all group, 576 women returned for an embryo transfer. The live birth rate following the first transfer was 23.0% in the freeze-all and 25.2% in the fresh group (NS). After six transfers, the cumulative live birth rate was (40.1%) in the freeze-all group, not different from the fresh group (38.2%) ($p = 0.24$). Of singletons born after the first transfer, 7.1% were born preterm in the freeze-all and 8.9% in the fresh group ($p = 0.30$). The low birth weight rate was 5.2% in the freeze-all and 7.0% in the fresh group ($p = 0.28$). For women with ≤15 oocytes collected, the cumulative live birth rate was 22.2% in the freeze-all and 34.3% in the fresh group ($p = 0.55$). For women with >15 oocytes collected, the cumulative live birth rate was 53.0% in freeze-all and 55.6% in fresh group ($p = 0.90$). After adjusting for the number of oocytes collected there were no statistically significant group differences in cumulative live birth or adverse perinatal outcome rates.
Limitations, reasons for caution: Potential confounders such as stimulation protocol and culture media are not collected in the dataset and may have affected the findings of this study. Selection bias is likely given the baseline differences between the two groups. Data was not collected on reason for the initial transfer plan.
Wider implications of the findings: This study suggests that frozen only transfers are not adversely affected which is reassuring for those women who have clinical indications not to have a fresh transfer. A randomized control trial is required to avoid the likely selection bias in this study.
Trial registration number: N/A.

[3]University of Oulu, Center for Life Course Health Research, Oulu, Finland
[4]Helsinki University Hospital and University of Helsinki, Department of Obstetrics and Gynaecology, Helsinki, Finland
[5]Finnish Institute, Occupational Health, Oulu, Finland

Study question: Is the history of endometriosis associated with an altered pain sensation and musculoskeletal (MS) pain symptoms at premenopausal age?
Summary answer: Women with history of endometriosis had lower pain threshold, lower maximum pain tolerance and a higher likelihood of MS pain symptoms at late premenopausal age.
What is known already: Thirty percent of women with endometriosis experience chronic pelvic pain (CPP) and up to 75% of adolescent girls with CPP or dysmenorrhea have laparoscopic evidence of endometriosis. Previous studies have shown increased pain sensitivity in fertile aged women with endometriosis in response to mechanical stimuli compared to non-affected women. Furthermore, pain threshold studies have observed hyperalgesia at extra-pelvic sites in young women with endometriosis. Up to date, population-based studies investigating the association of endometriosis with pain sensation and pain symptoms are lacking.
Study design, size, duration: In a prospective follow-up of a large national birth cohort, a postal questionnaire including questions on previously diagnosed endometriosis, number of pain areas and pain intensity was sent to 5080 women (72% response rate) at 46 years. Of all women, 284 reported having endometriosis whereas others (n = 3390) were defined as controls. A total of 2704 women also participated in a clinical examination assessing pressure pain threshold (PPT) and maximal pain tolerance (PPTo).
Participants/materials, setting, methods: 282 women with endometriosis and 3057 controls answered questions on MS pain, while pain sensitivity measurements were conducted for 234 endometriosis cases and 2470 controls. PPT/PPTo were measured in four sites (shoulder, tibialis anterior muscle, wrist joint, L5/S1 interspinous space) using an algometer (Somedic, Sweden). The association between endometriosis and PPT/PPTo (mean of four sites) was estimated using regression analysis. The results were adjusted for BMI, smoking, depressive/anxiety symptoms, education and use of hormonal contraceptives.
Main results and the role of chance: Women with endometriosis reported more pain sites than the controls: 0 areas for 9.6% of women with endometriosis vs. 17.9% of controls; 1–4 areas for 16.4 vs. 15.8%; 5–8 areas for 6.2 vs. 4.8%, $p < 0.001$. Furthermore, endometriosis was associated more often with disturbing pain at leisure time, during sleep and at work ($p = 0.02$, $p = 0.04$, $p = 0.01$, respectively). The women with endometriosis also reported higher pain intensity compared with controls ($p = 0.02$).

Pain sensitivity assessments showed that women with history of endometriosis had lower PPT (−34.0 kPa, $p < 0.05$) and PPTo (−48.2 kPa, $p < 0.01$) than the controls. Inclusion of all confounding factors in the analyses did not change significantly the strength of associations.
Limitations, reasons for caution: The diagnoses of endometriosis were self-reported. However, 37.7% of cases were available for validation using hospital patient records. The hospital register data confirmed endometriosis diagnosis for 76.3% of self-reported cases and of them 90.1% were diagnosed with laparoscopy.
Wider implications of the findings: This unique population-based data showed a higher likelihood of MS pain and altered pain sensation in women with endometriosis at 46 years. This implies that endometriosis has long lasting consequence on a woman's life as the women may be more prone to MS pain symptoms beyond fertile age.
Trial registration number: –

O-255 Laparoscopic excision versus ablation for endometriosis-associated pain – a systematic review and meta-analysis

J. Pundir[1], E. Kovoor[2], K. Omanwa[3], V. Pundir[4], P. Barton Smith[5]
[1]St Bartholomew's Hospital, West Smithfield, Centre for Reproductive Medicine, London, UK
[2]Maidstone and Tunbridge Wells NHS Trust, Obstetrics and Gynaecology, Tunbridge Wells, UK
[3]University of Nairobi, Obstetrics and Gynaecology, Nairobi, Kenya
[4]Maidstone and Tunbridge Wells NHS Trust, Otolaryngology, Tunbridge Wells, UK
[5]Singapore Hospital, Obstetrics and Gynaecology, Singapore

Study question: To systematically review and summarize all existing evidence related to the impact on endometriosis-associated pelvic pain when treated by laparoscopic excision or laparoscopic ablation/vaporisation.
Summary answer: Laparoscopic excision is associated with significantly better reduction in symptoms of dysmenorrhea, dyschezia and chronic pelvic pain compared with laparoscopic ablation/vaporisation in endometriosis.
What is known already: The evaluation and treatment of endometriosis has evolved in recent decades. It is recommended where possible to see and treat the lesions as there is evidence that their removal reduces endometriosis associated pelvic pain and improves spontaneous fertility. A recent Cochrane review concluded that there was low quality evidence that laparoscopic excision and ablation were similarly effective in relieving pain. However this review included only one trial. This study sought to systematically re-review and summarize all existing evidence related to the impact of laparoscopic excision on endometriosis-associated pelvic pain compared with laparoscopic ablation to update and further guide clinical practice.
Study design, size, duration: We searched MEDLINE (1950 to October 2014), EMBASE (1980 to October 2014), ISI conference proceedings, databases for registration of ongoing and archived RCTs, namely International Standard Randomised Controlled Trial Number (ISRCTN), Register and Meta-register for RCTs (http://www.controlled-trials.com), WHO trials search portal (ICTRP, apps.who.int/trialsearch/Trial); the Cochrane Library and the British Library of electronic theses online service (http://ethos.bl.uk) with the search term of "endometriosis." No language restriction was placed. Only RCTs were included.
Participants/materials, setting, methods: Studies were selected if the target population were women undergoing laparoscopic surgery for endometriosis with excision technique and were compared with women with an ablative/vaporisation technique. The primary outcome measure was reduction in dysmenorrhea (the most common pain symptom in endometriosis). Secondary outcomes were reduction in symptoms such as dyspareunia, chronic pelvic pain, dyschazia by VAS and improvement in QOL scores. Statistical analyses were performed using RevMan 5.2.7 software (Cochrane Collaboration, Oxford, UK) and StatsDirect.
Main results and the role of chance: Three RCTs included in this review with 222 participants. 114 women were randomised to treatment with excision and 108 women to ablation. Pooling of the results of these showed that the excision group had significantly more reduction in symptoms of dysmenorrhea (MD 0.99; 95% CI 0.00, 1.98; $p = 0.05$) and dyschezia (MD 1.31; 95% CI 0.33, 2.29; $p = 0.009$) as compared to those with ablation/vaporisation. There was no significant difference in reduction in VAS score for dyspareunia between the two groups (MD 0.96; 95% CI 0.07, 1.99; $p = 0.07$) even though there was a trend towards more reduction with the excision. Only one study reported on reduction in EHP30 Core pain score and reduction in VAS score for chronic pelvic pain and showed that the excision group had significantly more reduction in EHP30 Core pain scores (MD 13.20; 95% CI 3.70, 22.70; $p = 0.006$) and VAS score for chronic pelvic pain (MD 2.57; 95% CI 1.27, 3.87; $p = 0.0001$) compared with ablation/vaporisation. One study reported on reduction in pelvic pain and showed that there was no significant difference in the excision and ablation groups (MD – 0.10; 95% CI 1.30, 1.10; $p = 0.87$).
Limitations, reasons for caution: This systematic review found only 3 RCTs with overall population of only 222 women. The data could be pooled from only 2 RCTs for the meta-analysis. Some of the outcomes were reported only in one study, such as chronic pelvic pain which was clearly defined in only one study.
Wider implications of the findings: From the limited evidence available, Laparoscopic excision is associated with significantly better reduction in symptoms of dysmenorrhea, dyschezia and chronic pelvic pain compared to laparoscopic ablation in cases of endometriosis. Further larger trials are necessary to substantiate these results.
Trial registration number: None required.

O-256 Women with endometriosis do not have an increased miscarriage rate but suffer significantly more from endometriosis associated infertility

A.S. Kohl Schwartz[1,2], M.M. Wölfler[3], B. Alvera[2], K. Stojanow[4], F. Häberlin[5], K. Geraedts[2], M. von Wolff[1], P. Imesch[6], D. Fink[6], B. Leeners[2]

[2]*University Hospital of Zürich, Department of Reproductive Endocrinology, Zürich, Switzerland*
[3]*University Hospital Graz, Department of Obstetrics and Gynecology, Graz, Austria*
[4]*Universityhospital Berlin Charité, Clinic for Psychosomatic Medicine, Berlin, Germany*
[5]*Institute FIORE, Cantonal Hospital, St. Gallen, Switzerland*
[6]*University Hospital of Zürich, Department of Gynecology, Zürich, Switzerland*

Study question: Is the abortion rate in endometriosis women increased?
Summary answer: The abortion rate is not increased but the psychological distress following miscarriage is higher.
What is known already: Endometriosis is a chronic disease occurring in up to 10% of women during reproductive age. Compared to women without endometriosis the number of childbirths is reduced but can be augmented by artificial reproductive therapy (ART). Ovarian response and oocyte quality are discussed to be diminished in women with endometriosis but once implantation is achieved, the risk of miscarriage is not likely to be increased – current literature does not provide enough evidence for an association between endometriosis and miscarriages.
Study design, size, duration: Retrospective case control observational study. Data from 505 women with surgically/histologically confirmed endometriosis (WwE) and 505 control women (CW) matched for age were analysed. Women were recruited in eight Swiss and German hospitals between 2010 and 2015.
Participants/materials, setting, methods: Gynecologic and obstetric history, questions on quality of life, psychological wellbeing and socio-demographic data were collected using a self-administered questionnaire consisting of several validated questionnaires such as the Brief Pain Inventory, Perceived Stress Questionnaire 20, etc.
Main results and the role of chance: Data on miscarriages were provided by 954 women. There was no significant difference in the number of miscarriages between WwE (n = 74/of 470) and CW (n = 82/of 484). The distribution of the number miscarriages was similar in both groups: WwE: 54 with one, 13 with two, 7 with three and more miscarriages; CW: 57 with one, 18 with two and 7 with three and more miscarriages. In both groups the incidences of miscarriages increased with higher age. Staging for endometriosis was performed in 467/505 WwE. The number of women with miscarriages per WwE was not associated with the stage of the endometriosis: ASRM I: 18/87 (26%), II: 18/97 (18.5%), III: 20/132 (15.1%), IV: 17/151 11.2% (p = 0.21). The frequency of miscarriages was not correlated with specific localisations, such as ovarian (p = 0.218) or peritoneal (p = 0.094) endometriosis.

In contrast, among those women who wished to have a child, more women were childless in the group of WwE (52.5%) than in the CW group (13.1%) (p < 0.001).

WwE reported significantly higher emotional distress associated with undesired childlessness and reproductive therapy than CW (p = 0.001). They reported significantly more often feelings of inferiority (p = 0.005) but not feelings of depression (p = 0.17).
Limitations, reasons for caution: It was a retrospective, descriptive study conducted over several years at different centres. The endometriosis population, although very large, was heterogeneous for the duration of disease and the number of surgeries.
Wider implications of the findings: The abortion rate was not different in WwE, but childlessness and one-child families were significantly more frequent. As WwE experience significantly more emotional distress associated with childlessness and ART, and have more inferiority feelings than CW, they should be psychologically supported and counseled early about their reproductive potential and ART.
Trial registration number: ClinicalTrials.gov identifier: NCT02511626.

O-257 The oocyte and embryo quality are poorer in women with endometriosis compared to those without endometriosis

Y. Cheong[1,2], M. Hamdan[1,2,3], S. Ingamells[4], A. Price[4]
[1]*University of Southampton, Human Development and Health, Southampton, UK*
[2]*Complete Fertility Centre, Obstetrics and Gynaecology, Southampton, UK*
[3]*University of Malaya, Obstetrics and Gynaecology, Southampton, UK*
[4]*Wessex Fertility Southampton, Fertility, Southampton, UK*

Study question: Does endometriosis affect oocyte and embryo quality?
Summary answer: Women with endometriosis have lower number of oocyte collected per-mature follicle, unaffected fertilisation rate and higher rate of early embryo-arrest, which implicates poor oocyte quality.
What is known already: Endometriosis is known to be detrimental to fertility in many ways including poorer oocyte/embryo quality. Evidence drawn from studies on oocyte recipient cycles that showed poorer reproductive outcome in those who received oocytes from women with endometriosis, suggest that the oocyte quality of women with endometriosis is compromised. Studies that specifically examined the association between embryo quality and the presence of endometriosis or endometrioma are scarce and the question if endometriosis detrimentally impact on oocyte and/or embryo quality is still controversial.
Study design, size, duration: We performed a multi-centre retrospective evaluation of women with endometriosis undergoing IVF. We reviewed treatment cycle and embryology records via IDEAS™ database from January 2011 to December 2014. Data obtained from the database were exported to Excel (Microsoft, USA) before data analysis was performed using statistical analysis package. Comparative analysis was performed between groups and was expressed as means ± SD or percentages.
Participants/materials, setting, methods: Women who were <40 years old who underwent IVF treatment using their own gametes were included. The study group consisted of women who had endometriosis (EN) and the control group (tubal factor, TF and unexplained, UE) subfertility. Qualified and trained embryologists performed the oocytes and embryo assessment using Istanbul consensus workshop on embryo assessment by ESHRE special interest group of embryology.
Main results and the role of chance: Total of 678 women who had IVF treatment were analysed (EN, n = 89; TF, n = 214; UE, n = 375). The mean age for each group was EN, 34.4 ± 3.3; TF, 33.5 ± 3.7 and 34.6 ± 3.2 respectively. Number of mature follicles (>14 mm) on the day of trigger injection was similar (P = 0.746) between all groups. Percentage of oocytes collected per mature follicle was lower in endometriosis (EN, 65 ± 23; P = 0.008) compared to other groups (TF, 76 ± 20; UE, 71 ± 24). Fertilisation rate was similar across all groups (P = 0.758, EN, 67.5 ± 21; TF, 69.6 ± 21; UE, 69 ± 24, Higher percentages of embryos fail to achieve 8-cell stage in EN compared to TF groups [P = 0.02, MD 2.77, 95% CI (0.33, 5.21)] and UE [P = 0.03, MD 2.51, 95% CI (0.22, 4.79)]. Percentages of embryos at all grades (Grade 1–4) per women were similar between the comparison groups (P > 0.05). Endometriosis did not impair (P > 0.05) blastocyst development (P = 0.62, EN, 4.2 ± 2.5; TF, 3.8 ± 2.2; UE, 3.7 ± 2.2) or the development of Fully Expanded Hatching Blastocysts (FEHB) (P = 0.38, EN, 2.8 ± 2.1; TF, 3.0 ± 2.0; UE, 2.6 ± 1.9). The number of embryos utilised were similar among the comparison groups (P = 0.53, EN, 2.8 ± 2.1; TF, 2.9 ± 2.1; UE, 3.0 ± 2.2).
Limitations, reasons for caution: This study has following limitations: (1) restriction associated with a retrospective study, (2) subjective embryo assessment process despite using the newest assessment criteria, (3) incomplete assessment of the oocyte due to the intact cumulus cell layers required in IVF, and (4) unavailability of subgroups for the differential assessment of severity of disease.
Wider implications of the findings: The disparity between the number of collected oocytes and the number of mature follicles maybe due to the failure of oocytes to mature. The higher number of early embryo arrest at D1 suggests the presence of poor oocyte quality although further experimental studies will be required to confirm these findings.
Trial registration number: Nil.

O-258 ART outcomes in endometriosis-affected women after fresh versus frozen embryo transfer cycles: a matched cohort study

P. Santulli[1], M. Bourdon[1], V. Gayet[1], L. Marcellin[1], C. Maignien[1], V. Blanchet[1], J. Gonnot[1], C. Chapron[1]
[1]*Centre hospitalier universitaire CHU Cochin-Port Royal, Assistance publique-hopitaux de Paris AP-HP, Université Paris Descartes, Faculté de medecine, Department of Gynecology Obstetrics II and Reproductive Medecine, Paris, France*

Study question: To compare assisted-reproductive-technology (ART) outcomes between fresh versus differed frozen–thawed embryo transfer (dif-ET) in endometriosis women.
Summary answer: Frozen–thawed embryo transfer in endometriosis-affected women is associated with a significantly higher implantation rate, cumulative pregnancy rate and cumulative ongoing pregnancy rate.
What is known already: Controlled ovarian stimulation (COS) enhances the efficacy of ART by permitting multiple-oocyte yields, but also may alters endometrial receptivity by an advancement of endometrial development which could in turn contribute to diminished pregnancy chances. Recently, technical improvements in vitrification make Dif-ET a feasible alternative to fresh embryo transfer. In endometriosis-related infertility the eutopic endometrium is abnormal and its functional alterations are seen as likely to alter the quality of endometrial receptivity. One of the main questions in the endometriosis ART management is to know whether dif-ET could restore optimal receptivity in endometriosis-affected women leading to increase in pregnancy rates.
Study design, size, duration: This cohort study conducted in a tertiary care university hospital, evaluated all IVF/ICSI cycles for endometriosis infertility between 01/10/2012 and 31/12/2014. One hundred and thirty-five endometriosis women with a scheduled dif-ET cycle and 424 endometriosis women with a scheduled fresh ET cycle were eligible for matching. Diagnosis of endometriosis was based on published imaging criteria using transvaginal sonography and magnetic resonance imaging or histologically proven in women who had past surgery.
Participants/materials, setting, methods: Fresh and frozen–thawed ET were matched by age, number of previous ART cycles and endometriosis phenotypes (superficial peritoneal endometriosis, ovarian endometrioma or deeply infiltrating endometriosis). Two groups were compared: a group made up of "exposed" women (dif-ET group) who received only differed frozen–thawed embryos and an "unexposed" control group (fresh ET group), comprised of women who received fresh embryo(s) for the first transfer. Statistical analyses were conducted using univariate and multivariate logistic regression models.
Main results and the role of chance: A total of 270 women were included in the analysis: 135 in the fresh ET group and 135 in the dif-ET group. The cumulative clinical pregnancy rate was significantly increased in the dif-ET group compared to the fresh ET group [58 (43%) vs. 40 (29.6%), $p = 0.023$]. The implantation rate was 0.4 ± 0.5 in the dif-ET group and 0.2 ± 0.3 in the fresh ET group ($p < 0.001$). The cumulative ongoing pregnancy rate was 34.8% ($n = 24$) and 17.8% ($n = 24$) respectively ($p = 0.001$). After multivariate logistic regression, taking into account potential confounders as AMH level, type of protocol, total dose of injected gonadotropin (IU), type of embryo transfer, the number of oocytes retrieved and a previous history of endometrioma surgery the differed frozen–thawed embryo transfer was associated with a significant increase in cumulative ongoing pregnancy rate as compared to fresh ET (OR = 2.20, 95% CI 1.17–4.14, $p < 0.05$).
Limitations, reasons for caution: Given the significant higher rate of previous history of endometrioma surgery (and subsequent lower AMH levels) in Fresh ET group, we performed a logistic regression analyze to take into account such potential confounders. After multivariate analysis previous history of endometrioma surgery was not independently associated with IVF outcomes.
Wider implications of the findings: Our preliminary results evocate that differed frozen–thawed embryo transfer for endometriosis-affected women is an attractive option that could increase ART success rates. Future studies, with a randomized design, should be conducted to ascertain whether dif-ET enhances pregnancy rate in endometriosis-affected women.
Trial registration number: –

O-259 Serum AMH level is a misgiver in case of ovarian endometrioma

L. Marcellin[1], P. Santulli[1], C. Conté[1], G. Vanessa[1], C. Maignen[1], B. Borghese[1], D. De Ziegler[1], C. Chapron[1]
[1]*Université Paris Descartes, Sorbonne Paris Cité, Faculté de Médecine, Assistance Publique', Hôpitaux de Paris AP-HP, Hôpital Universitaire Paris Centre HUPC, Centre Hospitalier Universitaire CHU Cochin, Service de Chirurgie Gynécologie Obstétrique II et Médecine de la Reproduction, Paris, France*

Study question: Is there any correlation between serum anti-Müllerian hormone (AMH) levels and benign ovarian cyst size?
Summary answer: AMH serum levels are correlated with cyst size in case of OMA but not in case of non endometriotic cyst.
What is known already: Serum AMH level seems unrelated to the presence, dimension or nature of begin ovarian cyst but was found lower in women with bilateral benign ovarian cyst. In case of a previous history of OMA surgery, serum AMH levels are significantly reduced. Most previous studies have been conducted in infertile women and did not consider patient without past history of previous ovarian surgery. The strength of our study lies in the inclusion of women before first surgery.
Study design, size, duration: An observational, prospective, cross-sectional study of 228 non-pregnant women aged between 18 and 42 years and surgically explored for the first time for benign gynaecological disease, between January 2004 to June 2015, comparing AMH serum level according to presence and size of benign cyst. AMH levels were measured in serum samples drawn in the month preceding surgery.
Participants/materials, setting, methods: Women with available frozen serum sample for AMH dosage and without past history of gynaecological surgery were allocated in two group: women with histologically proven endometrioma (Study group, $n = 122$) and women with histologically proven benign ovarian cyst without endometriosis (Control group, $n = 106$).
Main results and the role of chance: AMH serum levels were not significantly different between the study and the control groups (4.0 ± 0.3 versus 3.9 ± 0.3 ng/ml; $p = 0.95$) although means age of women was significantly higher in the study group as compared to the control group (31.5 ± 0.4 and 29.1 ± 0.6; $p < 0.01$). (BB1) In the study group, serum AMH levels were higher in case of OMA diameter of more than 5 cm (3.4 ± 0.2 vs. 5.3 ± 0.5, $p < 0.001$). In addition we observed a significant positive correlation between the OMA diameter and AMH levels ($R^2 = 0.05$, $P = 0.009$) but not in the control group. Finally, in the study group no differences in serum AMH levels were found according to bilaterality or the existence of associated DIE lesions.
Limitations, reasons for caution: Our study population derived from a referral center for endometriosis surgery, included patients with severe forms of endometriosis requiring surgery. We cannot exclude that infertile women with OMAs associated with a diminished ovarian reserve were less likely to be referred for surgery and might therefore be underrepresented.
Wider implications of the findings: The link between AMH and OMA diameter may be responsible for an overestimation of ovarian reserve in such condition.
Trial registration number: None.

O-260 The role of environmental contaminants in the development of endometriosis: a systematic review

A. Conforti[1], C. Buonfantino[2], F. Caprio[3], P. Chiodini[4], G. Coppola[1], I. Strina[1], R. Vallone[1], S. Picarelli[1], P. De Rosa[1], G. De Placido[1], C. Alviggi[1]
[1]*Università di Napoli Federico II, Department of Neuroscience, Reproductive Science and Odontostomatology, Napoli, Italy*
[2]*Università di Napoli Federico II, Department of Neuroscience, Reproductive Science and Odontostomatology, Napoli, Italy*
[3]*Second University of Naples, Department of Woman, Child and General and Special Surgery, Naples, Italy*
[4]*Second University of Naples, Medical Statistics Unit, Naples, Italy*

Study question: What environmental contaminants could be involved in endometriosis?

Summary answer: Data suggest a relationship between endometriosis and several environmental pollutants. Specifically, organochlorines compounds represent the most suspected factors implicated in development of endometriosis.

What is known already: Based on experimental data, several pollutants have been implicated in the etiopathogenesis of endometriosis. However, more recent epidemiological studies have yielded contrasting results.

Study design, size, duration: A systematic review of the literature through electronic database was conducted without time restriction.

Participants/materials, setting, methods: Only articles and reviews on the association between endometriosis and environmental pollutants published in peer-reviewed journals were included. Exclusion criteria were: *in vitro* studies; Case reports or case series; unpublished data; studies involving animals; the use of not conservative statistic methods (e.g., Bayesian analysis). Studies with overlap between cases and controls and studies in which contaminants were not directly measured were also excluded.

Main results and the role of chance: The following articles were included in our analysis: 23 devoted to polychlorinated biphenyls (PCBs) and dioxin compounds; 10 to phthalate compounds; 5 to trace elements and heavy metals; 2 to organochlorine pesticides and bisphenols; and 1 to perfluorochemicals, particulate matter and benzophenone derivatives. Several studies indicated that dioxins and PCBs were involved in the etiopathogenesis of endometriosis. Specifically, the levels of polychlorinated dibenzo-p-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs) and PCBs (PCBs 138, 153, 180) were higher in patients with endometriosis than in control groups. There is also evidence that PCBs and dioxins play a role in the pathogenesis of deep endometriosis and adenomyosis. Results regarding the association between phthalates and endometriosis were contrasting. Regarding organochlorine pesticides, only β-hexachlorocyclohexane was associated with an increased odds of endometriosis. Only one study reported a significant association between perfluorochemicals (perfluorooctanoic acid and perfluorononanoic) and benzophenone metabolites (2,4-dihydroxybenzophenone) with endometriosis. The levels of such trace elements as copper and nickel were higher in endometriosis patients than in controls, however, a direct relation between trace elements and endometriosis has not been established. No association with bisphenols and particulate matter were reported in the few trials that addressed this issue.

Limitations, reasons for caution: Relevant differences were found among studies in terms of diagnostic method, type of pollutant analyzed, selection of controls and method adopted for the assessment of contaminates. Consequently, no definitive conclusion could be drawn regarding the association between pollutants and endometriosis.

Wider implications of the findings: Based on currently available data, an association between endometriosis and environmental pollution cannot be excluded. More prospective well-designed and less heterogeneous trials are warranted to shed light on this issue.

Trial registration number: N.A.

INVITED SESSION

SESSION 66: BASIC SCIENCE OF EARLY PREGNANCY

Wednesday 06 July 2016 **Hall 1** **12:00–13:00**

O-261 Molecular regulation of implantation

J. Aplin[1], P. Ruane[1], S. Berneau[1], P. Babbington[2], S. Kimber[3], M. Westwood[1], D. Brison[2]

[1]*University of Manchester, Maternal and Fetal Health, Manchester, UK*

[2]*Central Manchester Foundation Health Trust, Reproductive Medicine, Manchester, UK*

[3]*University of Manchester, Faculty of Life Sciences, Manchester, UK*

Implantation failure remains a major problem after embryo replacement, and experimental approaches to discover molecular mechanisms are required so that potential therapeutic approaches can be tested. We transferred blastocysts developing from 84 human fresh or frozen embryos to a constitutively receptive epithelial (Ishikawa) cell monolayer. Chemical hatching of blastocysts was adopted in the course of the experimental series in order to minimise variation in attachment kinetics. We observed stable attachment of all hatched embryos, progressing in some cases to breaching of the epithelium. Evidence of limited local apoptosis of epithelial cells was gained by expression of activated caspase 3 and nuclear fragmentation. Blastocoel collapse was usually observed. After 48 h of coculture (day 8), trophoblast differentiation had already begun and breaching of the epithelium was observed at multiple independent sites, with primary syncytium always involved. CDX2 and GATA3 were expressed by distinct subpopulations of cytotrophoblast, respectively proximal and distal to the blastocoel cavity. As expected, expression of HLAG and CG was initiated. Osteopontin, an epithelial secretory glycoprotein with pro-adhesive properties, and its receptors CD44 and integrin αvβ3, were all present at the human attachment sites.

Hatched mouse blastocysts also attach to the human epithelial monolayers, but require activation in order to progress to displacement and invasion. Though we have evidence that endogenous osteopontin and its receptors are involved in attachment, addition of exogenous recombinant human osteopontin did not advance implantation extent or speed.

Data obtained with both species of embryo suggest that the interaction between trophoblast and endometrial epithelium initiates differentiation of trophoblast, including stimulating the formation of multiple foci of primary syncytium and differentiated mononuclear cytotrophoblasts. Thus the early interaction with epithelium may have important influences on later stages of the implantation cascade.

O-262 H-Y immunity in early pregnancy

H. Svarre Nielsen[1]

[1]*Copenhagen University Hospital Rigshospitalet, The Fertility Clinic and Recurrent Pregnancy Loss Unit, Copenhagenà, Denmark*

Background: Approximately half recurrent pregnancy loss (RPL) cases remain unexplained after standard investigations. Secondary RPL (SRPL) is, in contrast to primary RPL, preceded by a birth, which increases the transfer of fetal cells into the maternal circulation. In previous RCT of immune therapy for SRPL we noted that eligible SRPL women more frequently had given birth to boys prior to the pregnancy losses than a girl. Mothers of boys are often immunized against male-specific minor histocompatibility (H-Y) antigens. H-Y immunity can cause graft-versus-host disease after stem-cell transplantation. We proposed the *H-Y hypothesis* that aberrant H-Y immunity is a causal factor for SRPL.

Methods: Epidemiological, immunogenetic and immunological studies in a 20 year cohort of unexplained SRPL (n = 358 women). Population and registry based epidemiological studies on the impact of previously born boys on subsequent obstetric outcomes.

Results: SRPL is more common after the birth of a boy and the subsequent live birth rate is reduced for SRPL patients with a firstborn boy. The male:female ratio of children born prior and subsequent to SRPL is 1.49 and 0.76 respectively. Maternal carriage of HLA-class II alleles presenting H-Y antigens to immune cells is associated with a reduced live birth rate and increased risk of obstetric complications in surviving pregnancies in SRPL patients with a firstborn boy. In early pregnancy, both antibodies against HLA and H-Y antigens are increased in SRPL patients compared with controls. Presence of these antibodies in early pregnancy is associated with a lower live birth rate and a low male:female ratio in subsequent live births, respectively. Births of boys are also associated with preeclampsia/eclampsia, placental abruption, stillbirth and preterm birth in subsequent births in the background population.

Conclusions: Epidemiological, immunogenetic and immunological studies support the hypothesis that aberrant maternal H-Y immune responses have a pathogenic role in SRPL.

INVITED SESSION

SESSION 67: ASRM/SOCIETY FOR REPRODUCTIVE ENDOCRINOLOGY AND INFERTILITY: PRIMARY OVARIAN INSUFFICIENCY: THE PROBLEM AND POSSIBLE SOLUTIONS

Wednesday 06 July 2016 **Hall 5 CB** **12:00–13:00**

O-263 The new science of folliculogenesis and follicle depletion: fact and fiction

J. Segars[1]
[1]*Johns Hopkins University School of Medicine, Gynecology and Obstetrics, Baltimore, MD, USA*

Oogenesis in women is inextricably linked and dependent upon proper folliculogenesis. Following migration of primary germ cells to the gonadal ridge and expansion of the germ cells, primordial follicles are formed with investment of oocytes by surrounding cells. Later in development these cells will nurture and support oocyte maturation. The primordial follicles may remain dormant for decades before resuming growth and development, but the brake holding the follicles in check is enigmatic and may be considered an unknown "X" factor. Knowledge of the processes involved in maintenance of follicle quiescence is crucial to an understanding ovarian aging and premature ovarian aging (diminished ovarian reserve) and has relevance to fertility preservation. Genetic and epigenetic approaches have emphasized the importance of telomere length and some key genes for oocyte maintenance; but although important, genetic mechanisms do not fully explain follicular quiescence. While the mechanisms that maintain follicle and oocyte quiescence remain incompletely defined, recent research has provided insight into some key signaling pathways involved. Still, much remains unknown and considerable confusion remains. For instance, conflicting reports exist regarding ovarian stem cells and the derivation of eggs from ovarian stem cells. Additionally, key questions remain unanswered, such as: what processes are critical to the storage of an oocyte for decades? Increasingly, work in several laboratories throughout the world have pointed to the crucial role of biomechanical signaling and mechanotransduction in oocyte maturation and folliculogenesis. Collectively, pioneering work in the laboratories of Drs. Evans, Woodruff, Hsueh, Conti, He and Kawamura have provided exciting insight into oocyte and follicle maturation. Importantly, these recent reports in murine and human species have suggested that mechanical signaling may be exploited to activate dormant follicles. Moreover, and taken together, the reports suggest that mechanical signaling itself may represent a key component to the "X" factor involved in maintenance of follicle quiescence. This presentation will examine the recent research on oogenesis and folliculogenesis in women. The objective is to answer key questions, to summarize recent developments with a focus on mechanical signaling, and to suggest new directions for future research.

O-264 Fertility treatment for women with POI-where are we are and where are we going?

V. Baker[1]
[1]*Stanford University, Obstetrics and Gynecology, REI Division, Stanford, CA, USA*

The rate of natural conception after a diagnosis of Primary Ovarian Insufficiency (POI) is commonly quoted to be in the range of 5–10%. However, this rate may be an overestimate, particularly for women with an advanced stage of POI presenting at an older age than in the past. With early diagnosis of diminishing ovarian reserve, natural conception or cryopreservation of oocytes may be possible. Oocyte cryopreservation is now commonly offered to women about to undergo gonadotoxic therapy. Early identification and appropriate counseling are needed to maximize the chance that a woman at risk of POI will be able to conceive with autologous oocytes.

Intermittent ovarian follicular development may occur with POI, but follicles may by dysfunctional and contain atretic oocytes. Ovulation induction for women with POI has been attempted with strategies such as administration of corticosteroids or suppression of endogenous gonadotropin (with gonadotropin releasing hormone agonist or estrogen and/or progestin) followed by ovarian stimulation with exogenous gonadotropin. It has been suggested that normalization of the elevated serum luteinizing hormone level common with POI could potentially prevent luteinization of ovarian follicles, and thereby improve follicle function. Conception is possible for some women with POI, even with undetectable anti-Müllerian hormone levels. However, for women with POI diagnosed at an advanced stage, oocyte or embryo donation are the only evidence-based treatments. *In vitro* maturation of primordial follicles as well as creation of induced pluripotent stem cells (iPSCs) are options being explored. Live births have been reported with an experimental treatment, *in vitro* activation, which may prove to be helpful for some women with POI.

SELECTED ORAL COMMUNICATIONS

SESSION 68: EMBRYO DEVELOPMENT AND NON-INVASIVE ASSESSMENT

Wednesday 06 July 2016 **Hall 1** **14:00–15:15**

O-265 Follicular fluid biomarkers for human embryo quality *in vitro* fertilization: proof of principle

F. Chen[1], S. Carpentier[2], T. D'Hooghe[1], K. Peeraer[1], C. Spiessens[1]
[1]*Leuven University Fertility Center, Leuven University Fertility Center, Leuven, Belgium*
[2]*KU Leuven, Facility for Systems Biology Based Mass Spectrometry SyBioMa, Leuven, Belgium*

Study question: Is the peptide profile in human follicular fluid (FF) associated with embryo quality in IVF/ICSI and can we use it to identify potential?
Summary answer: We demonstrated a panel of 24 peptides that were differentially detected in FF corresponding to embryos of top quality and poor quality.
What is known already: Human follicular fluid (FF) is a unique biological fluid in which the oocyte develops *in vivo*, and presents an optimal source for non-invasive biochemical predictors. A number of single peptides or proteins have already been assayed in FF and some seem to correlate with oocyte maturation. But most of the studies focused on known proteins, and rarely correlated them to embryo quality. Given the complexity of the numerous independent processes involved, it is unlikely that a single biomarker can predict embryo quality. Application of powerful peptidomic technologies may significantly contribute to biomarker discovery and also better understanding the reproductive processes.
Study design, size, duration: A total number of 67 individual follicular fluid samples from couples undergoing IVF/ICSI treatment at the Leuven University Fertility Center were analyzed in discovery and replication cohorts separately. All the patients were younger than 36 years old and underwent the first or second cycle. Samples were collected from January 2013 to September 2015.
Participants/materials, setting, methods: Follicular fluid with good embryos and non-good quality embryos were split into discovery (n = 51) and replication (16) cohorts. A total of 23 (45%) participants from the discovery cohort and 6 (37.5%) participants from the replication cohort were responded to poor quality embryos. The discovery cohort were split into two experiments, with 15 (8/7) and 36 (20/16) samples, respectively. Peptide profiles were acquired by nano-scale liquid chromatography coupled to tandem mass spectrometry (nano LC-MS/MS).
Main results and the role of chance: Twenty-four peptides were retained as potential biomarker candidates, distinguishing 45 out of 51 embryos in discovery experiment. The 24 peptides panel was further validated in the replication cohort and demonstrated an accuracy of 81.2% (13/16). A total number of 106 proteins were validated, reporting a protein false discovery rate (FDR) of 0.00% and peptide FDR of 0.00%. Seven potential biomarker peptides could be identified. They are involved in immune responses, complement activation, extracellular matrix binding, ion channel binding and cell adhesion.
Limitations, reasons for caution: The different methodologies and analytical tools each bring their own selectivity. The challenge of peptide concentration variability across samples and experiments remains a major constraint.

Wider implications of the findings: This study, for the first time, presents a panel of peptides in FF can be used as potential biomarker to predict quality of embryos. It also reveals that peptide profiling in individual follicular fluid samples can be a new promising innovative, non-invasive approach to assist embryologist with embryo selection.
Trial registration number: None.

O-266 Prediction of embryos at risk of chromosomal abnormalities and developmental arrest by metabolic profiling of >100 metabolites in spent culture media

K. Chatzimeletiou[1], E. Kolibianakis[1], I. Georgiou[2], L. Lazarou[2], C. Virgiliou[3], I. Sampsonidis[3], L. Valianou[3], G. Theodoridis[3], H. Gika[4], N. Raikos[4], E. Papadopoulou[1], A. Sioga[5], L. Oikonomou[5], K. Nicolaides[6], B. Tarlatzis[1]
[1]*Papageorgiou General Hospital, Aristotle University Medical School, First Department of Obstetrics and Gynaecology, Thessaloniki, Greece*
[2]*University of Ioannina, Department of Obstetrics and Gynaecology, Ioannina, Greece*
[3]*Aristotle University, Department of Chemistry, Thessaloniki, Greece*
[4]*Aristotle University, Department of Toxicology, Thessaloniki, Greece*
[5]*Aristotle University, Laboratory of Histology and Embryology, Thessaloniki, Greece*
[6]*King's College Hospital, Harris Birthright Centre for Foetal Medicine, London, UK*

Study question: Can metabolic profiling predict embryos at risk of chromosomal abnormalities and developmental arrest?
Summary answer: Metabolic profiling can predict aneuploid and chaotic embryos that arrest in culture and normal embryos that result in a viable pregnancy.
What is known already: Non-invasive methods of embryo selection including cell free mt-DNA and metabolic profiling have been proposed to distinguish between embryos with the potential to implant and those that arrest. Down's syndrome embryos and Monosomy 21 embryos have previously been shown to have differential expression of metabolites compared to normal embryos, while limited studies, have investigated in detail the metabolic profiling of embryos with other abnormalities in comparison to chromosomally normal embryos.
Study design, size, duration: This an ongoing study, initiated in 2011. 375 embryos cultured in 4 different culture media (Irvine $n = 80$, Origio $n = 90$, Sage $n = 138$, Vitrolife $n = 67$) were subjected to day 3 biopsy and processed for PGD/S. Culture media prior to biopsy (day 1–3) and following biopsy (day 3–5) were collected and analysed by hydrophilic interaction liquid chromatography tandem mass spectrometry HILIC-MS/MS.
Participants/materials, setting, methods: PGD/S was conducted in a private IVF Unit and an academic hospital with IVF/PGD laboratory. Metabolic analysis was conducted in a Forensic Toxicology Laboratory by HILIC-MS/MS which was developed to provide the quantitation of circa 100 metabolites in an UPLC system with a triple quadrupole spectrometer.
Main results and the role of chance: This study provides, so far, the largest series screening for >100 primary metabolites using HILIC-MS/MS in 4 different spent culture media (Irvine, Origio, Sage, Vitrolife). UPLC conditions were optimized for each culture medium separately and reached maximum peak capacity and retention for all hydrophilic metabolites in a single run of 40 min. The methodology was validated and proved to be reliable and robust. Unique biomarkers, in spent culture media, from embryos diagnosed as abnormal following PGS and reconfirmed as uniformy aneuploid, major-mosaics or chaotics following meta-analysis of all the nuclei on day 5, were identified and characteristic patient specific metabolic profiles were observed, which differed between chromosomally normal embryos that had developed to the blastocyst stage and resulted in a viable pregnancy and aneuploid and chaotic embryos that arrested in culture. Logistic regression analysis revealed a number of metabolites that had a high predictive value and models were created which in the future could serve as non-invasive markers for the detection of chromosomal abnormalities before embryo transfer.
Limitations, reasons for caution: Although all abnormal embryos were meta analysed on day 5 to confirm initial single cell diagnosis and their uniform or mosaic status was established, normal embryos transferred on the basis of single cell analysis but not resulting in a pregnancy could not obviously be tested for mosaicism.
Wider implications of the findings: This study provides unique biomarkers found in 4 different spent media from chromosomally abnormal embryos. Comparison of these metabolic profiles with those of chromosomally normal embryos by logistic regression showed distinct differences, which in the future could serve as non-invasive markers for the detection of chromosomal abnormalities before embryo transfer.
Trial registration number: A9850/11.

O-267 Detecting metabolic differences in mouse and human embryos through a novel imaging strategy

N. Resetkova[1], T. Sanchez[2], B. Kaye[2], D. Sakkas[3], K. Eggan[4], D. Needleman[2]
[1]*Beth Israel Deaconess Medical Center, Obstetrics and Gynaecology, Boston, MA, USA*
[2]*Harvard, Molecular and Cell Biology, Cambridge, MA, USA*
[3]*Boston IVF, Reproductive Endocrinology and Infertility, Waltham, MA, USA*
[4]*Harvard, Stem Cell and Regenerative Biology, Cambridge, MA, USA*

Study question: Are there distinct metabolic changes that occur in embryonic development that can be detected with metabolic imaging, and can they be used to select the healthiest embryos?
Summary answer: Metabolic imaging can sensitively detect shifts in embryo metabolism over the course of embryo development, and can distinguish between embryos of different metabolic states.
What is known already: Metabolic function changes as embryos develop, with both varying degrees of ATP synthesis and turnover at different developmental stages. Ratiologic redox fluometry was developed as a means of metabolic imaging using single photon autofluorescence of FAD and NAD, which are both integral components in the production of ATP. Although this form of imaging has been studied in human systems including brain tissue, cardiac and cancer cells, it has not yet been applied to embryos. This technology poses an advantage to current non-invasive embryo assessment tools including time lapse imaging and indirect assessment methods of embryo metabolism such as metabolomics.
Study design, size, duration: Mouse embryos were obtained from a commercial source. 100 embryos were used in this cohort study, while the metabolic imaging scope was optimized for embryo monitoring over a 1-year duration. The on-stage incubation system was used for long-term monitoring of cellular metabolism over the course of embryo development from the 1-cell to blastocyst stage. Human embryos selected for imaging were donated under an IRB approved protocol.
Participants/materials, setting, methods: Metabolic measurements were obtained by measuring NADH and FAD autofluorescence using fluorescence lifetime imaging microscopy (FLIM). Images were obtained every 3 h during the course of mouse embryo development using an on stage incubation system. Human embryos were thawed using a commercial thaw kit and metabolic images were acquired several hours after thawing. Embryos were then cultured in a conventional incubator to the day 5 Stage of development to assess for continued development after imaging.
Main results and the role of chance: FLIM-based metabolic imaging was able to distinguish between metabolic states in three separate experiments. First, cohorts of oocytes from old (9-month) vs. young (<3-month) mice were measured, displaying distinct metabolic profiles. As oocyte metabolic health and viability are known to decline with maternal age, this highlights the likely predictive potential of this imaging technology. Second, we observed distinct changes in measured metabolic FLIM signatures over the course of mouse embryo development from the 1-cell to the blastocyst stage.

In particular, NADH abundance peaks around compaction and decreases significantly during blastocyst formation, likely corresponding with an associated increase in energy demands. This pattern was preserved among the embryo cohort, and was significant with respect to measurement error. Through these experiments, we obtained real-time, high time-resolution, yet non-invasive representations of metabolic development. The continued development of the mouse embryos was consistent with controls and expected outcomes from the commercial distributor, despite many image captures throughout the course of development.

Finally, images of discarded human embryos were acquired at a single point in development. These embryos showed various aberrant morphologies. Correspondingly to the different forms of developmental failure, each embryo's metabolic measurement was significantly distinct from the others, indicating different metabolic states.

Limitations, reasons for caution: Although these findings represent an innovative mechanism of embryo evaluation, there is no defined standard for interpreting metabolic FLIM parameters. The hardiness of the mouse model presents a challenge to testing the implications of this method on mouse embryo development. Human embryo measurements represent only a preliminary data set.

Wider implications of the findings: This work represents a foundational tool for assessing the metabolic health of embryos. Preliminary results indicate promise for the use of metabolic imaging as a potential embryo selection tool. Future in-clinic measurements on clinical samples are planned, and will investigate possible correlations between metabolic signatures and final pregnancy outcomes.

Trial registration number: N/A.

O-268 Cell allocation patterning between the two-cell to the blastocyst stage might be associated with organ development in mouse offspring

L.P. Sepulveda-Rincon[1], N. Islam[1], N. Beaujean[2], B.K. Campbell[1], W.E. Maalouf[1]
[1]*University of Nottingham, Child Health, Obstetrics and Gynaecology, Nottingham, UK*
[2]*INSERM U1208, INRA USC1361, Stem Cell and Brain Research Institute, Bron, France*

Study question: Does cell allocation patterns during pre-implantation development affect implantation and further embryo development?

Summary answer: Cell allocation patterns from the two-cell stage embryo up to the blastocyst stage affect further embryo development and offspring heart weight in mice.

What is known already: During pre-implantation embryo development, the first cell fate decision is observed at blastocyst stage. The inner cell mass is situated at the embryonic (Em) axis and the trophectoderm at the abembryonic (Ab) axis. Some authors claim that the Em-Ab axis can be predicted by the first embryo cleavage plane which is orthogonal to the Em-Ab axis in the majority of embryos. However, this theory has been debated thoroughly in the literature. Also, the correlation between the first embryo cleavage plane with the Em-Ab axis and further putative offspring development has been demonstrated only in cloned mouse embryos.

Study design, size, duration: One-cell frozen B6C3F1 × B6D2F1 mouse embryos (n = 568, 3 repetitions) were thawed and cultured; from those, 259 classified blastocysts according to their cell allocation pattern were transferred to 2.5 days post-coitus (dpc) pseudo-pregnant CD-1 females (n = 17) by non-surgical embryo transfer (NSET) method. Two weeks old live offspring (n = 45) were dissected and heart, spleen, lungs, liver, kidneys were weighed. Pregnancy and implantation rates were also recorded.

Participants/materials, setting, methods: Embryos had one blastomere injected at the two-cell stage with a lipophilic tracer and *in vitro* cultured to the blastocyst stage. Then, blastocysts were classified into three groups: orthogonal, if the Em-Ab axis was orthogonal to the borderline between labelled and non-labelled cells; deviant, if it was parallel; or random, if labelled and non-labelled cells were intermingled. NSET was used to transfer classified blastocysts into pseudo-pregnant females. Progeny were sacrificed on day 14 for organ morphometry.

Main results and the role of chance: From the total cohort of blastocysts studied, those classified as random were significantly higher (52.3%, P = 0.037); when compared with orthogonal (27.0%) and deviant (28.3%) embryos. No significant differences were found among the three groups in terms of pregnancy rates (66% orthogonal, 83% deviant and 100% random), implantation rates (42% orthogonal, 39% deviant and 50% random), pregnancy loss (49% orthogonal, 79% deviant and 55% random), offspring total body weight (11.1 ± 0.4 g orthogonal, 9.7 ± 0.4 g deviant and 10.8 ± 0.2 g random) and relative weight (organ weight/total weight) of lungs, liver, spleen and kidneys (P > 0.05). However, a significant difference was found in the heart weight between the three groups (P = 0.023). The deviant blastocyst group resulted in offspring with the smaller heart weight.

Limitations, reasons for caution: The mechanism(s) causing the cell allocation patterns during pre-implantation development are not understood. The sample size was small and other effects would have reached statistical significance with more repeats. Patterning in human embryos has not been studied and so it is difficult to determine the clinical translation of these findings.

Wider implications of the findings: There is a defined presence of three different embryos according to their cell allocation pattern; correlation of these patterns with implantation and further development must be established (if any). If so, new embryo selection strategies might stem from this work to improve success rates after assisted reproductive treatments.

Trial registration number: N/A.

O-269 Inner cell mass of blastocyst grade and loosening of inner cell mass is related to monochorionic diamniotic twinning

J. Otsuki[1], T. Iwasaki[1], Y. Katada[1], H. Sato[1], Y. Tsutsumi[1], K. Hatano[1], Y. Tsuji[1], K. Furuhashi[1], Y. Matsumoto[1], S. Kokeguchi[1], M. Shiotani[1]
[1]*Hanabusa Women's Clinic, Reproductive Medicine, Kobe, Hyogo, Japan*

Study question: Is inner cell mass (ICM) grade and morphological configuration is related to the occurrence of monochorionic diamniotic (M-D) twinning?

Summary answer: Yes, low ICM grade and loosening of ICM can be the risk factors of M-D twinning.

What is known already: Monozygotic twinning (MZT), which includes monochorionic diamniotic (M-D), monochorionic monoamniotic (M-M) and monozygotic dichorionic diamniotic (D-D) is known to increase with ART procedures. Extended culture, younger age, oocyte/embryo manipulations such as assisted hatching (AH) and ICSI have been considered to contribute MZT, however, they are still controversial and it remains unknown what factors contribute to that increased risk.

Study design, size, duration: Retrospective cohort study involving 8435 women who underwent frozen–thawed single blastocyst transfer with hormone replacement treatment (HRT) between January 2011 and December 2014. 71 ICM of blastocysts observed by time lapse system (Embryo Scope) from June 2013 to December 2014 were also retrospectively analyzed.

Participants/materials, setting, methods: Statistical analyses were carried out to explore the cause of MZT. Any changes in configuration of the ICM observed by time lapse system was retrospectively analyzed. Loosening of the ICM was defined as when more than 5 cells were loosened after a tight ICM was once observed by the time lapse system. Pregnant patients underwent a vaginal ultrasound and monozygotic twinning (M-D, M-M and D-D) was confirmed at both 6–7 and 8–9 weeks.

Main results and the role of chance: A total of 8435 frozen–thawed single blastocyst transfer with HRT resulted in 3445 (40.8%) clinical pregnancies having a total of 80 MZT (2.32%). The number of M-D, M-M D-D twins and monochorionic triplet were 36 (1.04%), 3 (0.09%), 39 (1.13%) and 2 (0.06%) respectively. Gender discordance in twins was found in two D-D cases. The rate of dual live birth was also significantly higher in M-D twinning than in D-D twinning (p = 0.0017). The M-D twinning rate when blastocysts with a high grade ICM (grade A) were transferred was 0.38% (3/796), whereas it was 1.38% (34/2463) when blastocysts with a lower grade ICM (grade B and C) were transferred, and there was a significant difference between the two groups (p = 0.033). 71 frozen–thawed blastocysts were transferred after observation by time-lapse system. The hCG, GC, FHB positive rates were 74.2% (52/71), 63.4% (45/71), 57.7% (41/71) respectively, and there were two D-D and one M-D twins. Among the 41 cycles with positive FHB, 36 cases were delivered, 4 cases miscarried and 1 case lost contact. By careful observation of the embryo resulting in the one M-D case, it was found that the ICM became loose as a result of having 8 cells de-compacted, which was not observed in the other ICM of transferred blastocysts.

Limitations, reasons for caution: The birth of babies derived from natural conception cannot be eliminated although the occurrence is very small. As the occurrence of M-D twinning is around 1% and availability of data and time-lapse systems are limited, multi-center study is necessary to confirm these findings.

Wider implications of the findings: The occurrence of M-D twinning can be reduced by avoiding the transfer of embryos when the loosening of ICM is confirmed by time-lapse observation in addition to observing splitting of two or three inner cell masses in an expanded blastocyst.
Trial registration number: Not applicable.

INVITED SESSION

SESSION 69: ENDOMETRIOSIS, HOW DOES IT HURT?

Wednesday 06 July 2016 **Hall 5 A** **12:00–13:00**

O-270 Peripheral nerve mechanisms in endometriosis associated pain

M. Morotti[1]
[1]*Oxford, UK*

Pain remains the cardinal symptom of endometriosis. Similar to many other chronic conditions pain sensation in endometriosis appears to be a close interaction between the nociceptors and peripheral nerve fibres and central and hormonal modulation.

However, the exact pathomechanisms are still only poorly understood. This presentation focuses on factors important in the peripheral pain system.

Endometriotic lesions consist of glandular epithelial and stromal cells. Currently, endometriotic tissue is divided into three different entities: (a) peritoneal lesions, (b) ovarian cysts and (c) deep endometriosis. None of these locations/types of disease are correlated with a specific pain quality or severity.

Recently it was demonstrated that nerve fibres are found in close proximity to endometriotic lesions.

Mounting evidence indicates that these fibres are recruited in parallel to blood vessels through a process termed neuroangiogenesis. Blood vessel and nerve growth are linked by common pathways that involve the release of pro-angiogenic factors, such as vascular endothelial growth factor, β-nerve growth factor and neuropeptides.

Proangiogenic factors are also known to stimulate nerve growth, and molecules produced by vascular cells could both stimulate and guide nerve growth.

These factors are produced via different processes, not least by immune cells that are ubiquitously found in the peritoneal cavity of women affected by the condition. Conversely, the peripheral nerve fibres take an active part in inflammatory processes by regulating effector cell function and reallocation of energy to the immune system.

The upregulation of neurotrophic and angiogenic factors in peritoneal fluid of women with endometriosis, the increase of new nerve fibres and their spatial vicinity with the lesions have led to increased interest in peripheral changes in endometriosis-associated inflammation and pain generation.

The main features of this peripheral process are loss of sympathetic nerve fibres from sites of inflammation concomitant with increased innervation with sensory nerve fibres and increased sensory nerve fibre activity.

However, a clear link between the amount of new nerve fibres and pain severity in patients with endometriosis has so far not been demonstrated.

O-271 Central pain mechanisms relevant to endometriosis-associated pain

K. Vincent[1]
[1]*John Radcliffe Hospital, Nuffield Department of Obstetrics/Gynaecology, Headington, Oxford, UK*

It is well known that the severity of pain experienced by women with endometriosis correlates poorly with the extent of disease identified at laparoscopy. This observation suggests that factors other than the ectopic lesions are involved in the generation and/or amplification of pain. The experience of pain is both sensory and emotional and involves coordinated activity within a distributed network of brain regions. The brains of patients with chronic pain exhibit both structural and functional differences when compared to pain-free controls. Moreover, these changes are remarkably similar across chronic pain conditions, no matter what the underlying pathology. This presentation will firstly summarise the central changes associated with chronic pain and consider how they may apply to women with endometriosis-associated pain. Recent findings from functional brain imaging studies of women with endometriosis-associated pain will then be described and the potential of these findings to inform our clinical practice explored.

SESSION 70: SCREENING AND PREDICTING

Wednesday 06 July 2016 **Hall 5 CB** **14:00–15:15**

O-272 Implementation of an expanded carrier screening test for recessive genetic disorders in an oocyte donation program

A. Abuli Vidal[1], M. Boada[1], E. Clua[1], L. Latre[1], M. Luna[1], B. Rodríguez-Santiago[2], B. Coroleu[1], L. Armengol[2], L. Perez-Jurado[3], A. Veiga[1], X. Estivill[1], B. Pedro N[1]
[1]*Dexeus Women's Health, Obstetrics, Gynaecology and Reproductive medicine, Barcelona, Spain*
[2]*qGenomics Laboratory, Research and Development, Barcelona, Spain*
[3]*Pompeu Fabra University, Genetics Unit, Department of Experimental and Health Sciences, Barcelona, Spain*

Study question: Next-generation sequencing (NGS) is revolutionizing genetic research and diagnosis in reproductive medicine. What can expanded carrier screening (ECS) contribute to in an oocyte donation (OD) program?
Summary answer: The emergence of NGS-technologies has allowed the implementation of a NGS-based screening in an OD program to reduce the rate of livebirth with genetic disease.
What is known already: Genetic screening of gamete donors (GD) consists mainly of the assessment of personal medical and family history by a geneticist. However, many specific inherited conditions can remain unnoticed in a family. Therefore, based on scientific societies' recommendations, most ART centres include the karyotype and targeted-mutation screening for cystic fibrosis and Fragile X syndrome. In recent years, the cost of molecular genetic studies has been reduced due to the emergence of NGS-technologies, allowing the analysis of a large number of genes in a cost-effective manner. This claims for the extension of carrier screening to a larger number of genetic conditions.
Study design, size, duration: We describe the clinical implementation of a NGS-based panel (qCarrier test) for expanded carrier screening (ECS) in an OD program. The qCarrier test includes 200 genes associated with 218 autosomal recessive and 22 X-linked diseases. Our protocol in the OD program includes the karyotype and the qCarrier test. ECS is performed to OD candidates and the male partner of oocyte recipients. All patients have a pre and post-test genetic counselling session.
Participants/materials, setting, methods: The studied population consists of 1,118 individuals (483 oocyte donor candidates and 635 male partners of oocyte recipients) evaluated in the framework of an OD program. Carriers of X-linked conditions were discarded from the OD program, while a carrier state for an autosomal recessive condition was not an exclusion criterion for the female donors. We performed a manual "genetic-match" so that the donor and the recipient were not carriers for the same recessive condition.
Main results and the role of chance: The clinical implementation of ECS in our OD program has been in approximately 86% (545/635) of gamete donation cycles. We detected 1,102 pathogenic or likely-pathogenic mutations in the analyzed genes. The 10 most common autosomal recessive conditions detected with qCarrier test include: non-syndromic deafness, cystic fibrosis, galactosemia, phenylketonuria, familial Mediterranean fever, spinal muscle atrophy, alpha thalassemia, Smith–Lemli–Opitz syndrome, polycystic kidney disease and classical congenital adrenal hyperplasia. We identified 56.3% subjects who were carriers of at least one mutation in a gene responsible for a Mendelian genetic disease. The majority (64.1%) were carriers of only one mutation. The average carrier burden of genetic conditions was of 0.56 mutations per sample. In the context of our OD program, approximately 1.7%

(8/483) of oocyte donors were discarded because they were carriers of an X-linked condition and, we identified 3% (19/635) of pre-assigned donor–recipient matches with high reproductive risk for an autosomal recessive disease, which required a change in the selection performed. With the use of an ECS test we have decreased by 0.75% the risk of births with a genetic condition. Genetic counselling is an essential step before and after performing the genetic screening.
Limitations, reasons for caution: The limitations are the identification of previously unknown variations that challenge the communication of results and the psychological impact of the ECS results in oocyte donors. There is an absolute need for an adequate pre and post-test genetic counselling that clearly states the advantages, limitations and implications of the test.
Wider implications of the findings: We plan to offer the ECS to couples with reproductive projects, since they might also benefit from knowing their carrier status. Regarding technical improvements, it would be relevant to analyze the complete coding sequence of genes, expand the targeted genes to additional disorders and measure nucleotide-repeat expansions from NGS data.
Trial registration number: No clinical trial.

O-273 Repeated predictions of natural conception for the same couple

R. van Eekelen[1], I. Scholten[1], R.I. Tjon-Kon-Fat[1], F. van der Veen[1], J.W. van der Steeg[2], P. Steures[3], P. Hompes[4], B.W. Mol[5], M.J. Eijkemans[6], E.R. te Velde[7], N. van Geloven[8]

[7]*Eramus University Medical Center, Department of Public Health, Rotterdam, Netherlands*
[8]*Leiden University Medical Center, Department of Medical Statistics, Leiden, Netherlands*

Study question: How can we predict chances of natural conception in the same couple at various time points?
Summary answer: We developed a dynamic prediction model that can make repeated predictions over time for the same couple.
What is known already: The most frequently used prediction model for natural conception (the "Hunault model") is able to estimate the probability of a natural conception only once per couple, that is, after the completion of the fertility workup. This model cannot be used for a second or third time in the same couple who wish to know their renewed chances after a certain period of expectant management.
Study design, size, duration: A prospective cohort studying the long term follow up included subfertile couples in 38 centres in The Netherlands between January 2002 and February 2004. Couples with bilateral tubal occlusion, anovulation, or a total motile sperm count $<1 \times 10^6$ were excluded.
Participants/materials, setting, methods: The primary endpoint was time to a natural conception, leading to an ongoing pregnancy. Follow up time was censored at the start of treatment or at the last date of contact. We included the same predictors in our dynamic prediction model as the Hunault model, i.e., female age, duration of subfertility, female subfertility being primary or secondary, sperm motility and referral status. The performance of the model was evaluated in terms of calibration and discrimination.
Main results and the role of chance: Of the 4,999 couples in the cohort, 1,053 (21%) women reached a natural conception leading to an ongoing pregnancy within a mean follow up of 8 months (range 1–66 months). According to our newly developed dynamic prediction model, the median predicted probability in the first year after completion of the fertility workup was 27%. If pregnancy did not occur in the first half year, the median predicted chance of conceiving in the next year was 20% and decreased to 15% and 13% after 1 year and after one and a half years of unsuccessful expectant management, respectively. The model appeared to perform fair up to two and a half years of follow up in an internal validation.
Limitations, reasons for caution: The dynamic prediction model needs to be validated in an external population.
Wider implications of the findings: This dynamic prediction model allows reassessment of natural conception chances after various periods of unsuccessful expectant management. This gives valuable information to counsel couples with unexplained subfertility.
Trial registration number: Not applicable.

O-274 Biomarkers of ovarian reserve as predictors of reproductive potential

A. Steiner[1], F. Stanczyk[2], J. Kesner[3], J. Meadows[3], D. Baird[4]
[1]*University of North Carolina at Chapel Hill, Obstetrics and Gynecology, Chapel Hill, NC, USA*
[2]*University of Southern California, Obstetrics and Gynecology, Los Angeles, CA, USA*
[3]*National Institute for Occupational Safety and Health, NIOSH Reproductive Endocrinology Laboratory, Cincinnati, OH, USA*
[4]*National Institute of Environmental Health Sciences, Epidemiology Branch, Research Triangle Park, NC, USA*

Study question: Are biomarkers of ovarian reserve: anti-Müllerian hormone (AMH), inhibin B, and follicle stimulating hormone (FSH) predictive of reproductive potential, as measured by fecundability, in an older, reproductive age cohort?
Summary answer: Biomarkers of ovarian reserve are not predictive of reproductive potential in an older, reproductive-age cohort.
What is known already: Biomarkers of ovarian reserve, including AMH and early follicular phase inhibin B and FSH levels, have been shown to predict time to menopause and response to ovarian stimulation following controlled ovarian hyperstimulation. There is some evidence that they predict pregnancy after assisted reproductive technology. Prior studies on their ability to predict natural fertility have been conflicting. Urinary FSH kits are being marketed to women as tests for future reproductive potential.
Study design, size, duration: 755 women were enrolled in a prospective time-to-pregnancy cohort study, designed to determine the predictive value of biomarkers of ovarian reserve. Women provided a serum and urine sample at enrollment on menstrual cycle day 2, 3, or 4. They were followed until pregnancy was detected or up to 12 months of attempt.
Participants/materials, setting, methods: Women, 30–44 years old, with no history of infertility, who were trying to conceive for less than 3 months, were recruited from the community. Serum was analyzed for FSH, inhibin, and AMH. Urine was analyzed for FSH and creatinine-corrected (uFSHcr). uFSHcr was dichotomized at a cut-point equivalent to a serum value of 10 mIU/ml. Discrete Cox models were used to calculate fecundability ratios (FR) adjusting for age, race, prior pregnancy, body mass index, and smoking history.
Main results and the role of chance: Median AMH values (interquartile range) were 2.77 ng/ml (1.44–5.26) and FSH 6.6 mIU/ml (5.26–8.19). Ten percent of women had a urinary FSH value greater than 11.5 mIU/mg cr. AMH and age were inversely correlated ($r = -0.28$, $p < 0.001$). uFSHcr levels were correlated with serum FSH levels ($r = 0.62$, $p < 0.001$). AMH was not associated with fecundability [FR: 0.97, 95% Confidence Interval (CI): 0.89–1.06]. Neither was serum FSH (FR 0.92, 95% CI: 0.73–1.14) nor inhibin b (FR 1.0, 95% CI: 0.99–1.01). No significant association was observed between uFSHcr and fecundability when modeled as a continuous variable (FR: 1.14, 95% CI: 0.97–1.34) or dichotomized (FR: 0.99, 95% CI: 0.71–1.39). Limiting the sample to older women (≥35 years) had little impact (AMH: FR 1.03, 95% CI: 0.88–1.20; FSH: FR 0.92, 95% CI 0.59–1.44).
Limitations, reasons for caution: Pregnancy, not live birth, was the outcome for this study.
Wider implications of the findings: In this large, time-to-pregnancy study of women at risk for ovarian aging, we did not observe an association between markers of ovarian reserve and fecundability. Biomarkers of ovarian reserve do

not appear to predict reproductive potential independent of age. Women should be discouraged from using them as fertility tests.
Trial registration number: NCT01028365.

O-275 Oocyte cytoplasmic maturation, metaphase plate alignment and aneuploidies – impact on fertilization rate, embryo quality and pregnancy outcomes

C. Alvarez Sedo[1], M. Miguens[1], D. Lorenzi[1], N. Ortiz Maffei[1], M. Bilinski[1], F. Nodar[1], S. Papier[1]
[1]*CEGYR Fertimed S.A, Reproductive Biology and Genetics, Capital Federal, Argentina*

Study question: Is there a relationship between the oocyte cytoplasmic maturation and the metaphase plate conformation and aneuploidies?
Summary answer: An incomplete oocyte cytoplasmic maturation is related to metaphase plate anomalies and aneuploidies. Outcomes were poorer in cycles with oocytes from cohort with cytoplasmic immaturity.
What is known already: Nuclear and cytoplasmic oocyte maturation occurs *in vivo* during follicular growth and ovulation. Both processes are induced by changes in plasma levels of gonadotropins. During their growth, oocytes acquire the ability to restart meiotic maturation in response to gonadotropins stimulation, mainly LH increased. The nuclear envelope breaks down, the first polar body is released and meiosis progress until metaphase II (MII). The meiosis stops in MII and ovulation occurs. Maturation promoting factor (MPF) and mitogen activated protein kinases (MAPK) play an important role in oocyte maturation.
Study design, size, duration: Prospective comparative study. Fifty couples who underwent ART were selected. From January 2014 to December 2015.
Participants/materials, setting, methods: From nineteen patients, 22 metaphase II and 18 unfertilized oocytes after ICSI were studied.

The first polar body was collected for chromosomal analysis by aCGH.

Oocytes were processed by immunocytochemistry-ICC to determine oocyte maturation: assessment of inactive MPF status and the metaphase plate alignment.

Other 31 couples with sub-optimal fertilization (<50%) were selected: unfertilized oocytes were studied by ICC. Two groups were conformed according to the main feature observed: (A) cytoplasmic immaturity and (B) mature cytoplasm.
Main results and the role of chance: Regarding MII mature oocytes, 87% had a normal metaphase plate and 84% were chromosomally normal. Contrary, immature oocytes presented abnormal metaphase plate (86%) and just 33% were euploid.

In failed-fertilized oocytes: 100% of mature oocytes had a normal metaphase plate and 71% were euploid. When oocytes were cytoplasmic immature, 37% of them were normal (metaphase plate) and 50% were chromosomally normal.

The global rate of aneuploidies and metaphase plate disarrangements in immature oocytes (MII + failed-fertilized) were significantly higher than mature oocytes ($p < 0.05$).

In patients with sub-optimal fertilization, the percentage of top quality embryos and pregnancy rate was significantly higher in group B ($p < 0.05$).
Limitations, reasons for caution: More oocytes should be studied.
Wider implications of the findings: Our results suggest that cytoplasmic oocyte maturation has a higher relevance compared to nuclear maturity.

An inadequate cytoplasmic maturation is associated with altered levels of metaphase plate alignment and aneuploidies affecting pregnancy rates.
Trial registration number: None.

O-276 AMH levels, independent of age, are a significant marker for risk of miscarriage following post-IVF embryo transfer

[14]*Shady Grove Fertility, Clinic, Washington, DC, USA*

Study question: Maternal age is associated with both higher miscarriage rates and lower levels of AMH, however the individual contribution of AMH levels to miscarriage is unknown.
Summary answer: AMH levels are correlated with an increased miscarriage risk after IVF, independent of age.
What is known already: Advanced maternal age is a well established risk factor for pregnancy loss in general and after IVF treatment. Maternal age is also associated with lower markers of ovarian reserve such as AMH. It is less clear, however, how younger patients with abnormal markers of ovarian reserve, should be counseled with respect to the likelihood that a pregnancy will result in a loss.
Study design, size, duration: We performed a retrospective cohort study on patients who achieved pregnancy with IVF at 12 fertility treatment centers in the United States from 2009 to 2015. We excluded patients with ectopic pregnancies, cycles using donor oocytes or gestational carriers, and included patients 22–49 years old in which AMH testing had been performed. We included both fresh and frozen embryo transfer IVF and excluded cycles where PGS was performed. Our final analysis was performed on 13,463 patients.
Participants/materials, setting, methods: We analyzed 16,039 IVF cycles (corresponding to 13,463 patients), of which 10,748 cycles resulted in a live birth, 2,733 in a biochemical pregnancy loss (BP), and 2,558 in a clinical miscarriage (CM), defined as detection of a gestational sac by ultrasound. Time-dependent multivariate time-to-event models were used to evaluate the hazard (risk) of miscarriage for BP and CM when controlling for multiple clinical parameters. Predictors were refined using least absolute shrinkage and selection operator (LASSO).
Main results and the role of chance: Consistent with previous studies, we found that maternal age was a significant risk factor for both BP (4.3% increase/year, $P < 0.001$) and CM (6.9% increase/year, $P < 0.001$). We next explored the relationship between AMH levels and miscarriage risk. We found that risk of BP was significantly higher in patients with low AMH, independent of age. Patients with AMH less than 0.2 ng/mL were at a 29.1% higher risk of BP ($P = 0.01$) and patients with an AMH between 0.2 and 0.95 ng/mL had a 10.4% increased risk ($P = 0.051$). Additionally, we found that AMH was a significant predictor of risk of CM in patients with both very low and high AMH, independent of age. Patients with AMH less than 0.2 ng/mL had a 23.8% increased risk ($P = 0.034$), and, conversely, patients with AMH that was greater than 10 ng/mL had a 25.6% increased risk of CM ($P = 0.02$). Interestingly, for patients with AMH between 0.2 and 0.95 ng/mL, increased risk is dependent on maternal age, where each year increase in age results in a 3.2% increase in risk for CM ($P = 0.015$).
Limitations, reasons for caution: Our study was performed on retrospective data from the U.S. Future studies are needed to investigate whether findings could expand to European practice patterns. We also excluded cycles in which PGS was performed. Inclusion of PGS in future work, may better resolve the etiology of pregnancy loss in these groups.
Wider implications of the findings: Our study suggests that AMH is a powerful biomarker for determining risk of miscarriage during IVF treatment. Women who are at risk for miscarriages either due to abnormally low or high AMH level, independent of age, may benefit from increased counseling.
Trial registration number: None.

O-277 The effect of GV1001 and bevacizumab combination therapy on follicle loss of ovary

M. Kim[1], D. Jang[1], K. Chang[1], J. Lee[1], J.H. Lee[1], H.W. Lee[2], Y.W. Choi[2], K.J. Hwang[1]
[1]*Ajou University, School of Medicine, Department of Obstetrics and Gynecology, Suwon, Gyeonggi-do, South Korea*
[2]*Ajou University, School of Medicine, Department of Medical Oncology, Suwon, Gyeonggi-do, South Korea*

Study question: Can the combination therapy of GV1001 and bevacizumab effects on function of ovary and suppression of lung cancer?
Summary answer: GV1001 and bevacizumab combination therapy prevents follicle loss of ovary.
What is known already: Premature ovarian failure and infertility are major side effects of chemotherapy treatments in young cancer patients. A more thorough understanding of the mechanism behind chemotherapy-induced follicle loss is necessary to develop new methods to preserve fertility in these patients. Bevacizumab (Avastin®), a monoclonal antibody directed against VEGF, has shown promise in treating a variety of cancers. GV1001 is a 16-amino acid peptide vaccine derived from the human telomerase transcriptase (hTERT) sequence. It was developed as an anti-cancer agent. There are no report about the effect of these two combination therapy on lung cancer and the effect of normal ovarian function.
Study design, size, duration: Experimental animal study, 4 weeks study duration.
Participants/materials, setting, methods: Seven-week-old BALB/c athymic (Nu/Nu) mice (3 mice per group, 12 female, Orient Bio Co. Gyunggido, Korea) were inoculated with non small cell lung cancer cell lines (H441) subcutaneously, and then randomly divided into four groups. Mice were injected with PBS, GV1001 (50 μg/kg in 100 ml 0.9% NaCl solution), bevacizumab (2 mg/kg), or GV1001 plus bevacizumab twice a week for 4 weeks. Tumor sizes and growing follicle ratio of ovary were measured.
Main results and the role of chance: We show that the bevacizumab activates the growth of the quiescent primordial follicle population in mice, resulting in loss of ovarian reserve. Coadministration of a GV1001 reduced follicle activation and increased follicle reserve. These findings suggest that the mechanism in bavacizumab-induced loss of ovarian reserve is accelerated primordial follicle activation, which results in a "burnout" effect and follicle depletion. By preventing this activation, GV1001 shows potential as an ovarian-protective agent, which may be able to preserve fertility in female cancer patients.
Limitations, reasons for caution: Small number of subjects and only follicle counts of ovary are limitation of this study. We are going to test serum level of AMH, FSH, estradiol and VEGF. Further we will observe immunohistochemistry on tumor cells and ovary to make sure the effects of preserving effect and tumor suppression effect.
Wider implications of the findings: This is the first study by combination of GV1001 and bevacizumab in lung cancer mouse model.
Trial registration number: This is not a clinical study.

O-278 Novel microRNAs (miRNA) as biomarkers for toxic insult in the ovary

H. Furlong[1], M. Stämpfli[2], A. Gannon[1], W. Foster[1]
[1]*McMaster University, Obstetrics and Gynecology, Hamilton, ON, Canada*
[2]*McMaster University, Department of Pathology and Molecular Medicine, Hamilton, ON, Canada*

Study question: Are there miRNAs exclusive to toxic insult in the ovary and how are they associated with dysregulation of cellular death and increased loss of follicles?
Summary answer: There are miRNAs induced by toxic insult of the ovary that are associated with regulation of autophagy.
What is known already: It is estimated that 50–80 million people worldwide are infertile. Environmental toxicants and life-style factors are thought to adversely affect female fertility in part via impaired ovarian function. We have used the cigarette smoke (CS) exposure to model ovarian insult and to explore mechanisms of ovarian follicle loss. We have shown that CS-exposure induces autophagy and decreases the number of primordial and growing follicles. miRNAs are small noncoding RNAs that negatively regulate gene expression post-transcriptionally and involved in a number of cellular processes. The regulatory role of miRNAs in the ovary and their potential in fertility preservation is not well-known.
Study design, size, duration: We used our well-established CS-exposure model to investigate ovarian toxicity in C57BL/6 mice. Eight week old mice were exposed to CS (treatment; $n = 4$) or room air (control; $n = 4$) twice daily for 5 days/week for a period of 8 weeks. miRNAs were isolated from ovarian homogenates and profiled using a miRNA Array (Qiagen and SAbiosciences, Canada) to quantify the expression of the 940 most abundantly expressed miRNAs found in the mouse miRNA genome.
Participants/materials, setting, methods: Differentially expressed miRNAs with a statistically significant fold-change (p value ≤ 0.05) were grouped according to increasing/decreasing expression. Nine miRNAs were selected for qPCR validation; miR-let-7, miR-221, miR-1a-1-5p, miR-155-3p, miR-125b-1-3p, miR-15b-5p, miR-451a, miR-1b-3p and miR-101a-3p. To further understand biological significance, a list of mRNA targets for each miRNA was generated utilising an online miRNA-target resource program. Additionally, functional analysis was investigated to identify pathways central to toxic insult-induced dysregulation of ovarian function and autophagy.
Main results and the role of chance: A total of 162 miRNAs were differentially expressed with fold changes greater than 2. Ten miRNAs had increasing fold-change and 152 miRNAs had decreasing fold-change. Both the array and qPCR validation revealed increased expression of miR-let-7 and miR-1a-1-5p and decreased expression of miR-125b-1-3p. miR-let-7 had the greatest overall change in expression, and studies have shown that miR-let-7 is implicated in ovarian cancers through the regulation of autophagy. Comparably, our previous investigations have shown that CS exposure causes increased ovarian follicle loss which is mediated by autophagy, as shown by increased expression of autophagy markers (Beclin1 and LC3) and decreased expression of autophagy inhibitors (mTOR). The association between let-7e and autophagic signalling further elucidates the complex molecular mechanisms associated with ovarian toxicity and the additional functional and enrichment analysis will establish the role of the selected miRNAs with respect to function and disease.
Limitations, reasons for caution: Although the results from the miRNA Array are indicative of biological relevance, further study of the implicated pathways is required. It is not currently known if similar miRNA are expressed and can be detected in human follicular fluid of women who smoke vs. non-smokers.
Wider implications of the findings: We previously indicated that dysregulation of reparative autophagy is a sensitive marker of ovarian toxic insult and an important therapeutic target for fertility preservation. We predict that results of the current study will assist in identifying markers of ovarian health to guide oocyte selection for fertilization to maximize fertility potential.
Trial registration number: N/A.

O-279 Impact of environmental endocrine disruptor's exposure in controlled ovarian stimulation outcome in egg donors

F. Dominguez[1], I. Campos-Galindo[2], P. Alamá[3], J.L. Romero[3], C. Simon[4], C. Rubio[2]
[1]*Fundación Instituto Valenciano de Infertilidad FIVI, Instituto Universitario IVI/INCLIVA, Research, Paterna, Valencia, Spain*
[2]*Igenomix, Valencia, Spain*
[3]*Instituto Valenciano de Infertilidad IVI, IVF, Valencia, Spain*
[4]*Fundación Instituto Valenciano de Infertilidad FIVI, Instituto Universitario IVI/INCLIVA, Valencia University, Department of Obstetrics and Gynecology, School of Medicine, Stanford University, Valencia, Spain*

Study question: Does the endocrine disrupting compounds (EDCs) exposure affect controlled ovarian stimulation outcome in egg donors?
Summary answer: We found significant correlations between lifestyle EDCs exposure, levels measured in urine and follicular fluid and controlled ovarian stimulation outcome in egg donors.
What is known already: Endocrine disruptors are chemicals that can interfere with the endocrine system. Found in many household and industrial products EDCs interfere with the synthesis, secretion, transport, binding, action, or elimination of natural hormones. The central role of the estrogens in the reproductive system has suggested that environmental EDCs exposure that imitates the biological estradiol effect could be a cause for reproductive disorders. Several EDCs have been associated with infertility in women. The most studied EDCs are bisphenol A, parabens and phthalates. We also included caffeine, cotinine and isoflavones such as daidzein and genistein in our study.
Study design, size, duration: Prospective, observational study including female egg donors with proven fertility attending our IVF institution from December 2013 until July 2015. Two urine samples (5 days spaced) and follicular fluid during oocyte retrieval were collected and all the EDCs were quantified. Stimulation parameters were registered and statistical analysis were performed. The following parameters were considered: number of antral follicles, E2 (hCG day), total FSH administered, number of oocytes and MII retrieved.
Participants/materials, setting, methods: 31 female donors were recruited for the study. Lifestyle exposure to EDCs were evaluated using a 40 item questionnaire filled by all donors recruited. Two urine samples (5 days spaced) and follicular fluid (FF) during oocyte retrieval were collected from all the donors. Bisphenol A (BPA), methyl-paraben (mPb), propyl-paraben (pPB), Mono (2-etil-hexil) phthalate (MEHP), caffeine, cotinine, genistein and daidzein (soy-derived phytoestrogens) levels were measured in both urine and follicular fluid using UPLC-MS.
Main results and the role of chance: This study correlates for the first time a panel of environmental EDCs lifestyle exposure and the EDCs measured in urine and follicular fluid with the clinical outcome of controlled ovarian stimulation outcome in egg donors. We detected all the EDCs compounds studied in urine and follicular fluid. We found a positive significant correlation between caffeine levels in both urine and follicular fluid and the total number of oocytes ($p = 0.002$ urine and $p = 0.004$ for follicular fluid) and MII retrieved ($p = 0.005$ urine and $p = 0.008$ for follicular fluid). We also observed a significant increase in the number of antral follicles with the soy-related food products ingestion ($p = 0.0011$) in our female donors. A significant correlation between the habit of reheat food in plastic containers and the number of antral follicles in these women were also found ($p = 0.048$). Finally, we also observed a significant correlation between total FSH levels and the habit of store food in plastic containers ($p = 0.040$).
Limitations, reasons for caution: Our main limitation is the low number of donors used in the study and the lack of external validation of our results. Furthermore, our results were conditioned by the limit of detection of the technique used for each analyte.
Wider implications of the findings: We are highly exposed to several EDCs found in our daily routine work, environment and food that could be found in the urine and follicular fluid altering egg quality and stimulation parameters. More attention to this EDCs exposure is needed to avoid detrimental effects in IVF donors and patients.
Trial registration number: NA.

O-280 Random-start ovarian stimulation in patients without cancer: comparison between conventional-start and random-start in different ovarian reserve

H. Matsubayashi[1], K. Kitaya[1], R. Nishiyama[1], Y. Takaya[1], K. Yamaguchi[2], C. Takahashi[3], S. Mizuta[3], T. Ishikawa[2]
[1]*Reproduction Clinic Osaka, Obstetrics and Gynecology, Osaka, Japan*
[2]*Reproduction Clinic Osaka, Urology, Osaka, Japan*
[3]*Reproduction Clinic Osaka, Laboratory, Osaka, Japan*

Study question: To compare total amount of gonadotropins, stimulation length, number of retrieved oocytes and mature oocytes, fertilization rate, and clinical pregnancy rates between random-start and conventional-start.
Summary answer: Random-start is similar to conventional-start in terms of the number of retrieved oocytes and mature oocytes. Pregnancy rate was extremely high in patients with random-start.
What is known already: Random-start ovarian stimulation has usually been applied in patients with cancer for emergency fertility preservation. In such patients, utilizing their oocytes for fertilization and implantation is some years later after survival of cancer. Therefore, there are few studies to show fertilization, pregnancy, implantation and live birth rates just after oocyte retrieval. There are some patients who required fresh TESE-ICSI (oocyte retrieval and TESE are performed in the same day), whose viable sperms are predicted as very few and no longer tolerable after freeze and thaw if we can recover the sperms. Random-start ovarian stimulation might be useful in these patients.
Study design, size, duration: Our institute has dealt with more than 300 TESEs per year and more than 200 TESE-ICSI for past 2 years. We performed a retrospective cohort study between March 2014 and December 2015. We compared total amount of gonadotropins, stimulation length, number of retrieved oocytes and mature oocytes, fertilization rate, and clinical pregnancy rates between random-start (60 patients, 64 cycles) and conventional-start (149 patients, 162 cycles) as age-matched control. We included only patients without cancer.
Participants/materials, setting, methods: In random-start ovarian stimulation, the starting day was anytime except for during menstruation. In both groups, controlled ovarian stimulation was performed in the same manner. Less than 42 old and AMH >1.1 ng/mL was included in the study. We divided into two groups with ovarian reserve (AMH 1.1~4.0 and >4.0 ng/mL). Student's *t* test (non homogeneity, two-sided) was used for comparison between two groups. Chi-squared test was used for 2×2 contingency table.
Main results and the role of chance: The study population was limited to ICSI and freeze-all cycles only. In patients with AMH >4.0, age (32.4 vs. 33.6 years), AMH (8.0 vs. 6.9 ng/mL), total amount of gonadotropins (2294 vs. 2051 IU), stimulation length (10.1 vs. 8.4 days), number of retrieved oocytes (17.3 vs. 14.4) and mature oocytes (13.1 vs. 10.6), and fertilization rate (65.4 vs. 63.5%) were not different between random-start and conventional-start, respectively. Clinical pregnancy rate (80.0 vs. 35.7%), however, was significantly better in random-start than in conventional-start ($P = 0.001$). In patients with AMH 1.1–4.0, age (33.8 vs. 35.5 years), AMH (2.7 vs. 2.3 ng/mL), number of retrieved oocytes (9.2 vs. 8.7) and mature oocytes (6.4 vs. 6.3), fertilization rate (67.8 vs. 64.1%), and clinical pregnancy rate (35.0 vs. 24.3%) were not different between random-start and conventional-start, respectively. While total amount of gonadotropins (2912 vs. 2539 IU) and stimulation length (10.3 vs. 8.8 days) were significantly more in random-start than in conventional-start ($P < 0.001$). Although random-start has been reported to need 2 days more stimulation than conventional-start, this is applied to moderate ovarian reserve (AMH 1.1–4.0). With this additional stimulation period, oocytes were recovered as same as conventional-start.
Limitations, reasons for caution: Since this is a retrospective study, a prospective study is necessary for final conclusion. Because most patients in random-start are fresh TESE-ICSI patients and most patients in conventional-start are not, the former may not include female factor and the latter may include unexplained infertility, which relates to pregnancy rate.
Wider implications of the findings: This is the first study to show the relevance of random-start stimulation in patients without cancer. Random-start stimulation can be performed as same as conventional-start in patients with good ovarian reserve (AMH >4.0) such as patients who required fresh TESE-ICSI, and also in patients with moderate ovarian reserve (AMH 1.1–4.0).
Trial registration number: N/A.

O-281 Estimation of ovarian response with changing gonadotropin doses: a study of 14,805 women with repeated stimulation cycles

Z. Veleva[1], S.L. Boulet[2], S. Mäkinen[3], H. Tinkanen[4], T. Mikkilä[5], A. Haltia[6], A. Perheentupa[7], C. Tomás[8], H. Martikainen[9], A. Tiitinen[1], J.S. Tapanainen[1], D.M. Kissin[2]

[3]Family Federation of Finland, Helsinki and Oulu Infertility Clinics, Helsinki, Finland
[4]Tampere University Hospital, Obstetrics and Gynecology, Tampere, Finland
[5]Fimlab Laboratory, Tampere, Tampere, Finland
[6]Family Federation of Finland, Turku Infertility Clinic, Turku, Finland
[7]University of Turku, Obstetrics and Gynecology, Turku, Finland
[8]Ovumia Infertility Clinic, Tampere, Tampere, Finland
[9]University of Oulu, Obstetrics and Gynecology, Oulu, Finland

Study question: What are the changes in ovarian response in women with repeated ovarian stimulation cycles?
Summary answer: An increase in gonadotropin dose can improve ovarian response when fewer (<11) oocytes are retrieved in the initial cycle.
What is known already: Ovarian response can be quantified by dividing the total gonadotropin stimulation dose by number of oocytes retrieved (dose/oocyte); a lower dose per oocyte indicates a better response than a higher dose per oocyte. Research from our group has shown negative association between dose/oocyte and success rates. There is ongoing debate on the optimal gonadotropin dose for ovarian stimulation. Oocyte numbers do not always increase with higher gonadotropin doses, and it is not known how to estimate the change in ovarian response for individual patients. Therefore, in current practice, the change in dose from one cycle to the next varies considerably.
Study design, size, duration: Retrospective cohort study of 29,610 ovarian stimulation cycles for non-donor IVF/ICSI performed in 2008–2012 in the U.S. (National Assisted Reproductive Technology Surveillance System, $n = 26{,}996$) and Finland (LUMI database, $n = 2{,}614$). Included were first and second cycles of women treated twice with the same protocol [long gonadotropin-releasing hormone (GnRH) agonist or GnRH-antagonist protocol], with change in total gonadotropin dose in the second cycle between 4,000 and 5,000 IU and with ≥4 oocytes retrieved in both cycles.
Participants/materials, setting, methods: In all, 9,175 women were treated with the long and 5,630 with the antagonist protocol. Data were analyzed separately by protocol. We examined the relationship between number of oocytes retrieved, total gonadotropin dose and total gonadotropin dose/oocyte, and the change in total gonadotropin dose from the first to the second stimulation cycle. Results were stratified by number of oocytes retrieved in the first cycle (4–10 vs. ≥11 oocytes).
Main results and the role of chance: Total gonadotropin dose per oocyte showed a non-linear increase with higher stimulation dose. Increases were more pronounced and started at lower doses in cases with lower oocyte numbers as dose/oocyte was inversely related to the number of oocytes retrieved. In women stimulated with the long protocol, mean stimulation dose increased from 2,399.6 ± 1,995.5 to 2,606.8 ± 1,254.3 IU ($P < 0.0001$), the number of oocytes retrieved increased from 14.4 ± 6.8 to 14.8 ± 6.9 ($P = 0.02$), and dose/oocyte increased from 212.7 ± 180.9 to 230.9 ± 196.1 IU ($P < 0.0001$). Starting stimulation dose was higher in U.S. than in Finnish women (2383.5 ± 1182.2 vs. 2048.7 ± 795.6 IU, $P < 0.0001$). Results in antagonist cycles were similar.

The change in dose/oocyte differed based on the initial number of oocytes retrieved. In women with 4–10 oocytes retrieved, an increase of dose up to 530 (antagonist) and 600 IU (long protocol) was associated with improved ovarian response (lower dose/oocyte). With further increase of stimulation dose, response gradually worsened. In contrast, in patients with ≥11 oocytes retrieved, any increase in dose was associated with poorer ovarian response (higher dose/oocyte).
Limitations, reasons for caution: The second stimulation took place on average 0.6 (antagonist protocol) and 1.3 (long protocol) years after the first one. Despite the big difference in the number of cycles and different stimulation doses, the relationship between stimulation dose and dose/oocyte among U.S. and Finnish patients was similar.
Wider implications of the findings: Our findings may help in tailoring ovarian stimulation for patients with unsuccessful first treatment, especially when trying to estimate individual maximal gonadotropin doses. Future studies could account for differences in ovarian response by comparing treatment outcomes according to dose/oocyte values.
Trial registration number: None.

SESSION 72: THE SURROGATE AND PROSPECTIVE PARENTS EXPERIENCE OF SURROGACY

Wednesday 06 July 2016 **Hall 3 AB** **14:00–15:15**

O-282 Efficacy of a short educational video on fertility knowledge and intentions over 12 months: a randomised controlled trial in young adults.

M. Martins[1], J. Pedro[1], M.E. Costa[1]
[1]University of Porto, Faculty of Psychology and Education Sciences, Porto, Portugal

Study question: What are the effects of a short educational video in increasing fertility knowledge and intentions on young adults over the course of 12 months?
Summary answer: A brief inexpensive educational video increases knowledge and intended age for bearing the last child (but not the first), with most changes sustained over time.
What is known already: Young adults have low fertility knowledge, particularly regarding the effect of age on fecundity and ART success rates. Hence, the increasing childbearing postponement we have been witnessing in Europe for more than 50 years might not be entirely conscious, and raising awareness is imperative. Recent evidence shows that information increases fertility knowledge, but the long-term effectiveness has been seldom analysed, with no evidence regarding the use of RCTs or 1-year follow-ups. Additionally, the efficacy of a video-based intervention has never been evaluated, and these are typically more accessible in terms of language and communication and more cost-effective than written information.
Study design, size, duration: A prospective, two-arm, parallel group, single blind randomized controlled trial was performed between October 2014 and November 2015. A sample size of 73 participants per group (85% power to observe a significant difference $\alpha = 0.05$) was estimated. Participants ($n = 269$) were randomly allocated into intervention group (IG, fertility awareness video) and control group (CG, no intervention), and were assessed before (T0), immediately after (T1), 1-week (T2), 1-month (T3), and 1-year (T4) after the intervention.
Participants/materials, setting, methods: Participants were undergraduates aged 20 years (SD = 2.69) who completed self-report questionnaires including sociodemographic, fertility knowledge and childbearing intentions questions at all time-points. Participants in the IG were exposed to a 2-min video giving information on infertility definition and risk factors, and pregnancy chances according to women's age. Participants in the CC received no stimulus. Mixed models ANOVA with Bonferroni *post-hoc* comparison tested interaction, time and group effects on fertility knowledge and intention variables.
Main results and the role of chance: Subjects were excluded if they declared knowledge of a fertility problem ($n = 2$), being parents ($n = 10$), or were outliers ($n = 2$), leaving 255 subjects, 137 IG and 118 CC. Using a criterion of ≥3 moments within each outcome, missing values were handled using multiple imputation. There were no pretest differences among groups. A significant interaction was found between assessment time and group on knowledge variables (infertility definition; infertility risk factors; spontaneous pregnancy chance; and treatment success, Ps < 0.001) and on desired age for bearing the last child ($P < 0.05$). No significant interaction or main effects were found for the intended age of first child. The IG significantly increased awareness from pre to post test in all knowledge variables, and while there were significant decreases over time, values were still significantly higher compared to CC knowledge at all follow-ups. However, knowledge on female infertility risk factors was not sustained after 1 week. Regarding intentions, while there were no changes in both groups on the intended age of first child, IG subjects significantly reduced their intended age of last child, and this intention was maintained 1 year after visualizing the video. There were no significant differences over time within the CC.
Limitations, reasons for caution: Caution should be exerted when generalizing to older populations or subjects not attending college, as knowledge and

intentions might be different and alternative interventions might be more effective in these groups.
Wider implications of the findings: This study has shown the potential of a 2-min video in reaching a massive population of technology and media users, thus facilitating higher education students' reproductive health empowerment and behaviour change. Further studies should test the influence of knowledge in reproductive behaviours and decisions and analyse potential mediators.
Trial registration number: Clinicaltrials.gov NCT02607761.

O-283 The UK longitudinal study of donor insemination, egg donation and surrogacy families: a follow-up at adolescence

E. Ilioi[1], V. Jadva[1], L. Blake[1], S. Golombok[1]
[1]*University of Cambridge, Centre for Family Research, Cambridge, UK*

Study question: Do families formed through reproductive donation differ from natural conception families in psychological well-being and the quality of parent–child relationships as the children enter adolescence?
Summary answer: All family types were functioning well. Differences reflected particularly positive parent–adolescent relationships in surrogacy families. Egg donation families showed the least positive relationships.
What is known already: It has been suggested that reproductive donation may lead to detrimental outcomes for parent–child relationships and child adjustment due to the absence of a genetic and/or gestational link between parents and children. Although previous phases of this study when the children were aged 1, 2, 3, 7 and 10 years found positive outcomes in family functioning, adolescence may present particular challenges for these families as this is the developmental stage at which issues relating to identity and autonomy become salient and difficulties in parent–child relationships are most likely to arise.
Study design, size, duration: This is the sixth phase of a longitudinal study of surrogacy families, egg donation families, donor insemination families and a comparison group of natural conception families that commenced in 2000.
Participants/materials, setting, methods: This study uses a multi-method, multi-informant approach to data collection. Data were collected from mothers and their adolescent children in their homes and comprised a standardised interview of parenting quality, questionnaires of parent-adolescent relationships and a video-recorded observational task. At the present phase, data were obtained from 32 donor insemination, 27 egg donation, 28 surrogacy, and 54 natural conception families, representing 91, 84, 90 and 100% respectively of participants and Phase 5.
Main results and the role of chance: Interview data were transformed into factor scores of Positive Parenting (warmth, quality of interaction, and sensitive responding) and Negative Parenting (frequency and level of battle, and resolution). There was no difference between family types in Positive Parenting. However, a difference was found for Negative Parenting, F (3, 137) = 12.91, $p < 0.01$, reflecting less negative parenting in the surrogacy families than in the gamete donation families. There was also a difference for the Index of Family Relationships as rated by both mothers and adolescents, F (6, 184) = 5.11, $p < 0.001$, reflecting fewer family relationship difficulties in surrogacy families compared to gamete donation families, and greater family relationship difficulties in egg donation families compared to donor insemination families. Similarly, there was a difference in parental acceptance, F (6, 184) = 3.06, $p < 0.05$, indicating greater maternal acceptance as rated by mothers in surrogacy families compared to gamete donation families, and lower maternal acceptance in egg donation families compared to donor insemination families. There were no differences between family types for the observational measure of mother-adolescent interaction or adolescent adjustment. Longitudinal path analyses indicated stability in parent-child relationships from age 7 to 14 years.
Limitations, reasons for caution: The relatively small sample sizes may mean that differences between family types were not identified due to insufficient statistical power. Also, attrition may have resulted in sample bias such that families experiencing difficulties may have been more likely to drop out.
Wider implications of the findings: Contrary to concerns about potentially negative long-term psychological consequences, the findings of this longitudinal study indicate that families formed by reproductive donation, particularly surrogacy families, continue to function well when the children enter adolescence despite the additional challenges that these families face.
Trial registration number: None.

O-284 Gay men's journeys to parenthood via surrogacy: an exploratory study of UK residents

W. Norton[1], N. Hudson[1], J. Fish[1], L. Culley[1]
[1]*De Montfort University, Leicester, UK*

Study question: What are the motivations and experiences of UK resident gay men who have become fathers, or are considering fatherhood, via surrogacy?
Summary answer: Surrogacy is a complex, multi-faceted route to fatherhood. Men's decision-making is fluid and contextual. Men sought genetic and gestational arrangements in UK and cross-border settings.
What is known already: The number of people having children in the context of a lesbian or gay identity is increasing. However, the evidence available is disproportionately devoted to the experience of lesbian mothers. The limited research on gay fathers has primarily focussed on quality of parenting or transition to parenthood, and largely related to men who have become parents through adoption, co-parenting or through previous heterosexual relationships. There is a dearth of literature on gay men's desire and decision to parent, and few studies focusing on surrogacy as a pathway to parenthood; existing work is focused on the USA and Australia.
Study design, size, duration: This exploratory, qualitative study examined the perspectives of UK resident men. Data regarding the participants' motivations and experiences of surrogacy were collected from a purposive sample of 21 men by means of in-depth, semi-structured interviews conducted between May 2013 and November 2014.
Participants/materials, setting, methods: Fourteen in-depth, face-to-face interviews were conducted with 21 men. Eleven of these interviews were with men who had already become fathers via surrogacy, (7 couple interviews, 4 individual interviews), and the three remaining interviews were with men considering surrogacy (3 individual interviews). Interviews were recorded and transcribed verbatim. Data were analysed in NVivo10 using a systematic, thematic method, informed by an interpretivist approach.
Main results and the role of chance: The presentation reports on demographic characteristics of the participants, their motivation for choosing this specific route to become fathers, the type of surrogacy undertaken, their rationale for accessing surrogacy within the UK or overseas and their experiences of surrogacy. Men's journeys to parenthood via surrogacy were found to be complex and challenging. The participants engaged in multiple surrogacy arrangements in both UK and cross-border settings in their journey to become fathers. These arrangements are very much "planned" pregnancies; however men reported requiring a high level of resilience to achieve their desire of a family. The findings indicate that gay men's decision-making is fluid and contextual, and their needs and priorities change in relation to the length of time it takes to achieve a pregnancy.
Limitations, reasons for caution: The study's small, self-selecting sample limits the generalisation of the findings. However, to the authors' knowledge, no other research has yet to examine the perspectives of gay men choosing surrogacy to become parents within the UK context. This research is therefore an important addition to the limited empirical knowledge base.
Wider implications of the findings: A rapidly increasing number of gay men are exploring the possibility of surrogacy as a means of creating a family. These findings offer insights that may inform the development of policies and practice that are better able to support the needs of gay men throughout their surrogacy journey.
Trial registration number: N/A.

O-285 When the womb is overseas: the meaning-making of the gestational surrogacy in gay couples

N. Carone[1], R. Baiocco[1], M. Morelli[2], V. Lingiardi[2]
[1]*Sapienza University of Rome, Department of Developmental and Social Psychology, Rome, Italy*

[2]Sapienza University of Rome, Department of Dynamic and Clinical Psychology, Rome, Italy

Study question: How do gay couples deal with gestational surrogacy overseas?
Summary answer: Feelings of impotence due to the distance, the importance of a close relationship with the gestational carrier, and gratitude for pregnancy emerged.
What is known already: In the last two decades an increasing number of gay men has entered into surrogacy arrangements to become parents. Previous studies have addressed various aspects of this process, including changes associated with the transition to parenthood, the effect of upcoming fatherhood on how coping with the seemingly contradictory identities as gay and as parents, the motivations for seeking extraterritorial surrogacy, and the ethical issues regarding the potential exploitation of the women involved. However, there remains a dearth of studies that deals with the psychological implications of the physical distance between the gay fathers and the gestational carrier during the pregnancy.
Study design, size, duration: Cross-sectional study. Data were collected between February and August 2015 on 20 gay-partnered fathers who pursued gestational surrogacy overseas in America or Canada because in Italy surrogacy is prohibited by law. Gay fathers were eligible for the study if they were Italian, had at least one child born in their current relationship, and did not receive a friend or relative's oocyte donation.
Participants/materials, setting, methods: Gay fathers were recruited via the Italian Rainbow Families. Joint, semi-structured interviews took place at fathers' home and lasted 60–90 min. After the transcription, a draft was sent to each participant for amendment and approval, often with additional questions. An Interpretative Phenomenological Analysis was performed by two independent coders to identify recurrent themes. Critical feedback was discussed during all phases of analysis in team meeting.
Main results and the role of chance: This study showed three recurrent themes in how Italian gay fathers deal with their gestational surrogacy arrangement overseas. All themes are related to consequences of the distance between fathers and the physical pregnancy. The loss of a sense of control with the subsequent feelings of frustration and anxiety is the main implication of the inability to experience the physical presence of the fetus. As consequence, fathers highlighted the importance of establishing a close relationship with the gestational carrier also to be always posted about ultrasounds and test results. Most couples reported that their emotional involvement is mirrored by the gestational carrier, who want to be called "special auntie" for including in the relationship also their husbands and children. Finally, fathers represented their gestational carrier with images of hospitality and force of nature, expressing a deep sense of gratitude for making them parents.
Limitations, reasons for caution: Conjoint interviews process could have affected fathers' personal points of view, hindering their ability to express themselves if they perceived their opinions as inconsistent with those of their partner. Moreover, retrospectively constructed stories do not allow for an extrapolation of the conclusions made.
Wider implications of the findings: Our findings help in developing strategies to counsel Italian gay parents who experience distance with the gestational carrier and the fetus. The value of defining international guidelines for cross-border reproductive services is also supported at the aim of handling the uncertainty, unease and potential complications arising from the surrogacy process.
Trial registration number: N/A.

O-286 A longitudinal study of the experiences and psychological well-being of Indian surrogates

N. Lamba[1], V. Jadva[1], K. Kadam[2], S. Golombok[1]
[1]University of Cambridge, Centre for Family Research, Cambridgeshire, UK
[2]Corion Fertility Clinic, Corion Fertility Clinic, Mumbai, India

Study question: What is the psychological well-being of Indian surrogates during and after the surrogacy pregnancy?
Summary answer: Surrogates were similar to a matched group of expectant mothers on anxiety and stress. However, they scored higher on depression during and after pregnancy.
What is known already: The recent ban on trans-national commercial surrogacy in India has led to urgent policy discussions regarding surrogacy. Whilst previous studies have reported the motivations and experiences of Indian surrogates no studies have systematically examined the psychological well-being of Indian surrogates, especially from a longitudinal perspective. Previous research has shown that Indian surrogates are motivated by financial payment and may face criticism from their family and community due to negative social stigma attached to surrogacy. Indian surrogates often recruited by agencies and mainly live together in a "surrogacy house."
Study design, size, duration: A longitudinal study was conducted comparing surrogates to a matched group of expectant mothers over two time points: (a) during pregnancy (Phase1: 50 surrogates, 70 expectant mothers) and (b) 4–6 months after delivery (Phase 2: 45 surrogates, 49 expectant mothers). The Surrogates were recruited from a fertility clinic in Mumbai and the matched comparison group was recruited from four public hospitals in Mumbai and Delhi. Data collection was completed over 2 years.
Participants/materials, setting, methods: Surrogates and expectant mothers were aged between 23 and 36 years. All participants were from a low socio-economic background and had left school before 12–13 years of age. In-depth face-to-face semi-structured interviews and a psychological questionnaire assessing anxiety, stress and depression were administered in Hindi to both groups. Interviews took place in a private setting. Audio recordings of surrogate interviews were later translated and transcribed into English.
Main results and the role of chance: Stress and anxiety levels did not significantly differ between the two groups for both phases of the study. For depression, surrogates were found to be significantly more depressed than expectant mothers at phase 1 ($p = 0.012$) and phase 2 ($p = 0.017$). Within the surrogacy group, stress and depression did not change during and after pregnancy. However, a non-significant trend was found showing that anxiety decreased after delivery ($p = 0.086$).

No participants reported being coerced into surrogacy, however nearly all kept it a secret from their wider family and community and hence did not face criticism. Surrogates lived at the surrogate house for different durations. During pregnancy, 66% ($N = 33/50$) reported their experiences of the surrogate house as positive, 24% ($N = 12/50$) as negative and 10% ($N = 5/50$) as neutral. After delivery, most surrogates (66%, $N = 30/45$) reported their experiences of surrogacy to be positive, with the remainder viewing it as neutral (28%) or negative (4%). In addition, most (66%, $N = 30/45$) reported that they had felt "socially supported and loved" during the surrogacy arrangement by friends in the surrogate hostel, clinic staff or family. Most surrogates did not meet the intending parents (49%, $N = 22/45$) or the resultant child (75%, $N = 34/45$).
Limitations, reasons for caution: Since the surrogates were recruited from only one clinic, the findings may not be representative of all Indian surrogates. Some were lost to follow-up which may have produced sampling bias.
Wider implications of the findings: This is the first study to examine the psychological well-being of surrogates in India. This research is of relevance to current policy discussions in India regarding legislation on surrogacy. Moreover, the findings are of relevance to clinicians, counselors and other professionals involved in surrogacy.
Trial registration number: N/A.

SELECTED ORAL COMMUNICATIONS

SESSION 73: GONADOTOXICITY AND FERTILITY PRESERVATION

Wednesday 06 July 2016 **Hall 3 DE** **14:00–15:15**

O-287 ABVD chemotherapy for lymphoma affects number and morphology of primordial follicles in the adolescent and adult ovary

M. McLaughlin[1], T.W. Kelsey[2], W.H. Wallace[3], R.A. Anderson[4], E.E. Telfer[1]
[1]University of Edinburgh, Institute of Cell Biology and Centre for Integrative Physiology, Edinburgh, UK

[2]University of St Andrews, School of Computer Science, St. Andrews, UK
[3]Royal Hospital for Sick Children, Department of Haematology/Oncology, Edinburgh, UK
[4]University of Edinburgh, MRC Centre for Reproductive Health, Queen's Medical Research Institute, Edinburgh, UK

Study question: Does the chemotherapeutic regimen of adriamycin, bleomycin, vinblastine and dacarbazine (ABVD), used to treat lymphoma, effect the number and development of ovarian follicles?

Summary answer: This study reports an increase in the number of non-growing follicles in the ovarian cortex of adolescents and adults previously treated with ABVD for lymphoma.

What is known already: Chemotherapy can compromise oocyte reserve resulting in reduced fertility potential. Treatment of lymphoma is determined by a number of factors including patient age, and type and stage of disease. Early stage Hodgkin's Lymphoma is commonly treated by ABVD, a non-alkylating regimen which has a low risk of premature ovarian insufficiency. Spontaneous ovulation, pregnancy and live births have been reported in patients treated with ABVD. Given the ovarian sparing qualities of ABVD it is important to investigate the histological appearance and distribution of follicles within ABVD-treated ovarian tissue obtained from young and adult patients.

Study design, size, duration: Histological analysis and immunohistochemical investigation of fixed human ovarian cortex from adolescent and adult women with lymphoma treated with ABVD, to ascertain developmental stage and concentration of follicles in comparison with untreated controls and samples from lymphoma patients treated with vincristine, etoposide, prednisone, doxorubicin (OEPA) and cyclophosphamide, vincristine, prednisone, dacarbazine (COPDAC). Human ovarian biopsies (n = 14, ages 12–30 years) were collected with informed consent and Ethical Committee approval.

Participants/materials, setting, methods: Cortical sections were analysed and follicle number and maturity evaluated. Only follicles with a visible germinal vesicle and nucleolus were evaluated to avoid over-counting. Tissue volume was calculated as the sum of the area of all analyzed sections per patient, multiplied by the section thickness. Mean follicle concentration was determined by dividing the total number of follicles per patient by the volume of tissue analyzed. Anti-DDX4 antibody was used to determine germ cell marker expression.

Main results and the role of chance: The majority of follicles in controls and ABVD tissue-treated were non-growing with <25% in controls and significantly fewer (<2%) in post-ABVD group at the primary stage or beyond ($p < 0.01$). Mean follicle concentration observed in pre-chemotherapy tissue closely matched predicted age-matched model-generated values whilst fewer follicles were present in patients treated with OEPA-COPDAC. Tissue from patients treated with ABVD had more than 3 times higher cortical follicle concentration than predicted ($p < 0.01$) with no evidence of increased growth initiation. The length of time between ABVD administration and biopsy collection from patients varied from 4 to 52 weeks. No correlation was detected between this interval and follicle numbers observed. Clusters of follicles and bi-ovular follicles, characteristics of fetal and infant ovaries, were frequently observed in ABVD-treated tissue. The germ cell marker DDX4 was localised in these clustered and multi-ovular structures, indicating that in the post-ABVD adolescent and adult ovary, the morphology of some follicles resembles that seen in infancy. These preliminary data suggest that unlike alkylating chemotherapeutic agents, ABVD treatment does not result in a reduction in the non-growing follicle population in the adult human ovary *in vivo* but may in fact cause an increase. The mechanisms for this are unclear at present.

Limitations, reasons for caution: The concentration of non-growing follicles was not depleted by ABVD in the adolescent and adult ovary, whereas other treatments showed the expected loss of follicle number. The appearance and distribution of non-growing follicles post-ABVD treatment resembled that of the infant human ovary. Mechanisms underpinning these observations are, as yet, undetermined.

Wider implications of the findings: This study corroborates reported ovarian sparing qualities of ABVD, confirming no depletion of non-growing follicles following ABVD. This is the first report of a morphological similarity between post-ABVD treated adult tissue and infant human ovary. Future experiments will investigate the basis for the apparent increase in follicle number post-ABVD.

Trial registration number: N/A.

O-288 Pharmacological administration of ceramide-1-phosphate (C1P) prevents chemotherapy-induced premature ovarian failure (POF)

N. Pascuali[1], L. Scotti[1], M. Di Pietro[1], M. Fragomeno[1], I. de Zúñiga[2], M. Tesone[1], D. Abramovich[1], G. Irusta[1], A. Gómez-Muñoz[3], F. Parborell[1]
[1]Instituto de Biología y Medicina Experimental, IByME, CONICET, Buenos Aires, Argentina
[2]Centro Médico PREGNA Medicina Reproductiva, Buenos Aires, Argentina
[3]University of the Basque Country UPV/EHU, Department of Biochemistry and Molecular Biology, Bilbao, Spain

Study question: We investigated whether the administration of the sphingolipid ceramide-1-phosphate (C1P) can preserve ovarian function from gonadotoxicity caused by cyclophosphamide (CTX) in a mouse model.

Summary answer: C1P protects against CTX-induced gonadotoxicity by preserving the ovarian reserve and contributing to blood vessel formation, providing a novel strategy to avoid chemotherapy-induced POF.

What is known already: Premature ovarian failure (POF) is often a consequence of gonadotoxic chemoradiotherapy. Depleted follicle reserve can present with transient or permanent amenorrhea, infertility and premature menopause. In particular, alkylating agents such as cyclophosphamide (CTX) induce severe follicle loss, the proposed mechanisms being apoptosis and/or damage to ovarian microvascularization. Bioactive sphingolipids, such as C1P, are important regulators of cell homeostasis. As well as sphingosine-1-phosphate (S1P), C1P has a proangiogenic and anti-apoptotic role, with the advantage of a greater stability. Since the efficacy of gonadotropin-releasing hormone analogs is still controversial, we propose C1P as a potential protective molecule for fertility preservation.

Study design, size, duration: Twenty-four 8-week-old female F1 mice (BALB/c × C57BL/6) were separated into four groups (n = 6/group). Mice received either a single intraperitoneal injection of saline (control group) or 75 mg/kg of CTX. Besides, CTX mice received intrabursal administration of vehicle (CTX group) or C1P in two different doses (CTX+C1P groups: 5 µl/ovary; 0.5 mM or 10 µl/ovary; 0.6 mM). Animals were euthanized on day 14, and their ovaries removed and fixed in Bouin's solution for further study.

Participants/materials, setting, methods: Bouin-fixed, paraffin-embedded slides of ovarian tissue were stained with hematoxylin and eosin (H&E) and the number of different stages of follicles was determined in 3 sections per ovary. Data are expressed as the percentage of each follicle type per ovary. Ovaries were also immunostained for anti-Müllerian hormone (AMH) and for vonWillebrand factor by immunohistochemistry (IHC). Quantification of relative vascular areas was performed with ImageProPlus software.

Main results and the role of chance: Firstly, we analyzed follicular structures in H&E-stained ovarian slides. In CTX-treated ovaries, percentages of primary and preantral follicles were lower (both $p < 0.01$) and the percentage of atretic follicles was higher ($p < 0.01$) when compared with control ovaries. Local administration of C1P in CTX-treated ovaries (both CTX + C1P groups) increased the percentage of primary and preantral follicles, and decreased the percentage atretic follicles compared to CTX alone ($p < 0.001$). No significant differences were observed in the% of corpora lutea between groups.

Next, we studied the protein expression of AMH, a well-known marker of ovarian function, by IHC. Consistent with follicular count results, AMH expression decreased in the CTX group compared to the control group, while both doses of C1P increased AMH expression in CTX-treated ovaries.

Furthermore, the IHC for Von Willebrand factor, an endothelial cell marker, showed decreased vascular area in CTX-treated ovaries compared to control ($p < 0.05$). Administration of C1P in both doses restored the vascular area to levels comparable to those of control ovaries ($p < 0.05$).

In all cases, one-way ANOVA, followed by Tukey comparisons, were performed to test for statistical significances. P values < 0.05 were considered significant.

Limitations, reasons for caution: Caution is required for translation of results to human patients. Possible doses and routes of C1P administration remain to be elucidated.
Wider implications of the findings: Our results suggest that C1P preserves ovarian reserve in CTX-induced POF by improving follicular dynamics and ovarian angiogenesis. Given the increasing number of cancer survivors, finding effective, low-cost fertility-extending options for women undergoing life-preserving treatments is critical. C1P could be a novel strategy for fertility preservation in cancer patients.
Trial registration number: NA.

O-289 Evidence that administration of an antioxidant with anticancer properties can prevent cyclophosphamide gonadotoxicity by modulating early ovarian response to oxidative stress

G. Di Emidio[1], M. Vitti[1], M. Di Carlo[1], G. Rossi[1], P.G. Artini[2], R. Sferra[3], A. Vetuschi[3], G. Carta[1], A.M. D'Alessandro[1], C. Tatone[1]
[1]*University of L'Aquila, Department of Life, Health and Environmental Science, L'Aquila, Italy*
[2]*University of Pisa, Department of Clinical and Experimental Medicine, Pisa, Italy*
[3]*University of L'Aquila, Department of Biotechnological and Applied Clinical Sciences, L'Aquila, Italy*

Study question: This work investigates whether oral administration of a natural carotenoid affects ovarian early response to cyclophosphamide (CPM) and prevents gonadotoxicity in female mice.
Summary answer: Crocetin administration prior to CPM prevents gonadotoxic effect on ovarian reserve by modulating SIRT1 levels and mitochondrial damage.
What is known already: Although oxidative stress (OS) is considered one of the mechanisms involved in CPM ovarian toxicity, the efficacy of *in vivo* antioxidant interventions has been poorly investigated. Dietary intake of some carotenoids, including saffron-derived crocetin, is known to exert potent anti-tumor effects and to protect non-malignant tissues against CPM toxicity throughout antioxidant and anti-inflammatory effects. An early sensor of OS is SIRT1, a deacetylase activated in response to changes in the redox state due to ROS increase and mitochondrial failure. By activating numerous targets SIRT1 orchestrates early response to OS and promotes cell survival or apoptosis.
Study design, size, duration: Eighteen CD-1 female mice were divided in three groups and received a single intraperitoneal injection of 100 µl of PBS (CTRL), or an equal volume containing CPM (100 mg/kg) (CPM) or crocetin extracted from saffron (100 mg/kg) *per os* for 15 days prior to CPM administration (Crocetin+CPM).
Participants/materials, setting, methods: Ovaries were analysed at 24 h post-CPM for SIRT1, SOD2, PGC1alpha, pAKT and pFOXO3a expression by Western blotting (WB). At 7 days post CPM ovaries were monitored for relative abundance of ovarian follicles by hematoxylin and eosin staining.
Main results and the role of chance: Crocetin administration prior to CPM-treatment decreased follicles loss and inhibited PI3K/PTEN/AKT pathway involved in activation of follicle recruitment. Primordial and antral follicles were significantly increased in the crocetin+CPM group when compared with CPM-mice (One-way ANOVA and Student–Newman–Keuls Multiple comparison $p < 0.001$). SIRT1 expression in CPM-mice was found to increase revealing the occurrence of OS. Mitochondrial superoxide dismutase SOD2 and the mitochondrial biogenesis activator PGC1alpha decreased suggesting that CPM-induced OS was associated with mitochondrial damage. Crocetin administration under conditions preventing follicle damage allowed the maintenance of basal levels of SIRT1 suggesting that preservation of redox balance can help the ovary counteracting ovarian damage by CPM. We also found that SOD2 and PGC1alpha were increased in crocetin + CPM mice providing evidence for mitochondrial protection.
Limitations, reasons for caution: The main limitation of this study was the absence of direct quantification of SIRT1 enzymatic activity. Results can be translated to humans with caution.
Wider implications of the findings: Our results aim to increase the knowledge of mechanisms underlying ovarian damage by CPM and will be helpful to develop new therapeutic opportunities for preserving fertility in cancer patients based on administration of antioxidants with anticancer properties. SIRT1 may be a biomolecular marker for evaluating cytotoxicity of other chemotherapeutic agents.
Trial registration number: Not required.

O-290 Seminiferous tubule integrity, Sertoli cell maturation and Leydig cell functionality after long-term organotypic culture of human immature testicular tissue

F. De Michele[1]
[1]*Cliniques Universitaires St Luc, Gynecology, Unit 94, Brussels, Belgium*

Study question: Is an organotypic culture system able to provide the appropriate testicular microenvironment for *in vitro* maturation of human immature testicular tissue (ITT)?
Summary answer: Our organotypic culture system provided a microenvironment capable of preserving seminiferous tubule (ST) integrity and Leydig cell (LC) functionality, and inducing Sertoli cell (SC) maturation.
What is known already: Cryopreservation of human ITT containing spermatogonial stem cells (SSCs) is a well-established strategy to preserve fertility in prepubertal boys facing cancer, with a view to obtaining sperm. While in mice spermatogenesis has been replicated in organotypic culture, yielding reproductively efficient spermatozoa, this process has not been achieved in humans as yet. Only a few steps have been completed with adult testicular tissue, with differentiation of preleptotene spermatocytes into early spermatids over the course of 16 days of culture, despite considerable loss of germ cells. To date, no culture system has been described for human ITT.
Study design, size, duration: The study was designed to attempt to *in vitro* mature frozen–thawed ITT. For this purpose, 1 mm^3 tissue fragments from three prepubertal patients aged 2 (P1), 11 (P2) and 12 (P3) years were placed in organotypic culture for 139 days. Culture media, supplemented with either human chorionic gonadotropin (hCG) or testosterone, were compared.
Participants/materials, setting, methods: ST integrity and tissue viability were assessed by histological score and lactate dehydrogenase (LDH) dosage in supernatant. MAGE-A4 and Ki67 immunohistochemistry (IHC) identified spermatogonia, proliferating cells and proliferating spermatogonia. Glial cell line-derived neurotrophic factor (GDNF) was used as a marker of SC functionality. SC maturation was evaluated by anti-Müllerian hormone (AMH) IHC and immunoenzymatic assay, and androgen receptor (AR) IHC. LC functionality was determined by testosterone levels. A mixed linear regression statistical model was applied.
Main results and the role of chance: Results are presented as a mean for all patients (except for AR expression). Tissue viability was preserved, as demonstrated by the decrease in and stabilization of LDH release, and evolution of ST scoring, with the percentage of well preserved STs out of the total number of STs showing no statistical difference during culture ($p \geq 0.05$). GDNF was expressed until day 139, exhibiting SC functionality. Moreover, a significant reduction in AMH expression and release evidenced SC maturation, further confirmed in P2 by a statistically significant increase in AR. Testosterone concentrations in supernatant increased (to 52 nM) in both culture media, indicating LC functionality. Spermatogonia were present up to day 139, although the ratio between MAGE A4-positive cells and well preserved tubules was significantly reduced over the culture period. Intratubular Ki67 staining increased on day 10, followed by a decrease on day 27 and stabilization. While SC showed a proliferation peak on day 10 and day 16, the proliferation rate of spermatogonia remained stable. No statistical difference was observed between the two culture media.
Limitations, reasons for caution: Our work on AR expression is not conclusive, probably due to age differences, and should therefore be extended to subgroups of different ages. Loss of spermatogonia constitutes another limitation to evaluating full functionality of SSCs, and merits further investigation.
Wider implications of the findings: Our culture system mimicking the peripubertal testicular microenvironment with SC maturation and LC functionality, the first to use human ITT, opens the door to a deeper understanding of niche and culture conditions to obtain sperm from cryostored ITT, with the aim of restoring fertility after gonadotoxic treatments.
Trial registration number:/

O-291 Protective effects of *N*-acetylcysteine (NAC) on human spermatozoa exposed to etoposide

A. RabaÃ§a[1], C. Ferreira[1], A. GonÃ§alves[2], A. Barros[3], M.G. Alves[4], M. Sousa[5], P.F. Oliveira[1], R. Sá[1]

[4]*Health Sciences Research Centre CICS, University of Beira Interior UBI, Health Sciences, Covilhã, Portugal*
[5]*Institute of Biomedical Sciences Abel Salazar University of Porto, Centre for Reproductive Genetics Alberto Barros, Laboratory of Cell Biology, Department of Microscopy, Unit for Multidisciplinary Research in Biomedicine UMIB, Porto, Portugal*

Study question: Determine the effect of etoposide, a chemotherapeutic agent, on human spermatozoa and the NAC's cytoprotective properties to preserve spermatozoa quality during exposure to etoposide.
Summary answer: Exposure to etoposide induced severe chromatin alterations and DNA fragmentation on human spermatozoa, however, NAC addition protected the genomic integrity of spermatozoa.
What is known already: Male reproduction is adversely affected by chemotherapeutics. Thus far fertility preservation relies on sperm cryopreservation, but most patients fail to collect semen before treatment and pre-pubertal boys do not produce mature spermatozoa. Etoposide is a semi-synthetic chemotherapeutic that induces permanent double-stranded breaks, affecting spermatogenesis and the overall male reproductive capacity. Therefore, there is a need to identify compounds able to preserve fertility during etoposide exposure without interfering with treatment. *N*-acetylcysteine (NAC), is an L-cysteine precursor with known chemopreventive and antioxidant properties. Additionally, it has been reported that NAC improves semen parameters and protects Sertoli cells from damage induced by oxidative-stress.
Study design, size, duration: During 2015 and after patients (mean age of 33.8 ± 1.2 years) had given informed and written consent, 10 human semen samples presenting absence of known pathologies and intake of medicines; normal physical examination, hormonal profiles and karyotypes; semen analysis without agglutination, immature forms, leukocytes and microorganisms, and a sperm concentration > 15×10^6/ml were subjected to the chemotherapeutic etoposide, to NAC and both drugs in combination *in vitro*.
Participants/materials, setting, methods: Human semen samples were obtained from patients performing spermiogram analysis at a private ART clinic. After incubation for 2 h with etoposide (25 µg/ml), NAC (50 µM) and both drugs in combination, sperm parameters (motility, vitality and morphology) were evaluated according to the WHO guidelines. Sperm DNA fragmentation and chromatin condensation were evaluated by TUNEL and Aniline Blue assays, respectively. Oxidative damages were measured and sperm metabolism was studied by proton nuclear magnetic resonance spectroscopy (^{1}H-NMR).
Main results and the role of chance: Our results demonstrate that etoposide exposure induces severe spermatozoa chromatin alterations and DNA fragmentation. Moreover, exposure of human spermatozoa to etoposide does not induce cellular oxidative damages nor glycolytic profile alterations, providing evidence that etoposide directly affects the cells' DNA. NAC's addition to spermatozoa exposed to etoposide preserved sperm chromatin condensation and reduced sperm DNA fragmentation. Suggesting that NAC acts as a cytoprotector agent, shielding human sperm DNA from etoposide-induced damages.
Limitations, reasons for caution: Etoposide exposure induces DNA damages to human spermatozoa, compromising fertility and being transmittable to the next generation. While NAC addition seems promising, additional research to identify an effective therapy that preserves male reproductive functions must be performed. Until then, fertility preservation options must be deliberated, before treatment, to allow parenthood.
Wider implications of the findings: NAC's ability to preserve human spermatozoa DNA damages induced by etoposide may be of clinical relevance as most cancer patients fail to collect semen prior to treatment. NAC addition may preserve spermatozoa integrity after chemotherapy, assuring sperm would have genomic integrity and could be safely used in Medically Assisted Procreation.
Trial registration number: Not applicable.

O-292 Dysregulation of steroids pathways in granulosa cells may contribute to overexpression of anti-Müllerian hormone system in women with polycystic ovary syndrome

A. Pierre[1], J. Taieb[1], R. Fanchin[1], H. El Hachem[1], M. Grynberg[1], J. Cohen-Tannoudji[1], N. di Clemente[1], C. Racine[1]
[1]*Univ. Paris VII, INSERM U1133, CNRS UMR8251, Paris, France*

Study question: Is the expression of the anti-Müllerian hormone (AMH) system dysregulated by steroids in granulosa cells (GCs) from women with the polycystic ovary syndrome (PCOS)?
Summary answer: Our results demonstrate a dysregulation of steroids signaling in GCs from PCOS women that can contribute to the overexpression of AMH system.
What is known already: AMH and its specific receptor (AMHRII) are expressed in GCs of growing follicles. AMH exerts a repressive role on folliculogenesis. AMH and AMHRII are overexpressed by GCs of women with the PCOS, the most common cause of female infertility. Previously, we have shown that LH could be one of the factors responsible for this AMH system overexpression, but the influence of local steroids cannot be excluded. Indeed, in healthy ovaries, testosterone has been shown to repress AMH expression and oestradiol (E2) to up- and down-regulate it through the estrogen receptor alpha (ERα) and beta (ERβ) respectively.
Study design, size, duration: Twenty-five control women and sixteen dysovulatory PCOS women undergoing assisted reproduction technology procedures were included between September 2013 and June 2015. The effects of E2 and dehydrotestosterone (DHT), a non-aromatic androgen, on AMH and AMHRII expression were studied in lutein GCs from control and PCOS women. The expression levels of ERβ, ERα and androgen receptor (AR) mRNAs were compared in GCs from both groups. The intrafollicular levels of AMH and testosterone were also measured.
Participants/materials, setting, methods: After ovarian puncture, CGs were isolated from the follicular fluids of each woman through a percoll gradient. GCs were cultured for 48 h with E2 or DHT before RNA extraction. When possible, an aliquot of CGs was used to compare ERa, ERb and AR mRNA levels in control and PCOS women before culture. Accumulation of AMH, AMRII, ERa, ERb and AR mRNA was quantified by real-time PCR. Intrafollicular AMH and testosterone concentrations were measured by Elisa.
Main results and the role of chance: AMH and AMHRII expression in GCs from control women was not affected by DHT treatment whereas it up-regulated AMH mRNA levels in GCs from PCOS women (2.3-fold, $p < 0.01$). This stimulatory effect of DHT was associated with an overexpression of AR in GCs from PCOS women (1.4-fold, $p < 0.05$). E2 down-regulated both AMH and AMHRII expression in GCs from control women (1.4-fold, $p < 0.001$ and 1.8-fold, $p < 0.01$ respectively) but had no effect on the expression of these genes in GC from PCOS women. Interestingly, GCs from PCOS women expressed more of ERa than GCs from control women (2-fold, $p < 0.05$). Furthermore, a positive correlation was observed between the ERa/ERb ratio and the intrafollicular AMH concentration in PCOS women. The absence of effect of E2 in GCs from PCOS women could thus be due to a dysregulation of E2 signaling in these cells.
Limitations, reasons for caution: Lutein GCs poorly express AMH and AMHR-II genes. However, AMH and AMHR-II mRNAs can be reliably quantified by real time PCR. Assisted reproduction technology procedures are the only way to get enough cells to perform RNA expression studies and to compare cells from control and PCOS women.

Wider implications of the findings: Our results demonstrate that the regulation of AMH and AMHRII by DHT and E2 is altered in PCOS GCs, in a way which promotes their overexpression. Because AMH inhibits follicles sensitivity to Follicle Stimulating Hormone, this dysregulation could participate to the follicular arrest and the anovulation observed in PCOS patients.
Trial registration number: 0.

O-293 A novel method to demonstrate that pregnant women with PCOS hyper-expose their fetus to androgens: a possible stepping stone for the developmental theory of PCOS

R. Homburg[1], M. Dilgil[1], G. Blum[1], G. Tovar[1], E. Burt[1], A. Gudi[1], A. Shah[1], A. Diamantopoulos[1], A. Layton[2]
[1]*Homerton University Hospital, Homerton Fertility Centre, London, UK*
[2]*Harrogate and District NHS Foundation Trust, Dermatology, Harrogate, UK*

Study question: Are neonatal sebum excretion rates, as indicators of *in utero* exposure to excess androgens, greater in infants born to mothers with PCOS compared to those without?
Summary answer: Neonatal sebum excretion, indicating *in utero* exposure to excess androgens, is evident in most infants of mothers with PCOS compared to none from mothers without PCOS.
What is known already: PCOS has a high degree of heritability. The developmental hypothesis for the origin of PCOS suggests that maternal excess androgens may transfer to the fetus and influence imprinting, leading to altered genetic expression in adult life. Studies on pregnant monkeys injected with testosterone, prevalence of tom-boy behaviour of female children and even an increased incidence of autism have all corroborated the influence of hyper-exposure to testosterone *in utero*. Studies in cord bloods have mainly failed to demonstrate increased concentrations of androgens in newborn but the use of cord bloods has inherent problems.
Study design, size, duration: Prospective case control study to discern whether neonatal sebum excretion is greater in female infants of PCOS mothers compared to non-PCOS. Women with known PCOS (all 3 Rotterdam criteria) and non-PCOS controls, with a female fetus, were recruited at 24 weeks pregnancy and serum testosterone estimated. Sebum was measured for 30 and 60 min within 24 h of birth, at 1 week, 4–6 weeks and 6 months after birth in both mother and child.
Participants/materials, setting, methods: Both PCOS and control group women consented to participate at 20 weeks pregnancy, had blood sampled and were next seen during labour at a single University Hospital. Sebum excretion was measured using Sebutape® in mother and child at birth and at regular intervals at home for 6 months after birth. All semi-quantitative sebum excretion estimations were compared between the two groups and correlated with testosterone concentrations during pregnancy.
Main results and the role of chance: So far in this ongoing study, 17 women have completed the 6 month examination period. The PCOS group (n = 10) and the controls (n = 7) were demographically similar. Mean testosterone was 7.2 nmol/L in PCOS mothers and 3.1 nmol/L in controls at 24 weeks pregnancy. At all time frames, the results of sebum excretion at 30 and 60 min were consistent. The sebum excretion of the mothers in both groups was constant from birth throughout 6 months. All babies were born between 37 and 41 weeks gestational age. Six newborns had detectable sebum excretion at birth, all of them in the PCOS mothers group compared to none in the controls (P = 0.01). Only in one was sebum detectable at 4–6 weeks following delivery. These results suggest that women with PCOS could hyper-expose their fetus to androgens *in utero* and that this may be detected using a simple novel test.
Limitations, reasons for caution: So far, relatively small numbers have completed the full 6 month follow-up. Dry/greasy skin, gestation dates, breast feeding could impact on results. Due to the wider implications of this novel method of examining hyper-exposure to androgens *in utero* and results so far, this is presented as a proof of concept study.
Wider implications of the findings: Higher sebum production in babies of PCOS mothers suggests hyper-exposure of the fetus *in utero* to androgens. Confirmation required but according to the developmental theory of PCOS, this simple novel method could potentially be used to predict development of PCOS in adult life and induce research to eliminate symptoms of PCOS.
Trial registration number: NCT 02654548.

O-294 Prevalence of type 2 diabetes (DM2) at first presentation among women with polycystic ovarian syndrome (PCOS) and normal ovulatory controls

T.Y.T. Ngan[1], T. Fineberg[2], D.V. Morris[3], M.H. Dahan[2]
[1]*McGill University Health Centre, Obstetrics and Gynaecology, Montreal, QC, Canada*
[2]*McGill University Health Centre, Reproductive Endocrinology and Infertility, Montreal, QC, Canada*
[3]*McGill University Health Centre, Endocrinology, Montreal, QC, Canada*

Study question: What is the prevalence of DM2 screened by fasting and 2-h serum glucose levels in a large prospective population of PCOS and control women?
Summary answer: DM2 occurred 6.3% of PCOS and the 2-h oral glucose tolerance test detects a significant number of women who are missed with fasting glucose levels.
What is known already: Between 25 and 40% of women with PCOS are insulin resistant, which puts them at increased risk of DM2, hyperlipidemia, metabolic syndrome, intra-vascular plaque formation and in theory coronary events. DM2 is itself a risk for cardiovascular disease, malignancy and death. Few large studies have been performed prospectively to detect the rate of DM2 in women with PCOS and the relationship to serum androgen levels. This study was performed to see the rate of DM2 in a large prospective North American population of women with PCOS and normal ovulatory controls using both fasting and 2-h oral glucose tolerance test.
Study design, size, duration: An observational cross-sectional analysis from a longitudinal prospective cohort study was held by a University Health Centre at an endocrinology clinic. Enrolment was commenced in 1987 and continues. IRB approval was obtained and subjects signed consents. A total of 1260 participants were recruited. 841 women had PCOS according to the Rotterdam criteria and 419 were ovulatory controls. Even prior to 2003 women with ovulation, clinical or biochemical hyperandrogenism and polycystic ovaries were classified as PCOS.
Participants/materials, setting, methods: Women were screened for congenital adrenal hyperplasia, androgen secreting tumors of the ovary and adrenals. At initial evaluation they underwent a fasting level and 2-h oral glucose tolerance test (OGTT). Age, BMI and serum markers between control and PCOS subjects were compared. Statistical analysis was performed by logistic regression to control for the confounding effects of age, BMI and serum steroid levels. Correlations were also performed.
Main results and the role of chance: Compared to the control group, PCOS participants are younger (p = 0.0001) and heavier (p = 0.0001), and have higher serum androsteinedione (p = 0.0001), testosterone (total, p = 0.0001 and free, p = 0.0001), dehydroepiandrosterone (DHEA) p = 0.0001), dehydroepiandrosterone-sulfate (DHEA-S) (p = 0.0001) and fasting insulin (p = 0.0001) levels.

Among PCOS women, there was a significant correlation between fasting and 2 h serum glucose levels (r = 0.56, p = 0.0001). As expected serum glucose levels at baseline and 2 h correlated significantly with age (p = 0.004, p = 0.0003) and BMI (p = 0.0001, p = 0.0001) respectively. There were significant negative correlations with serum fasting and 2 h glucose levels and serum DHEAS levels (p = 0.03, p = 0.006), as well as 2 h OGTT results and serum estrone (p = 0.01), estradiol (p = 0.003) and baseline DHEA levels (p = 0.05).

The rate of diabetes at first presentation was 6.3% in PCOS women and 8.3% in control subjects. Among PCOS, the detection rate with FG was 2.7% and 5.7% with 2-h OGTT. PCOS had rates of DM based on body mass index (BMI) groupings of <20, 20–24.9, 25–29.9, 30–39.9, ≥40 kg/m^2 of: 2.8, 5.0, 3.1, 8.1 and 35%, respectively. Controls had rates of DM2 based on these BMI groups of: 0, 2.4, 0, 30 and 20%, respectively.
Limitations, reasons for caution: Subject selection bias may have played a role given the recruited control participants may have volunteered in screening of DM2 because they already knew or thought they belong to a population at risk (e.g., family history of diabetes, high BMI).

Wider implications of the findings: There was a strong negative relationship between serum estrogens or adrenal androgens and blood sugar levels. DM2 is a disease of all BMIs in PCOS, becoming common when BMI ≥40 kg/m^2. Among controls it is a disease of BMI ≥30 kg/m^2. This conclusion is from a young population at initial visit.
Trial registration number: This project was started before registration existed. Also it has not been registered yet given it is an observational study, and not interventional.

O-295 Polycystic ovary syndrome (PCOS), hyperandrogenism and overweight/obesity, independently and interactively, increase the risk of metabolic syndrome

M.M. Ollila[1], S. Keinänen-Kiukaanniemi[2], T. Piltonen[1], J. Jokelainen[2], M.R. Järvelin[3], J. Tapanainen[4], S. Franks[5], L. Morin-Papunen[1]

Study question: What is the impact of PCOS, hyperandrogenism and body mass index (BMI) in the development of metabolic syndrome (MetS) or its components in perimenopausal age?
Summary answer: Overweight/obesity, PCOS and hyperandrogenism, independently and interactively, increased risk of MetS. In normal-weight women, PCOS increased risk of dyslipidaemia, but not of other MetS components.
What is known already: Previous studies (mainly cross-sectional) arising from hospital-based populations have reported a cluster of metabolic risk factors and an increased prevalence of MetS in women with PCOS, but the roles of BMI and hyperandrogenism are not clear. Thus, the present study aimed to investigate in a prospective longitudinal population-based cohort the respective roles of PCOS per se, hyperandrogenism, BMI and weight gain on the risk of developing MetS or its individual components [e.g., dyslipidaemia, hypertension or abnormal glucose metabolism (AGM)] by the age of 46.
Study design, size, duration: In a prospective, general population-based follow-up birth cohort (n = 5889), postal questionnaires were sent at ages 14 (95% answered), 31 (81% answered) and 46 (72% answered). Questions about oligoamenorrhea/hirsutism were asked at age 31, and a question about PCO/PCOS diagnosis at age 46. Clinical examination and blood sampling were performed at age 31 in 3115 women, and at age 46 in 3280 women, and oral glucose tolerance test was performed at age 46 in 2780 women.
Participants/materials, setting, methods: Women reporting both oligoamenorrhea + hirsutism at age 31 and/or diagnosis of PCO/PCOS by age 46 were considered as women with PCOS (N = 279). Women without any symptoms at age 31 and without PCO/PCOS diagnosis by age 46 were considered as controls (n = 1577). MetS was defined according to criteria designed for women with PCOS (Rotterdam 2003 PCOS consensus). Pregnant women and current users of hormonal preparations were excluded. Odds ratios (ORs) were calculated by logistic regression analysis.
Main results and the role of chance: MetS (31.2 vs. 16.6%, $p < 0.001$) and its components [hypertension (63.5 vs. 48.5% $p < 0.001$), dyslipidaemia (77.9 vs. 67.5% $p = 0.002$), waist circumference ≥88 cm (57.7 vs. 43.1% $p < 0.001$) and AGM (24.6 vs. 14.2% $p < 0.001$)] were significantly more prevalent in women with PCOS compared with controls.

Normal-weight (BMI <25.0 kg/m^2) women with PCOS had similar prevalence of MetS (3.2% for both groups), hypertension and AGM, but greater prevalence of dyslipidaemia (75.4 vs. 53.7%, $p = 0.001$) compared to normal-weight controls. Overweight/obese (BMI≥25.0 kg/m^2) women with PCOS had a significantly greater prevalence of MetS (46.8 vs. 28.9%, $p < 0.001$), hypertension (72.8 vs. 63.1%, $p = 0.022$) and AGM (33.9 vs. 20.6%, $p = 0.001$), but similar prevalence of dyslipidaemia to overweight/obese controls.

Women with PCOS+MetS had significantly greater BMI at age 14 (p = 0.026) and 31 ($p = 0.002$), weight gain between 31 and 46 years ($p = 0.011$) and free-androgen-index (FAI) at age 46 ($p = 0.026$ after adjustment for BMI) compared with controls with MetS.

In multivariate logistic regression analysis, overweight/obesity, PCOS and hyperandrogenism, independently and interactively, increased risk of MetS. In model I, the OR for overweight/obesity was 13.7 [95% confidence interval (95% CI): 8.54–22.0] and for PCOS 2.02 (95% CI: 1.37–2.98). In model II, the OR for overweight/obesity was 10.30 (95% CI: 7.42–14.32) and for hyperandrogenism 1.75 (95% CI: 1.24–2.46) for the third and 3.14 (95% CI: 2.27–4.34) for the fourth FAI-quartile.
Limitations, reasons for caution: The symptoms and the diagnosis of PCOS were based on self-reporting. The questionnaire at 46 years did not distinguish between polycystic ovaries only in ultrasonography and the syndrome. Ovarian ultrasonography was not available to aid the diagnosis of PCOS.
Wider implications of the findings: These results emphasize the role of early weight management in prevention of MetS and its components in PCOS, as PCOS and overweight seem to increase synergistically the prevalence of MetS. Also normal-weight women with PCOS are at risk for dyslipidaemia, and therefore lipid screening should be considered.
Trial registration number: NA.

O-296 GnRH agonist for triggering final oocyte maturation in patients with PCO at high risk for severe OHSS: factors predicting live birth in subsequent FRET cycles

T. Tarlatzi[1], J. Bosdou[2], C. Venetis[3], G. Lainas[4], I. Sfontouris[4], A. Makedos[2], K. Chatzimeletiou[2], L. Zepiridis[2], A. Mitsoli[2], D. Savaidou[2], T. Lainas[4], B. Tarlatzis[2], E. Kolibianakis[2]

[2]*Aristotle University of Thessaloniki, Unit for Human Reproduction, Medical School, First Department of Obstetrics and Gynecology, Thessaloniki, Greece*
[3]*University of New South Wales, Department of Women's and Children's Health, St George Hospital, School of Women's and Children's Health, Kogarah, NSW, Australia*
[4]*Eugonia, Assisted Reproduction Unit, Athens, Greece*

Study question: Which are the factors that predict live birth in frozen–thawed (FRET) cycles, following gonadotrophin-releasing hormone (GnRH) agonist triggering in high-risk for OHSS patients with PCO?
Summary answer: Number of 2pn oocytes and male factor infertility positively predict live birth during FRET cycles after GnRH-agonist triggering in high-risk for OHSS patients with PCO.
What is known already: The substitution of human chorionic gonadotrophin (hCG) with GnRH agonist for triggering final oocyte maturation is known to eliminate severe ovarian hyperstimulation syndrome (OHSS), thus, enhancing safety of ovarian stimulation. Cryopreservation of all embryos and postponement of embryo transfer in subsequent FRET cycles has been proposed to manage the decreased probability of pregnancy, following agonist triggering and fresh embryo transfer. However, it is still not known whether there are any factors that can predict live birth in these patients.
Study design, size, duration: This is a prospective, observational study of 150 patients with polycystic ovaries (PCO), according to Rotterdam criteria, in whom GnRH final oocyte maturation was triggered with GnRH agonist and embryo transfer was performed in 227 subsequent FRET cycles (range: 1–4), between September 2011 and December 2015.

Participants/materials, setting, methods: Following stimulation with recombinant gonadotrophin, GnRH antagonist and triggering of final oocyte maturation with GnRH agonist, all resulting 2-pronuclei (2pn) oocytes were cryopreserved. The number of 2pn oocytes thawed in each subsequent FRET cycle varied according to the couple's choice, regarding number and stage of embryos to be transferred. Cumulative live birth was estimated by Kaplan–Meier survival function, while Cox proportional-hazards regression was used to assess the predictive ability of various factors on live birth.

Main results and the role of chance: The mean (95% CI) age of patients included was 31.7 (31.2–32.3) years. On the day of agonist triggering, the mean level of estradiol was 4174 (3913–4436) pg/ml, while the mean number of follicles ≥11 mm developed was 25.2 (24.1–26.3). At oocyte pick-up, 20.4 (19.2–21.7) oocytes were retrieved and following fertilization, 11.4 (10.6–12.2) 2pn-oocytes were cryopreserved. Cumulative live birth rate after up to four FRET cycles (1.8, 95% CI: 1.7–1.9 cycles per patient) was 59.8% (95% CI: 45.6–74.4).

Multivariable analysis showed that the presence of male factor (HR: 1.81, 95% CI: 1.04–3.16, $p = 0.036$) and the number of 2pn oocytes (HR: 1.05, 95% CI: 1.02–1.08, $p = 0.001$) significantly predicted live birth, controlling for the effect of female age, number of embryos thawed, number of embryos transferred and stage of embryos at transfer, variables which were not significant in predicting the probability of live birth in univariable analysis. Controlling for the above variables, the presence of male factor in a couple, relatively increased the risk of live birth by 81% per FET cycle, while every additional 2pn oocyte resulted in a relative increase in the risk of live birth by 5% per FET cycle.

Limitations, reasons for caution: A larger study would be necessary to increase the precision of the estimates derived from Cox regression analysis.

Wider implications of the findings: The findings of this study might help clinicians counsel patients with PCO, at high risk for OHSS, regarding the probability of live birth and the presence of relevant predictive factors after GnRH agonist triggering, cryopreservation of all embryos and embryo transfer in subsequent FRET cycles.

P-001 Anti-oestrogen administration increases pregnancy rates in patients with idiopathic male subfertility: a systematic review and meta-analysis

S. Khashaba[1], M. Chapman[1], E. Kolibianakis[2], J. Bosdou[2], M. Costello[1], S. Kim[3], C. Venetis[1]
[1]*UNSW, Women's & Children's Health, Sydney, Australia*
[2]*Medical School – Aristotle University of Thessaloniki, 1st Department of Obstetrics and Gynaecology, Thessaloniki, Greece*
[3]*IVFAustralia, Andrology, Sydney, Australia*

Study question: Is the use of anti-estrogens associated with a higher probability of pregnancy in patients with idiopathic male subfertility?
Summary answer: The use of anti-oestrogens in patients with idiopathic male subfertility is associated with a higher probability of pregnancy as compared to no treatment/placebo.
What is known already: Idiopathic oligoteratoasthenospermia (OTA) represents a challenging clinical condition for the andrologist and several treatment alternatives have been proposed in the published literature. These include anti-oestrogens, anti-oxidants, various forms of androgens, as well as combinations of the above. Anti-oestrogens (tamoxifene and clomiphene citrate) have been used extensively, although there is conflicting data on whether their administration is associated with an improvement in semen characteristics and most importantly in the probability of pregnancy.
Study design, size, duration: This is a systematic review and meta-analysis of randomized controlled trials in which the administration of anti-estrogens was compared to placebo or no treatment in patients with idiopathic male subfertility. Following the development of a search strategy, a computerized literature search was performed in the MEDLINE, EMBASE, CENTRAL, Scopus and Web of Science aiming to identify eligible studies published until 8/1/2016.
Participants/materials, setting, methods: Eligible studies were those offering comparative data from parallel randomized studies. Retrieved citations were screened by two independent reviewers. Primary outcome measure was the achievement of pregnancy and secondary outcome measures included semen analysis characteristics. The effect of anti-oestrogen administration on the hormonal profile (FSH, LH, testosterone) was also evaluated. Standard meta-analytic methodology was used to statistically synthesize the results while the quality of the retrieved studies was also assessed.
Main results and the role of chance: Eleven RCTs, published between 1983–2015, were identified (study median size: 70 patients). Most studies compared tamoxifen with placebo/no treatment (n = 7), while four RCTs studies compared clomiphene citrate with placebo/no treatment. The quality of the included RCTs was generally considered moderate-to-low.

Administration of anti-oestrogens for 3 months resulted in an increase in serum testosterone concentration (standardized mean difference-SMD:+0.69, 95% CI:+0.39 to +0.98) and serum FSH (SMD:+0.80, 95% CI:+0.50 to +1.10) as compared to placebo/no treatment. Serum LH was not significantly different between the anti-oestrogen and control group at 3 months (SMD:+0.46, 95% CI:−0.61 to +1.53).

Sperm count was increased in patients who received anti-oestrogens as compared to those who did not both at 3 (SMD:+0.34, 95% CI:+0.11 to +0.57) and 6 months (SMD:+1.56, 95% CI:+1.25 to +1.88) of treatment. Sperm motility was not significantly increased at 3 months (SMD:+0.24, 95% CI:−0.02 to +0.51) but it appeared significantly higher at 6 months (SMD:+0.86, 95% CI:+0.50 to +1.22). Sperm morphology at three months was not associated with the administration or not of anti-oestrogens.

The probability of spontaneous pregnancy at six months of clomiphene or tamoxifene administration was significantly higher than in the placebo/no treatment group (OR: 1.73, 95% CI:1.03–2.92, n = 531 patients).

Limitations, reasons for caution: Most of the studies included are relatively small and of moderate-to-low quality. Furthermore, heterogeneity between those studies was not negligible and should be taken into account when interpreting the results of this meta-analysis.
Wider implications of the findings: Available evidence suggests that the administration of anti-oestrogens in subfertile men with idiopathic OTA might increase the probability of spontaneous conception. Moreover, it might improve sperm count and motility potentially rendering the provision of intrauterine insemination a more attractive option. Further relevant RCTs are warranted.
Trial registration number: None.

P-002 Levels of reactive oxygen species (ROS) in the seminal plasma predicts the effectiveness of L-carnetine to improve sperm function in men with infertility

W. Vessey[1], C. McDonald[1], A. Virmani[1], P. Almeida[2], C. Jayasena[1], J. Ramsay[1]
[1]*Imperial Healthcare NHS Trust, Andrology, London, United Kingdom*
[2]*Chelsea and Westminster NHS Trust, Andrology, London, United Kingdom*

Study question: To investigate whether L-carnetine significantly improves sperm function, and whether baseline levels of seminal plasma ROS predicts its effectiveness.
Summary answer: 3 month course of L-carnetine (Proxeed Plus) therapy significantly increased total motile sperm count (TMC) in patients with oligoaesthenospermia and elevated baseline levels of ROS,
What is known already: Anti-oxidants such as L-carnetine are commonly used to treat male infertility. Some previous reports suggest L-carnetine improves sperm quality in men, but its mechanism of action is currently unclear. No previous study has investigated whether the anti-oxidant effects of L-carnetine relate to changes in sperm quality, in men with infertility.
Study design, size, duration: Outcome data from a single specialist male fertility clinic were analysed retrospectively. All subjects were treated with Proxeed Plus for ninety days.
Participants/materials, setting, methods: Semen analysis and ROS levels were measured immediately before and following Proxeed Plus treatment. All patients (n = 29) fulfilled the following criteria: infertility >18 months; no previous reported anti-oxidant therapy; no varicocele or intrascrotal pathology. ROS measured in relative light units per second (RLU/s) using an established chemiluminescence assay.
Main results and the role of chance: In men with oligoaesthenospermia (n = 29), L-carnetine reduced ROS markedly (ROS in RLU/s: 105 ± 83, pre-treatment; 6.6 ± 1.8, post-treatment, $P < 0.05$ vs. pre-treatment). Overall, sperm total motile count (TMC) did not change significantly following L-carnetine therapy in men with oligoaesthenospermia (TMC in millions: 24.7 ± 5.7, pre-treatment; 30.4 ± 9.9, post-treatment, $P = 0.37$ vs. pre-treatment). However in men with oligoaesthenospermia and a pre-treatment ROS >10RLU/s (n = 12), L-carnetine increased sperm TMC more than 2-fold (sperm TMC in millions: 18.6 ± 8.8, pre-treatment; 51.2 ± 27.0, post-treatment, $P < 0.01$ vs. pre-treatment).
Limitations, reasons for caution: An RCT is required to confirm the novel observations of this pilot study.
Wider implications of the findings: Men with infertility are increasingly prescribed anti-oxidants, but there remains a paucity of data investigating their effectiveness. We suggest patients with oligoaesthenospermia and elevated levels of ROS may benefit clinically from L-carnetine therapy. These data have important potential implications which warrant further clinical investigation.
Trial registration number: no required.

P-003 Cryopreservation of spermatozoa by means of small and large volume vitrification compared with conventional slow freezing and the effects on post-thaw sperm quality

A. Thijssen[1], T. Nelissen[1], E. Vandormael[2], E. Creemers[2], A. Cox[2], I. Van Der Auwera[2], W. Ombelet[2]
[1]*Hasselt University, Department of Physiology, Hasselt, Belgium*
[2]*Ziekenhuis Oost-Limburg, Department of Obstetrics and Gynecology, Genk, Belgium*

Study question: This study aimed to compare two methods of cryoprotectant-free vitrification, i.e., large volume vitrification and small volume vitrification, with conventional slow freezing.
Summary answer: Compared with conventional slow freezing, small volume vitrification resulted in a significantly higher percentage of post-thaw progressive sperm motility.
What is known already: Due to the rapid cooling rates, vitrification generally requires high concentrations of permeable cryoprotective agents (CPA), such as glycerol or dimethylsulfoxide (DMSO), in order to avoid the formation of damaging ice crystals. While this has proven to be successful for the vitrification of human oocytes or embryo's, this method is inappropriate for the cryopreservation of human spermatozoa because of their low tolerance to permeable CPA. Cryoprotectant-free vitrification, whereby a mixture of human serum albumin (HSA) and sucrose is used, could provide a solution to this problem.
Study design, size, duration: The study was designed as an auto-controlled split-sample study. In total, 41 semen samples were collected from men visiting the fertility centre for a routine sperm analysis. After routine sperm analysis and density gradient centrifugation (DGC) with Pure Sperm, the remainder capacitated sperm samples were divided into three aliquots and cryopreserved by conventional slow freezing, large volume (400 µl) vitrification and small volume (40 µl) vitrification respectively.
Participants/materials, setting, methods: Inclusion criteria were based on WHO reference limits for a normal semen sample: healthy viscosity, pH between 7.2–7.8, concentration of ≥15 million/ml with a good forward progressive motility of ≥32% and ≥4% normal morphology. Sperm quality parameters were analysed after DGC prior to freezing and after thawing of the spermatozoa. The routine parameters sperm motility and morphology were taken into account, as well as acrosome reaction, apoptosis and dead spermatozoa analysed by flow cytometry.
Main results and the role of chance: All three cryopreservation methods resulted in a significant reduction of progressive sperm motility and normal morphology and an increased percentage of acrosome reacted, apoptotic and dead spermatozoa compared with the DGC prepared unfrozen sperm sample ($p < 0.05$). Cryopreservation using large volume vitrification generated a significantly lower post-thaw progressive sperm motility (17.05 ± 1.19 vs. 22.12 ± 1.13; $p < 0.0001$) and higher percentages of acrosome reacted (26.70 ± 3.19 vs. 20.23 ± 2.42; $p = 0.0003$) and dead spermatozoa (69.53 ± 3.45 vs. 60.79 ± 3.55; $p = 0.007$) compared with conventional slow freezing. Small volume vitrification on the other hand, showed a significantly higher post-thaw progressive sperm motility (24.68 ± 1.48 vs. 22.12 ± 1.13; $p = 0.0244$) compared with conventional slow freezing, but also significantly increased the percentage of acrosome reacted spermatozoa (27.39 ± 3.45 vs. 20.23 ± 2.42; $p = 0.0028$). When comparing small and large volume vitrification, small volume vitrification resulted in a significantly higher post-thaw progressive sperm motility (24.68 ± 1.48 vs. 17.05 ± 1.19, $p < 0.0001$) and significantly lower percentages of apoptotic (8.27 ± 1.13 vs. 11.42 ± 0.76; $p = 0.0011$) and dead spermatozoa (69.44 ± 2.114 vs. 69.53 ± 3.45; $p = 0.0266$).
Limitations, reasons for caution: The amount of DNA damage was not taken into account as a parameter of sperm quality. Furthermore, vitrification of spermatozoa has only been researched *in vitro*. There are no results indicating fertilisation and pregnancy rates or birth numbers of healthy new-borns.
Wider implications of the findings: With further research, vitrification of spermatozoa could provide interesting options for future IVF lab practices, as it has previously been described as a simpler, faster and more cost-effective technique than conventional slow freezing.
Trial registration number: Not applicable.

P-004 Determining the prevalence of human papillomavirus in sperm donors

S. Zamora Lopez[1], A. Yoldi[2], Á. Vaquero[2], G.P. Miguel[2], D. Rocío[3], M. Rosaura[2], L.S. Juan[4], G. Candela[5], A. Javier[6], Á. José Antonio[4], O. Carmen[5], G.U. Antonio[3], R. Juan Pablo[7], C. José Antonio[7], F. Rocío[8]
[1]*CEIFER, Quality, Granada, Spain*
[2]*CEIFER, Andrology Laboratory, Granada, Spain*
[3]*MásVida Reproducción, IVF Laboratory, Sevilla, Spain*
[4]*GENETAQ, Genetic Laboratory, Málaga, Spain*
[5]*MásVida Reproducción, Gyneacology, Sevilla, Spain*
[6]*CEIFER, Andrology, Granada, Spain*
[7]*CEIFER, Science, Granada, Spain*
[8]*MásVida Reproducción, Nursery, Sevilla, Spain*

Study question: Which is the HPV prevalence in sperm donors?
Summary answer: The presence of HPV in donor semen poses risks for women taking part in a programme of assisted reproduction with donor sperm.
What is known already: Among both men and women, human papillomavirus (HPV) is one of the pathogens that is most commonly transmitted through sexual relations. Over 100 serotypes have been identified, of which about 40 infect the genital tract. Studies have reported reduced rates of fertilisation and pregnancy and higher rates of miscarriage when semen samples with HPV are used in *in vitro* fertilisation and in intracytoplasmic sperm injection.
Study design, size, duration: 678 sperm ejaculates corresponding to 210 sperm donors were cryopreserved between 2010 and 2014. After thawing HPV was determined. When a positive HPV result was obtained the amplified product was then classified by sequencing.
Participants/materials, setting, methods: 435 ejaculates were cryopreserved after direct addition of cryoprotectant medium to the ejaculate. 243 ejaculates were cryopreserved after selection of the motile sperm according to density gradients, after which cryoprotective medium was added. Computerised system was used for subsequent freezing. Samples were thawed following a rapid thawing protocol at room temperature for ten minutes. The presence of HPV was determined by conventional PCR. The amplified product was detected by agarose electrophoresis and ethidium bromide staining.
Main results and the role of chance: None of the donors presented clinical symptoms of HPV infection at the time of sperm donation. Of the 210 donors studied, the PCR for HPV was negative in 206 cases (98%), non-quantifiable in 3 (1.5%) and positive in 1 (0.5%), in which the presence of DNA from HPV type 66 was detected.
Limitations, reasons for caution: The presence of HPV in donor semen poses risks for women taking part in a programme of assisted reproduction with donor sperm. Therefore, the detection of HPV in donor semen by screening for sexually transmitted diseases during donor selection would enhance patient safety.
Wider implications of the findings: The low prevalence observed (0.5%) may be due to stringent values for donation (concentration >80 × 106 spermatozoids/mL; full motility >50%; morphology >15%). Researchers have shown that the presence of HPV in semen samples is often associated with alterations to sperm parameters such as volume, viscosity, pH, concentration, motility and vitality.
Trial registration number: No.

P-005 Lamivudine, a reverse transcriptase inhibitor, impairs sperm parameters in mice

C. Kitsou[1], L. Lazaros[1], G. Vartholomatos[2], K. Giaka[1], P. Sakaloglou[1], C. Kostoulas[1], P. Ladias[1], I. Bouba[1], T. Tzavaras[3], K. Zikopoulos[1], I. Georgiou[1]
[1]*University of Ioannina, Genetics and IVF Unit, Department of Obstetrics and Gynecology, Ioannina, Greece*
[2]*University of Ioannina, Laboratory of Hematology, Molecular Biology Unit, Ioannina, Greece*
[3]*University of Ioannina, Department of General Biology, Ioannina, Greece*

Study question: To address the effect of Lamivudine, a reverse transcriptase inhibitor, on sperm parameters of FVB/N mice.
Summary answer: Lamivudine caused a significant reduction on the sperm concentration and on percentage of progressively motile spermatozoa. Increased morphological anomalies, especially in midpiece, were also observed.
What is known already: Reverse transcriptase inhibitors have been used in HIV and Hepatitis patients. Several studies have reported a significant effect of antiretroviral drugs on the sperm parameters of HIV-infected patients causing a decrease in the ejaculate volume, the percentage of motile spermatozoa, the sperm motility and in the normal sperm morphology.
Study design, size, duration: Immature male FVB/N mouse 21 days old, were treated with the nucleoside analog reverse transcriptase inhibitor Lamivudine in a dose of 50 mg/kg, for 7 weeks. After treatment, sperm parameters were examined.
Participants/materials, setting, methods: Male mice were sacrificed by cervical dislocation and sperm was collected from cauda epididymis. Sperm concentration and morphological anomalies were determined using a Neubauer hemocytometer. The motility was classified in rapid progressive motility, slow progressive motility, non-progressive motility and no motility.

Main results and the role of chance: The administration of the reverse transcriptase inhibitor Lamivudine impaired the sperm characteristics of male FVB/N mice. The concentration of spermatozoa was markedly reduced in Lamivudine treated mice compared to control mice. The percentage of rapid progressively motile spermatozoa was also decreased and the majority of spermatozoa were moved slowly in circles. Increased morphological anomalies especially in the midpiece and neck defects were also observed. We conclude that the reverse transcriptase inhibition impairs the sperm parameters in mice possibly through the disruption of normal cell growth and differentiation.
Limitations, reasons for caution: Nucleoside analog reverse transcriptase inhibitors may act against reverse transcriptase but also through other pathways such as inhibition of mitochondrial DNA polymerase. However, the exact mechanism of Lamivudine action needs to be further elucidated.
Wider implications of the findings: The results of present study indicate a negative effect of Lamivudine on sperm parameters and potentially on reproductive outcomes. Lamivudine is used as an antiretroviral drug in HIV and Hepatitis patients. Men undergoing such treatment should be regarded as a high risk infertility group in need for a specialized approach.
Trial registration number: No clinical trial.

P-006 A new simple and quick method for sperm preparation and selection prior to ICSI procedure

D. Vizziello[1]
[1]*Milano, Italy*

Study question: The aim of this study is to validate new sperm preparation technique using as reference the standard ones. The primary outcome is clinical pregnancy rate.
Summary answer: The results show that our sperm preparation method for ICSI is not inferior compared to traditional techniques, involving several benefits.
What is known already: Semen preparation procedures before ICSI help either to select the best spermatozoa in terms of motility and morphology, or to separate ROS (Reactive Oxygen Species) through washing and centrifugation. Actually in IVF laboratories the most used are swim-up and gradient centrifugation. During these procedures, the sample is centrifuged and passed from a tube to another many times in a period of time that ranges from 45 to 60 min for swim-up to 60 to 90 min for gradient centrifugation making the process time-consuming.
Study design, size, duration: This is retrospective cohort study including 460 couples treated in our Centre between January 2013 and December 2104. Inclusion criteria were: at least 2 millions motile spermatozoa, female age <38 years, no previous pregnancy, no PCOD, no endometriosis, normal AMH, and at least 4 MII oocytes retrieved. The patients were divided in two similar groups: Group A underwent the new technique was used ($N = 230$) and Group B underwent the standards preparation techniques were used ($N = 230$).
Participants/materials, setting, methods: The new preparation technique consist in the preparation of the ICSI plate with three big drops of medium. Depending on it's concentration, 1 to 3 microliters of it were injected in the proximal drop some minutes before adding the oocytes. We were able to select motile spermatozoa also in case of hyper viscous sperm samples, simply using a micropipette to take a very small amount of sample. No additional procedures were necessary.
Main results and the role of chance: At the moment of ICSI, an adequate number of spermatozoa (>20) reached the superior edge of the distal drop in 100% of cases. De facto we performed an "horizontal layering swim-up", removing spermatozoa from the oxidant environment of the seminal plasma. The final dilution of the semen in the clean buffered culture medium was from 1:60 to 1:20.

The clinical pregnancy rates obtained in the 2 groups were similar: 87/230 (37.7%) in Group A and 84/230 (36.5%) in Group B. Laboratory outcomes were al similar in terms fertilization rate, cleavage rate and blastocysts formation. Moreover, none of the cases developed bacterial infection during handling.
Limitations, reasons for caution: It remains to evaluate if our method can also be beneficial to reduce spermatozoa stress during *in vitro* manipulation.
Wider implications of the findings: The results show that our method for ICSI is not inferior compared to traditional techniques.

However compared to the traditional method, our undoubtley reduces strongly the time need for semen preparation with a lower risk of samples mix-up. Unnecessary semen centrifugation may also be beneficial for the spermatozoa avoiding mechanical stress.
Trial registration number: no trial number for this work.

P-007 Characterization of sperm DNA quality in men presenting with reproductive and non-reproductive cancers

K. Kumar[1], S. Lewis[1], S. Vinci[2], T. Riera-Escamilla[2], M. Fino[2], L. Tamburrino[2], C. Krausz[2]
[1]*Queens University Belfast, Centre for Public Health, School of Medicine Dentistry and Biomedical Science, Belfast, N. Ireland, United Kingdom*
[2]*University of Florence, Andrology Unit, Department of Experimental and Clinical Biomedical Sciences, Florence, Italy*

Study question: Do men presenting with cancer have different types of sperm DNA damage, dependant on disease origin?
Summary answer: Men with both types of cancer had higher levels of both single stranded (SS) and double stranded (DS) DNA damage compared with healthy fertile donors.
What is known already: The presence of SS, but not DS sperm DNA damage has been reported in cancer patients. Further, since different assays were employed to measure sperm DNA damage, the proportion of damage is conflicting. In this study, we compared the levels of DS and SS DNA breaks in the same semen samples using three different DNA damage assays: alkaline and neutral Comet and TUNEL in men presenting with testicular cancer and haematological malignancies in comparison with fertile donors.
Study design, size, duration: Men presenting with testicular cancer ($n = 19$) and haematological malignancy ($n = 13$) at the Andrology Unit, Department of Experimental and Clinical Biomedical Sciences, University of Florence between 2014 to 2015 were recruited into the study. The project was approved by the local research ethics and clinical governance committees and written informed consent for participation was obtained from each subject.
Participants/materials, setting, methods: Semen samples were obtained after 3–7 days of sexual abstinence. All semen samples were analysed according to World Health Organisation guidelines (WHO 2010). Semen samples were used immediately for analysis for DNA damage by the TUNEL assay, and an aliquot were cryopreserved for the later analysis of DNA damage by both Comet assays. Comparisons of DNA damage and seminal parameters between cancer patients and fertile donors were assessed using Mann-Whitney U test ($p < 0.05$).
Main results and the role of chance: The mean values of semen parameters of the two patient groups were above the normal ranges of the WHO standards, 2010. Sperm DNA damage was significantly higher in testicular cancer patients; both in terms of DS breaks (13.4% vs. 7.5%; $p < 0.05$) and in the more abundant SS breaks (37.4% vs. 12.4%; $p < 0.001$) than in the fertile donor group. Similar results were obtained in the sperm of men with haematological malignancy. Here, the average amount of single strand breaks per sperm was 35.0% compared with 12.4% in the donor group; ($p < 0.001$), and there was 10.7% of DS damage per sperm against 7.0% in donor sperm ($p < 0.001$). In contrast, there was no significant difference in sperm DNA damage between patient [(25.6% vs. 27.9% for testicular cancer, and 27.7% vs. 27.9% for haematological malignancies; $p>0.05$)] and donor groups when measured with the TUNEL assay.
Limitations, reasons for caution: The study was limited by the limited number of samples included in each group. Also, as the sperm concentration was inadequate for the performance of all assays on every subject's sample, some samples were only included in two of the three assays.
Wider implications of the findings: The novelty of this study lies in comparing DS with SS DNA damage and test sensitivity in men with two types of cancer and ascertaining sensitivities. Longitudinal studies are ongoing to investigate the inducibility and reversibility of SS and DS breaks following cytotoxic therapy.
Trial registration number: N/A.

P-008 Total motile sperm count has a superior predictive value over the WHO 2010 cut-off values for the outcomes of intracytoplasmic sperm injection cycles

E. Borges Jr.[1,2], A.S. Setti[2,3], D.P.A.F. Braga[2,3,4], R.R. Provenza[5], R.C.S. Figueira[6], A. Iaconelli Jr.[1,2]

[2]*Instituto Sapientiae, Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific Research, Sao Paulo/SP, Brazil*

[3]Fertility Medical Group, Scientific Research, Sao Paulo/SP, Brazil
[4]Universidade Federal de São Paulo UNIFESP, Disciplina de Urologia, Área de Reprodução Humana, Departamento de Cirurgia, Sao Paulo/SP, Brazil
[5]Fertility Medical Group, Andrology Laboratory, Sao Paulo/SP, Brazil
[6]Fertility Medical Group, IVF laboratory, Sao Paulo/SP, Brazil

Study question: Does the total motile sperm count (TMSC) have a superior predictive value for the ICSI outcomes over the World Health Organization (WHO) cut-off values?
Summary answer: In couples with male infertility, the TMSC has a superior predictive value over the WHO 2010 cut-off values for laboratory and pregnancy outcomes after ICSI.
What is known already: Semen analysis is recommended for the investigation of sperm quality and relies on cut-off values that were defined by the WHO in 2010 to distinguish between normal and abnormal samples. However, several reports suggest that the correlation between the WHO classification system and the probability of natural or assisted conception is minimal, if any. Individual semen parameters like volume, concentration, and motility can be combined, resulting in an alternative way to express sperm quality (TMSC), which is obtained by multiplying the volume of the ejaculate by the sperm concentration and the proportion of progressive motile sperm divided by 100%.
Study design, size, duration: This prospective study included patients undergoing ICSI from December 2012 to April 2014 at a private fertility centre. Inclusion criteria were: couples undergoing their first ICSI cycle with fresh embryo transfer performed on day 5 of development, as a result of male infertility as per the WHO 2010 classification system. Three individual statistical analyses were performed.
Participants/materials, setting, methods: Couples were divided into: group-I, TMSC $<1 \times 10^6$; group-II, $1–5 \times 10^6$; group-III, $5–10 \times 10^6$; group-IV, $10–20 \times 10^6$; and group-V, $>20 \times 10^6$, the latter being considered a normal TMSC value. Groups I-IV were combined to form the abnormal TMSC group, and the ICSI outcomes in this group and the normal TMSC group were compared. Finally, the influence of the WHO cut-off value and TMSC on ICSI outcomes was investigated.
Main results and the role of chance: A total of 518 ICSI cycles were analysed. All 518 men were diagnosed with male factor infertility according to the WHO classification system. Conversely, when TMSC was used, 36.7% had abnormal sperm and 63.3% were normal. According to the TMSC, 26 couples were in group-I, 50 in group-II, 38 in group-III, 76 in group-IV, and 328 in group-V. The fertilization rate was significantly lower in group-I compared to group-V (72.5 ± 17.6 vs. 84.9 ± 14.4). The normal TMSC group demonstrated significantly higher fertilization (84.9 ± 14.4 vs. 81.1 ± 15.8) and lower miscarriage (17.9% vs. 29.5%) rates than the abnormal TMSC group. The fertilisation rate was influenced by the sperm concentration (RC: 3.994, R^2: 1.4%), morphology (RC: 8.735, R^2: 0.9%) and TMSC (RC: 3.784, R^2: 1.5%). The formation of high-quality zygotes was influenced by the sperm concentration (OR: 1.64, CI: 1.09–2.46) and TMSC (OR: 1.13, CI: 1.01–1.28). The TMSC was the only parameter to influence the formation of high-quality embryos on D2 (OR: 1.18, CI: 1.03–1.35) and D3 (OR: 1.12, CI: 1.07–1.29), the formation of blastocysts (OR: 1.16, CI: 1.04–1.26), blastocyst expansion (OR: 1.27, CI: 1.01–1.60), and the odds of miscarriage (OR: 0.52, CI: 0.28–0.90).
Limitations, reasons for caution: In this study, a TMSC $> 20 \times 10^6$ was considered normal. Even though previous studies have used this cut-off value, there is no consensus on the normal value. Moreover, an alteration to any seminal parameter, as per the WHO 2010 guidelines, was considered as male factor infertility.
Wider implications of the findings: This is the first study to investigate the association between the TMSC and ICSI outcomes. As these are novel findings for infertile patients undergoing ICSI treatment, prospective randomized studies should be performed to investigate whether the TMSC grading is superior to the WHO classification system for classifying male infertility.
Trial registration number: N/A.

P-009 Sperm DNA integrity test and ART outcome

V. Slavcheva Rilcheva[1], N. Ayvazova[2], L. Ilieva[2], E. Konova[3]
[1]Clinical Institute for Reproductive Medicine, Andrology, Pleven, Bulgaria
[2]Clinical Institute for Reproductive Medicine, Embriology, Pleven, Bulgaria
[3]Center for Reproductive Health, Medical University – Pleven, Immunology, Pleven, Bulgaria

Study question: To investigate influence of sperm DNA fragmentation index (DFI) on pregnancy outcome and pregnancy loss after ART procedure (autologus ICSI, donation eggs ICSI) and IUI.
Summary answer: The three group categories showed that samples with DFI>27% were associated with increased risk of early pregnancy loss.
What is known already: Results from assessment of sperm DNA fragmentation [DFI] by analyzing sperm chromatin structure (DNA Integrity test), have impact on both natural pregnancy and that achieved through ART.

Pilot studies have shown that high levels of DNA fragmentation [DFI>27%] decrease fertility potential in patients undergoing ART procedure, even in men with completely normal standard sperm parameters Therefore, the lack of correlation between conventional parameters of sperm and DNA fragmentation determine DNA fragmentation as a potential source of male infertility in normozoospermic men. That is why further evaluation of sperm DNA fragmentation is required in the study of male infertility.
Study design, size, duration: A prospective study.
Participants/materials, setting, methods: Patients: We investigated men from 531 couples undergoing autologous ICSI procedure [$n = 416$], from couples undergoing donation eggs procedure [$n = 39$] and IUI [$n = 76$].

Interventions: semen analysis, DNA integrity test, embryo scoring by Gardner and Schoolcraft grading system [1999].
Main results and the role of chance: The study shows no statistically significant differences between the group regarding pregnancy rate. [$\chi^2 = 0.55$. $p > 0.05$, OR = 1.25]. However, with increased levels of DFI, the number of pregnancy losses became higher [including biochemical pregnancies and spontaneous abortions] at OR = 5.65. We examined the percentage of grade I blastocysts [by Gardner and Schoolcraft] before donation eggs embryo transfer and found a statistically significant correlation with both the DFI [$\chi^2 = 7.80$, $p < 0.05$] and sperm morphology [$\chi^2 = 6.14$; $p < 0.05$]. Analysis of the relationship between DFI and IUI output (clinical pregnancy, miscarriage) revealed significant correlations in both directions: between DFI and pregnancy rate after IUI ($\chi^2 = 6.29$, $p < 0.05$) and between the DFI and pregnancy development after IUI ($\chi^2 = 6.87$; $p < 0.05$).
Limitations, reasons for caution: No limitation.
Wider implications of the findings: Men with infertility should undergo DNA fragmentation assay in addition to the standard semen analysis. When DFI exceeds 27%, ICSI should be a method of choice, even in cases where the conventional parameters of semen analysis tests are normal.
Trial registration number: NO.

P-010 In male infertility folate cycle genes variants associate with sperm aneuploidy and DNA fragmentation

E. Zhylkova[1], O. Feskov[2], I. Feskova[3], O. Yegunkova[4]
[1]Centre of Human Reproduction Sana-Med, Kharkiv, Ukraine
[2]Ceter of Human Reproduction Clinic of Professor Feskov A.M., IVF Department, Kharkiv, Ukraine
[3]Center of Human Reproduction, IVF Department, Kharkiv, Ukraine
[4]Center of Huma Reproduction, PGD Department, Kharkiv, Ukraine

Study question: Do the polymorphic variants of genes MTHFR (C677T, A1298C) and MTRR (A66G) associate with sperm quality in men with low reproductive function?
Summary answer: Polymorphic alleles in genes of folate metabolism are associated with sperm aneuploidy. The correlation between the genotypes and sperm DNA fragmentation is proved.
What is known already: Polymorphic variants of individual genes controlling stages of spermatogenesis may be associated with motility, morphology and fertility properties of sperm. A decrease in the functional activity of enzymes of folate metabolism is discussed as possible reason of failures in formation of the mature male gametes. Spermatogenesis failures in different stages can lead to DNA damage and chromosome abnormalities in sperm nuclei.
Study design, size, duration: Totally the DNA samples of 136 infertile men with mean age 37.3 ± 5.9 years old were used to study the genotypes of genes MTHFR (C677T, A1298C) and MTRR (A66G). Group I consisted of 112 men: a level of sperm DNA fragmentation was determined for patients in Group I. Group II consisted of 24 men: the level of aneuploid sperm in the ejaculate was determined in Group II. Study's protocol was approved by IRB.
Participants/materials, setting, methods: Real-time PCR was done with the ABI PRISM 7500 real-time PCR system (USA), and SNPs determinations in

the MTHFR and MTRR genes were performed with Applied BioSystem kits (USA). Sperm DNA fragmentation analysis was performed using the method of sperm chromatin dispersion (SCD). The sperm aneuploidies in chromosomes 13, 16, 18, 21, X any Y were analyzed exploiting the method of fluorescence in situ hybridization (FISH) using DNA probes Vysis-Abbott (USA).

Main results and the role of chance: The association of the genotype frequencies of polymorphic variants A66G in MTRR with high level of DNA fragmentation in sperm is proved (df = 2, χ^2 actual = 37.95, χ^2 critical = 9.21, $P < 0.01$). It was found that homozygotes CCAA, TTAA, CCCC for single nucleotide polymorphisms C677T and A1298C in MTHFR gene the level of aneuploidy in sperm for chromosome 16 was significantly higher than in heterozygotes CTAC, CTAA, CCAC (Uempiric = 0, Ucritical = 0, $P \leq 0.05$). For heterozygotes A66G in gene MTRR the average level of aneuploidy in sperm is significantly lower than homozygotes A66A (Uempiric = 1.0 Ucritical = 4.0 $P < 0.05$) for all analyzed chromosomes. A positive correlation between the number of polymorphic alleles of single nucleotide polymorphism A1298C of the MTHFR gene and the level of aneuploidy for chromosome 16 in patients younger then 35 years old (rs = 0.86 ± 0.21, Rcritical = 0.72, $P < 0.05$) is found out.

Limitations, reasons for caution: Present technique can evaluate the DNA fragmentation and aneuploidy level in cases, when the sperm count excides 2 mln/mL.

Wider implications of the findings: The aneuploid sperm or sperm with damaged DNA is able to fertilize the oocytes, but the further formation of the blastocyst and embryo implantation may be blocked at various stages of development. Understanding the genetic basis of aneuploidy in sperm of men will lower the reproductive losses in ART.

Trial registration number: No registration number.

P-011 The novel device of male infertility screening with single-ball lens microscope and smartphone

Y. Kobori[1], T. Shin[1], T. Kobayashi[1], T. Iwahata[1], K. Suzuki[1], Y. Shimomura[1], A. Miyata[1], O. Hiroshi[1], P. Gail[2], N. Craig[2]
[1]*Dokkyo Medical University Koshigaya Hospital, Urology, Koshigaya, Japan*
[2]*University of Illinois at Chicago, Urology, Chicago, USA*

Study question: What is a new method to screen male infertility at home?

Summary answer: We developed an novel semen analysis device consisting of a single-ball lens microscope paired with a state-of-the-art smartphone equipped with a camera.

What is known already: Semen analysis is the key element in the diagnosing the reproductive potential of a male subject. In current practice men must use a clinic or other hospital facility to have their semen analyzed. Once at the clinic, they are asked to produce a semen sample, which is then analyzed by staff at the clinic. Many subjects are not comfortable with this procedure, which they often find embarrassing and expensive.

Study design, size, duration: This study is a laboratory investigation performed in a single university hospital from November 2015 to January 2016.

Participants/materials, setting, methods: We developed a Leeuwenhoek's microscope constructed with a single-ball lens of 0.8mm in diameter inserted into a plastic jacket that attaches to commercial smart phone. The magnification provided by this ball lens was 555 times. A total of 35 semen samples obtained from volunteers were analyzed with a ball lens and three types of smartphone. We analyzed semen samples both with our device and CASA software.

Main results and the role of chance: Sperm concentration counted with a ball lens and each smartphone showed a very strong correlation with the CASA results ($P < 0.001$). In addition, Sperm motility calculated with our device showed significant correlations to CASA ($P < 0.001$). If we found 8 spermatozoa or less on the field of view of iPhone 6s; 5 spermatozoa or less on the field of view of iPhone 5s and LG Optimus, the semen specimens were considered to below the lower reference limit for sperm concentration of WHO 2010 (15 million/ml spermatozoa). The sensitivity was 87.5% and specificity was 90.4% with iPhone 6s. The sensitivity was 100% and specificity was 95.2% with iPhone 5s. The sensitivity was 100% and specificity was 90.4% with LG Optimus Exceed 2.

Limitations, reasons for caution: A disadvantage of ball lens device are the pincushion and reduction in resolution at the periphery of the field of view, which results in only small region of the capture image being in focus due to spherical nature of the focal surface.

Wider implications of the findings: Smartphones have great potential to support semen analysis because they are portable and contain excellent digital cameras. Single-ball lens microscope is inexpensive and easy to use for acquiring digital microscopic movies. This single-ball lens microscope provides an easy solution for global users to screen male infertility at home.

Trial registration number: None.

P-012 Seminal fluid static oxidation reduction potential is lower in seminal fluid that meets WHO criteria for fertile men

H. Elbardisi[1], M. Arafa[2], A. Agarwal[3], S. AlSaid[1], A. Majzoub[3], F. Keyvanifard[1], M. Abohalawa[1], K. AlRumaihi[1], D. Bar-Or[4], K. Bjugstad[4]
[1]*Hamad Medical Corporation, Urology, Doha, Qatar*
[2]*Cairo University, Egypt, Andrology Department, Cairo, Egypt*
[3]*Glickman Urological and Kidney Institute, Cleveland Clinic-Center for Reproductive Medicine, Urology, Cleveland, OH, USA*
[4]*Swedish Medical Center, Research, Englewood, Sweden*

Study question: Identify a cut-off value for sORP that can be used to identify semen that meet the normal reference range of WHO parameters from ones that fail.

Summary answer: Over 90% of samples with a sORP <1.635 mV/sperm concentration were correctly identified as meeting all WHO parameters.

What is known already: Discrete measures of free radicals, antioxidant activity, and oxidative damage suggest an ambiguous relationship between the redox system and male fertility. sORP measures the balance between all oxidants and antioxidants providing a comprehensive status of the redox system. In previous studies, sORP was elevated in brain trauma, stroke, and multitrauma patients, indicating a state of oxidative stress; thus sORP levels may be used to clarify the relationship between the redox system and semen parameters associated with male infertility. Further, a sORP cut-off value may identify semen samples that meet the WHO normal reference values.

Study design, size, duration: This prospective study was carried out in the Male Infertility Clinic of Hamad Medical Corporation on 400 subjects. The study was approved by the institutional review board and patients signed a consent prior to participation. The study subjects were grouped into those that had all normal semen parameters by WHO 2010 guidelines (Group A) and those who failed to meet one or more criteria (Group B).

Participants/materials, setting, methods: Exclusion criteria included azoospermia, presence of STD or chronic disease, use of prescription or OTC medications or antioxidants. Samples were collected and semen parameters assessed using the WHO guidelines (5th edition, 2010). Parameters included: volume, total number, concentration, total motility, progressive motility, and morphology. sORP was measured (mV) using the MiOXSYS system and normalized to concentration (mV/10^6 sperm/mL). For group comparisons, only those samples with a concentration >0.999 × 10^6 sperm/mL were included.

Main results and the role of chance: 364 samples failed to meet one or more criteria for sperm quality; 36 met all WHO criteria. sORP values were significantly lower in samples from Group A ($p < 0.05$). A cut-off value of >1.635 mv/10^6 sperm/mL correctly identified 91.43% of those that met all WHO criteria. Majority of samples (96%) with four or more abnormal sperm parameters ($n = 135$) were identified by the cut-off value. With an increasing number of failed parameters, sORP values also increased suggesting an elevating state of oxidative stress with increasing abnormality. The most commonly failed parameter was progressive motility (97.3%) but this alone did not significantly contribute to increased sORP values. Morphology was the next frequently abnormal parameter (59.0%). Controlling for other criteria, morphology significantly increased sORP, suggesting that oxidative stress is associated with abnormal morphology ($p < 0.05$). The sORP cut-off value (>1.635 mV/sperm concentration), while excellent at differentiating semen with multiple abnormal parameters, was less useful in identifying those samples with only a singular abnormality or marginal infertility.

Limitations, reasons for caution: The current study was performed out of a single fertility clinic and since semen parameters as well as the redox system are subject to many lifestyle variables (ie. regional diets and lifestyles) it would be beneficial to explore the sORP values in regards to semen quality using culturally diverse populations.

Wider implications of the findings: sORP levels may be used as an indicator of sperm quality. Patients with high sORP levels in their semen are good

candidates for treatment of underlying pathology (varicocele, infection, etc.) and may benefit by antioxidant supplementation.
Trial registration number: Not a clinical trail.

P-013 Oxidation reduction potential: a new predictor for sperm morphology in infertile men

M. Arafa[1], H. Elbardisi[1], A. Agarwal[2], S. ALSaid[1], A. Majzoub[1], F. Keyvanifard[1], M. Abohalawa[1], K. AlRumaihi[1]
[1]*Hamad Medical Corporation, Urology/Surgery, Doha, Qatar*
[2]*Center for Reproductive Medicine, Glickman Urological and Kidney Institute, Cleveland Clinic, Cleveland, USA*

Study question: To measure the ORP in semen samples of infertile men and assess its predictive value for abnormal sperm morphology.
Summary answer: ORP level higher than 3.29 mV/106 sperm/ml has an 85.7% chance of having abnormal morphology.
What is known already: Oxidative stress has been associated with infertility in men, and specifically with morphology. sORP measures the balance between all oxidants and antioxidants providing a comprehensive status of the redox system. In previous studies, sORP was elevated in brain trauma, stroke, and multitrauma patients, indicating a state of oxidative stress; thus sORP levels may be used to clarify the relationship between the redox system and semen parameters associated with male infertility.
Study design, size, duration: This prospective study was carried out in the Male Infertility Clinic of Hamad Medical Corporation on 400 subjects over a period of 3 months. The study was approved by the institutional review board and patients signed a consent prior to participation. The patients were grouped in 3 consecutive groups (group 1; $n = 107$; Group 2; $n = 197$; Group 3; $n = 96$) to evaluate the reproducibility of ORP.
Participants/materials, setting, methods: Exclusion criteria included azoospermia, presence of STD or chronic disease, use of prescription or OTC medications or antioxidants. Samples were collected and semen parameters assessed using the WHO guidelines (5th edition, 2010). Parameters included: volume, total number, concentration, total motility, progressive motility, and morphology. sORP was measured (mV) using the MiOXSYS system and normalized to concentration (mV/10^6 sperm/mL). For group comparisons, only those samples with a concentration >0.999 × 10^6 sperm/mL were included.
Main results and the role of chance: There was no statistically significant difference between the 3 data sets as regards patients demographics, semen parameters or hormonal level. The sORP results showed high degree of correlation between 3 datasets which means that a single test reading can provide reliable results.

Significantly higher sORP values were seen in semen samples with abnormal sperm parameters compared to normal in the three data sets with regards to total sperm count, sperm concentration, percentage total motility, progressive motility and percentage normal sperm morphology. Based on data set 1, an sORP cut off value of 3.29 mV/106 sperm/mL was determined to differentiate between semen samples with normal and abnormal sperm morphology percentage. This cut off value was confirmed as being reliable using data sets 2 and 3 with an overall specificity of 89.1% and PPV of 85.7%.
Limitations, reasons for caution: The current study was performed out of a single fertility clinic and since semen parameters as well as the redox system are subject to many lifestyle variables (ie. regional diets and lifestyles) it would be beneficial to explore the sORP values in regards to semen quality using culturally diverse populations.
Wider implications of the findings: sORP levels may be used as a new key perfomance indicator of sperm quality. sORP levels can be determined in patients with different diseases like Varicocele or infection and may help to identify the benefit of using antioxidant supplementation.
Trial registration number: Not a clinical trial.

P-014 Clinical value of ultrasonographic (US) analysis of seminiferous tubules for predicting successful sperm retrieval in patients with non-obstructive azoospermia (NOA)

S. Nariyoshi[1], K. Nakano[2], T. Sho[1], G. Sukegawa[2], Y. Tsuji[1]
[1]*Tenjin Tsuji Clinic, Urology, Fukuoka, Japan*
[2]*Ebisu Tsuji Clinic, Urology, Shibuya, Japan*

Study question: Can US analysis of seminiferous tubules predict the outcome of microdissection testicular sperm extraction (micro-TESE) in patients with NOA?
Summary answer: Thick seminiferous tubules (over 300 μm in diameter) on US images may help predict successful sperm retrieval on micro-TESE in patients with NOA.
What is known already: Micro-TESE has become a technique of choice for retrieving sperm in NOA. At present, however, there are no reliable predictors of the presence of testicular sperm in NOA patients. The concept that underlies micro-TESE is that seminiferous tubules containing germ cells are likely to be larger and more opaque than tubules without sperm production. To our knowledge, there has been no previous US analysis of seminiferous tubules with the aim of predicting successful micro-TESE.
Study design, size, duration: This prospective observational study involved 621 patients with NOA or cryptozoospermia who underwent micro-TESE in our private clinic from July 2003 to December 2015. Endocrinological measurements and US images of the testis were obtained before surgery, and compared with the results of micro-TESE.
Participants/materials, setting, methods: We evaluated 621 patients who underwent micro-TESE. The preoperative evaluation included serum FSH, LH, testosterone measurement and US evaluation of the testis, which involved measurement of the testicular volume and the diameter of seminiferous tubules. US was performed using a 10- or 14-MHz linear array transducer. To optimize US images for visualization of the seminiferous tubules, gain and contrast were appropriately adjusted with graphic software.
Main results and the role of chance: Seminiferous tubules over 200 μm in diameter can be visualized by our method, and we defined those of more than 300 μm in diameter as thick seminiferous tubules. Testicular sperm were retrieved successfully in 128 of the 215 patients (60%) with thick seminiferous tubules observed by US. On the contrary, testicular sperm were found by micro-TESE in only 35 of the 406 patients (9%) whose seminiferous tubules were under 300 μm in diameter. When we used a cut-off value for the seminal tubule diameter of over 300 μm, the sensitivity and specificity for predicting a successful outcome of micro-TESE were 0.79 and 0.81, respectively. Age, serum testosterone, FSH, LH and testicular volume were not correlated with the surgical detection of sperm by micro-TESE.
Limitations, reasons for caution: In patients with intrascrotal calcification including severe testicular microlithiasis, testicular parenchyma cannot be assessed by US.
Wider implications of the findings: US analysis of seminiferous tubules can provide valuable information for determining the extent of spermatogenesis in patients with hypogonadotropic hypogonadism being treated with gonadotropins.
Trial registration number: Not required.

P-015 Randomized correlations of trace elements with reproductive hormones and semen quality among Sudanese infertile males

A.F. Al-Obeid Omer[1], A. Abdella[2]
[1]*Banoon IVF Center, Khartoum, Sudan*
[2]*Al Neelain University, Medical Laboratory Science, Khartoum, Sudan*

Study question: To correlate the serum and semen concentrations of trace elements with reproductive hormones and semen quality among infertile Sudanese males.
Summary answer: The seminal cadmium and lead concentrations had affected the spermogram and reproductive hormones levels, and their serum concentrations had correlated with these parameters.
What is known already: The concentrations of trace elements significantly correlate with azoospermia, oligospermia, and abnormal sperm motility among infertile males. The reproductive hormones levels in male infertility reflect a positive relationship with trace elements concentrations in seminal and serum specimens; and specifically strongly correlated between the luteinizing hormone and seminal cadmium in azoospermic patients.
Study design, size, duration: The study was a case finding hospital, laboratory-based, and prospective. It is a comparative, cross-sectional, quantitative study. 500 infertile males were enrolled in this study that was carried out in Khartoum (Sudan) within a period of two years. The patients studied were infertile males The patients were divided into four groups: 150 azoospermic, 150 oligospermic, 100 asthenozospermic patients, and 100 patients with abnormal sperm morphology. Control group included 100 fertile males.

Participants/materials, setting, methods: A structured interview was conducted to collect demographic and reproductive history. A complete physical and andrological examination was carried out. Semen samples were obtained by masturbation. Serum and semen samples were analyzed for reproductive hormones and trace elements. The reproductive hormones were assayed by ELISA technique; and trace elements were measured by atomic absorption spectrometry. Data were expressed in mean, standard error, standard deviation, and analyzed by the *t*-test, one- way analysis of variance.
Main results and the role of chance: Seminal cadmium concentrations were significantly increased in both azoospermic and oligospermic patients ($p < 0.05$). Seminal lead concentrations showed an insignificant elevation in azoospermic and oligospermic patients ($p < 0.05$). Magnesium and calcium were significantly reduced in azoospermic and oligospermic patients ($p < 0.05$). Manganese, cobalt, chromium and copper concentrations showed no significant variations in seminal plasma. In serum, cadmium concentration was significantly increased in azoospermic ($p < 0.05$), and other trace elements indicated variable concentrations fluctuating within normal range. Lead concentrations were well correlated in both serum and semen of azoospermic and oligospermic patients. Also semen and serum cadmium concentrations were significantly correlated in abnormal sperm motility patients ($p < 0.05$). Serum lead concentrations were well correlated with liquefaction times in azoospermic patients ($p < 0.05$). Significant correlation was recorded between luteinizing hormone and semen cadmium in azoospermic patients, between prolactin hormone and serum lead concentrations, and between follicle stimulating hormone and serum cadmium in abnormal sperm motility patients ($p < 0.05$).
Limitations, reasons for caution: No specific limitations or reasons for caution.
Wider implications of the findings: An increasing number of reports suggest that chemical and physical agents in the environment, introduced and spread by human activity, may affect male fertility.
Trial registration number: This research was approved by the Research Committee of Al Neelain University, Khartoum, Sudan. An oral consent was obtained from both infertile and control patients.

P-016 investigation of the effects of ion channel expression in infertile men patients

S. Carkci[1], A. Karakeci[1], E. Onalan[2], T. Ozan[1], F. Firdolas[1], N. Pirincci[1], I. Orhan[1]
[1]*Firat University Hospital, Urology, Elazig, Turkey*
[2]*Firat University, Medical Biology, Elazig, Turkey*

Study question: To evaluate ion channel expressions in infertile man
Summary answer: These ion channels have an effect on sperm progressive motility and morphology in these ion channels may result in infertility.
What is known already: Infertility which is described as not receiving pregnancy despite unprotected and regular sexual intercourse in a one year period is detected by 15% of the couples. Male and female factor in the aetiology may be detected in similar rates. Especially idiopatic infertility which is recorded as 20% of the cases is a new topic of research.
Study design, size, duration: A hundred and twenty patients, 30 healthy controls were included the study between June 2014 and June 2015. they were divided into 5 equql groups. Group 1 was the normozoospermia (control) group, Group 2 consisted of oligozoospermic, group 3 asthenozoospermic, group 4 teratozoospermic and group 5 oligoasthenoteratozoospermic patients.
Participants/materials, setting, methods: We used total RNA Isolation, Spectrophotometric RNA Measurement, Complementary DNA Synthesis, DNA Amplification with Real Time Polymerase Chain Reaction, methods used for ıon channel assessment.
Main results and the role of chance: In our study we have detected a decrease in the gene expression of CatSper1, 2, 3, 4, KCNU1, Slo3, TMEM16A by asthenozoospermic patients and no significant difference in the Hv1 gene expression. The teratozoospermic group revealed a decrease in CatSper1, 2, 3, 4, KCNU1, TMEM16A and no significant difference in Hv1 and Slo3 gene expressions. By the oligozoospermia group an increase was observed in CatSper1, CatSper4, Hv1, Slo3, TMEM16A gene exspressions, no significant difference was detected in the gene expressions of CatSper2 and CatSper3 wheras a decrease was found in KCNU1 gene expression. The oligoasthenoteratozoospermia group revealed a decrease in CatSper1, CatSper4, Hv1, Slo3 and TMEM16A gen expressions, no difference in gene expressions of CatSper2 and KCNU1 and a decrease in CatSper3 gene expression.
Limitations, reasons for caution: There is a need for detailed evaluation in future studies with larger numbers to investigate this mentioned relation by oligozoospermic and oligoasthenoteraotozoospermic patients.
Wider implications of the findings: We believe that complete clarification of the ion channel functions and developing activator/inhibitör molecules targeting these channels could bring therapeutic options for patients with idiopathic infertility into existence. Also these activator/inhibitor molecules could affect solely on sperm cells and may be the precursors of drugs providing male contraception.
Trial registration number: Firat university local ethic commitee approved study with the registration number:30.10.2013/06-14.

P-017 The structure of human sperm transition proteins of normo- and subnormospermia and its relationship with DNA integrity and conventional sperm parameters

N. Shelko[1], M.F. Hamad[1], M. Montenarh[2], M.E. Hammadeh[1]
[1]*University of Saarland, Department of Obstetrics & Gyneacology, Homburg/ Saar, Germany*
[2]*University of Saarland, Department of Medical Biochemistry & Molecular Biology, Homburg/Saar, Germany*

Study question: What is the relationship between TNP1 and Protamine 1 and 2 in normo and subnormosperm and their relation to conventional sperm parameters?
Summary answer: There are a positive correlation between TNP1, protamine 2 and chromatin condensation and DNA fragmentation of spermatozoa.
What is known already: During spermiogenesis, haploid spermatids undergo complex morphological and physiological changes to differentiate into spermatozoa (Grzmil et al., 2008). These processes include chromatin remodelling mediated by the replacement of histones through protamines (PRM) and transition nuclear proteins (TNPs). Expression levels of PRM1 have been correlated with the DNA damage in mice (Suganuma et al., 2005), Inactivation of Tnps in mice generates a subfertile phenotype, showing less condensed sperm nuclei and elevated level of breaks in the DNA strand and other morphology defects (Yu et al., 2000).
Study design, size, duration: Prospective controlled trail.
Participants/materials, setting, methods: This study carried out at the department of Obstetrics and Gynecology University of Saarland.
20 noromospermia (G.1); and 30 with subnormospermia (G.2) men were enrolled in this study. Semen samples were prepared according to WHO guideline 2010 and sperm nuclear protein were extracted from each semen sample using acid-urea-PAGE and western blot as described previously by Mengual et al. (2003). Chromatin condensation was measured by Chromomycine A3 staining and DNA fragmentation evaluated by TUNEL assay.
Main results and the role of chance: The levels of TNP1 and protamines 1, 2 in normospermia (G.1) were (37.50 ± 3.64 ng/10^6; 416.2 ± 22.61 ng/10^6; 406.8 ± 21.53 ng/10^6) and the corresponding values for G.2 were (128.5 ± 11.89 ng/10^6; 429.7 ± 22.14 ng/10^6 and 323.8 ± 13.77 ng/10^6respectively). A significant differences between G.I and G.II were observed in the concentrations of TNP1 ($p = 0.0001$) and Protamine 2 ($p = 0.001$). Besides, TNP1 correlate significantly negative with sperm vitality ($r = -0.567$; $p = 0.0001$) and sperm motility ($r = -535$; $p = 0.001$) and correlate positively significant with chromatin CMA3 ($r = 0.390$; $p = 0.005$) and TUNEL value ($r = 0.340$; $p = 0.02$).
Beside, G.I showed a significantly higher ($p = 0.0001$) sperm count (78.00 ± 6.19 mill/mL) motility ($51.50 \pm 4.85\%$), vitality ($65.50 \pm 2.58\%$) and membrane integrity ($74.50 \pm 1.69\%$) in comparison to the values in G. II. (39.53 ± 5.34 mill/mL; $23.33 \pm 1.79\%$; vitality $36.33 \pm 2.57\%$; and $55.00 \pm 1.88\%$ respectively).
Limitations, reasons for caution: No limitations.
Wider implications of the findings: Funding from University of Saarland Budget.
Trial registration number: No registration.

P-018 A prospective double-blind randomized placebo-controlled study of the effect of vitamin E on semen parameters in infertile men

A. Exposito[1], J. Perez-Sanz[1], L. Crisol[2], F. Aspichueta[3], S. Quevedo[4], M. Diaz-Nuñez[1], R. Mendoza[1], J.I. Ruiz-Sanz[5], T. Martinez-Astorquiza[1,4], R. Matorras[1,3]
[1]*Cruces Hospital, Human Reproduction Unit, Cruces Baracaldo Vizcaya, Spain*

[2]San Sebastian Hospital, Human Reproduction Unit, San Sebastian Guipuzcoa, Spain
[3]IVI Bilbao, Human Reproduction Unit, Leioa Vizcaya, Spain
[4]Quiron Bilbao, Human Reproduction Unit, Bilbao Vizcaya, Spain
[5]University of the Basque Country, Department of Physiology, Leioa Vizcaya, Spain

Study question: To evaluate the efficacy of an oral vitamin E on semen quality parameters, administrated once daily for three months in infertile couples just prior to *in vitro* fertilization (IVF)cycles.
Summary answer: Our study has reported that treatment with vitamin E has a beneficial effect on sperm parameters and pregnancy rates after IVF cycles.
What is known already: Oxidative stress (OS) plays an important role in the pathophysiology of male infertility. Human spermatozoa are redox active cells capable of generating small amounts of reactive oxygen species (ROS) which are needed for maduration, capacitation, hyperactivación, acrosome reaction and oocyte fusion. ROS levels are continuously neutralized by antioxidant systems such as enzymes (superoxido dismutase (SOD), catalase, Glutatuhione System (GSH) and non-enzymatic antioxidants (vitamins (E, C, D), polyphenols (flavonoids) and trace mineral among others).

It has not been established yet the optimal dose of vitamin E, duration of treatment or the subpopulation of infertile patients who might benefit most from vitamin E therapy.
Study design, size, duration: This study was designed as a prospective, placebo-controlled and double blinded analysis of the *in vivo* effects of vitamin E, administered orally for 3 months in men undergoing *in vitro* fertilization cycles. It was perfomed at Cruces University Hospital in Spain from 2010 to 2014.

The study was approved by the Institutional Review Board of Cruces Hospital, and all participants signed written informed consent for the research.

The semen samples were obtained from 114 males subjects.
Participants/materials, setting, methods: 114 men were included in the study. Of these, 55 patients were treated with vitamin E (alpha-tocopherol) and 59 patients with placebo daily for three months.

The variables taken into consideration before and after antioxidant treatment were sperm concentration ($n \times 10^6$/mL), sperm count (10^6/ejaculate) and progressive motility (a + b%).

The patients were grouped into three categories such as normozoospermic, oligozoospermic and asthenozoospermic.

All patients were evaluated for sperm parameters according to the 2010 WHO criteria.
Main results and the role of chance: During the pretreatment phase no differences in baseline parameters or semen parameters were found between the placebo and vitamin E group.

After treatment, the sperm concentration ($n \times 10^6$/mL) had an improvement of 8.6% (68.9 ± 47.2 to 76.1 ± 40.1) in the placebo group and 23.8% (49.9 ± 41.7 to 72.3 ± 41.2) in the vitamin E group. The differences were statistically significant between groups ($p = 0.049$).

The percentage of progressively motile spermatozoa (a + b) increased a 5.8% (42.8 ± 19.5 to 49.1 ± 18.8) in the vitamin E group but in the placebo group (47.6 ± 17.4 to 46.2 ± 19.1) no changes were observed. The differences were statistically significant between groups ($p = 0.020$).

Although the sperm count (10^6/ejaculate) was improved in both groups (211.1 ± 188.5 to 221.2 ± 181.9 in placebo group and 164.4 ± 171.5 to 228.4 ± 187.0 in vitamin E group) the differences were not statistically significant ($p = 0.050$).

The pregnancy rate was 25.0% in placebo group and 45.2% in vitamin E group with differences statistically significant ($p = 0.049$).

When the patients of both groups (placebo and vitamin E groups) were divided into three categories as normozoospermic, oligozoospermic and asthenozoopermic some differences were found: 50% of oligozoospermic men improved sperm concentration ($n \times 10^6$/mL) ($p = 0.016$) and sperm count (10^6/ejaculate) ($p = 0.004$) at normozoospermic levels.

This trend was also observed in asthenozoospermic men but differences were not significant ($p = 0.057$).
Limitations, reasons for caution: Reduced sample size.
Wider implications of the findings: Understanding the physiologic and pathologic effects of free radical on sperm function will help in designing new and effective treatment strategies in male infertility. Our study has clinical relevance because the treatment with vitamin E shows a significant improvement in sperm motility and pregnancy rates comparing with placebo group.
Trial registration number: EudraCT 2007-000960-25.

P-019 Oxidation-reduction potential (ORP) of spermatozoa selected for intracytoplasmic sperm injection (ICSI) after exposure to polyvinylpyrrolidone (PVP) and hyaluronic acid (HA)

A. Agarwal[1], S. Roychoudhury[1], S. Esteves[2], I. Maldonado Rosas[3], R. Sharma[1], S. Gupta[1]
[1]The Cleveland Clinic Foundation, American Center for Reproductive Medicine, Department of Urology, Cleveland Clinic, Cleveland, OH, USA
[2]ANDROFERT, Center for Male Reproduction, Campinas, Brazil
[3]Ingenes Mexico, IVF Clinic, Mexico City, Mexico

Study question: Are there differences in the ORP of human spermatozoa exposed to PVP and HA prior to ICSI?
Summary answer: After exposure for 20 minutes and 1 hour, the lowest levels of ORP were noted in PVP-treated spermatozoa compared with the controls and HA-treated group.
What is known already: PVP is used in ICSI to facilitate sperm immobilization. It may, however, adversely impact the sperm function including DNA fragmentation, delays in calcium oscillations and loss of membrane integrity. Use of HA, a physiologic alternative to PVP, has been shown to help deselect sperm with DNA fragmentation, which may result in better embryo development after ICSI. ORP is a comprehensive measure of oxidative stress as it provides the overall balance between all available oxidants and antioxidants in a given sample. Static ORP (sORP) measures the current state of activity between oxidants and antioxidants.
Study design, size, duration: Human semen samples from healthy consented donors ($n = 11$) with normal semen parameters according to the 2010 WHO guidelines were used for sperm preparation by density gradient centrifugation. Washed specimens were incubated with either PVP (Origio, Denmark) or HA (SpermCatch, Nidacon, Sweden). Controls were treated with sperm wash medium only (Quinn's Advantage medium with HEPES; Origio, Denmark). sORP was measured after 20 minutes and 1 hour of exposure.
Participants/materials, setting, methods: Sperm preparation adjusted to 5×10^6/mL was added to PVP, HA or control group in a 3:10 ratio (vol./vol.). ORP was measured using a novel galvanostat-based technology with a MiOXSYS Analyzer (Aytu Bioscience, Englewood, CO) in triplicate at room temperature. Data were normalized and represented as mV/10^6 sperm for sORP. Paired-t test was used to compare the data and differences were considered statistically significant at the level of $p < 0.05$.
Main results and the role of chance: Sperm sORP levels differed significantly ($p < 0.05$) among the three groups after both 20 min and 1 h of exposure. The lowest sORP levels were noted in PVP-treated group followed by the HA-treated group and control group after 20 min and 1 h of exposure. Prior to any treatment with PVP or HA (Time 0), the sORP level in the control group (mean ± standard deviation) was 57.60 ± 0.63 mV/10^6 sperm. After 20 minutes, sORP levels were as follows: PVP-treated = 46.27 ± 0.37; HA-treated = 50.88 ± 0.15 and control = 57.49 ± 0.79, respectively. These values were not significantly different after 1 hour: PVP-treated = 47.04 ± 1.01; HA-treated = 50.80 ± 1.23 and control = 57.30 ± 2.66, respectively.
Limitations, reasons for caution: Samples were obtained from normozoospermic men. Further experiments involving sperm from infertile men may be helpful in confirming our findings. Embryo development and implantation potential of resulting embryos from sperm populations with different ORP were not assessed.
Wider implications of the findings: Levels of oxidative stress as represented by sORP levels were lowest in PVP-treated group, possibly because PVP contains a synthetic serum replacement – a chelating agent not present in HA. The findings indicate that PVP may have antioxidant properties and support continued use of PVP for sperm manipulation in ICSI processes.
Trial registration number: Not applicable.

P-020 Two-cell mouse embryo assay (MEA) outcome after intracytoplasmic injection of human sperm selected in polyvinylpyrrolidone (PVP) or hyaluronic adid (HA)

I. Maldonado Rosas[1], S. Roychoudhury[2], R. Sharma[2], A. Agarwal[2]
[1]Instituto Ingenes, IVF Lab, Mexico City, Mexico
[2]Cleveland Clinic, American Center for Reproductive Medicine, Department of Urology, Cleveland, OH, USA

Study question: Does immobilization in HA rather than the commonly used PVP affect the embryo development potential after intracytoplasmic sperm injection (ICSI) into mouse oocytes?

Summary answer: No significant differences were noted in oocyte degeneration rate and percentage of embryos at the two-cell stage among the PVP-treated, HA-treated and control groups.
What is known already: PVP is used to facilitate handling and immobilization of sperm before ICSI. However, it can adversely affect the sperm including loss of integrity of plasma membrane, acrosomal and mitochondrial membranes. Such damage induces deterioration of the chromatin, axonemal tubules, fibrous sheath, and accessory fibres. Also, this synthetic compound can cause sperm DNA damage, remain in the oocytes for a prolonged period after injection and further cause decondensation within the oocyte. HA, on the other hand, is a substance that naturally occurs in human reproductive tract, and some preliminary data suggest that it may represent a good physiologic alternative to PVP.
Study design, size, duration: Human semen samples with normal semen parameters according to WHO 2010 guidelines were prepared by density gradient centrifugation followed by sperm selection in PVP (Origio, Denmark) or HA (SpermCatch, Nidacon, Sweden) or culture medium only (Quinn's Advantage medium with HEPES, Origio, Denmark; control). Immobilized sperm from each group were microinjected into mouse oocytes to assess oocyte degeneration rate, and the percentage of embryos at the two-cell stage as surrogate for sperm decondensation.
Participants/materials, setting, methods: Frozen mouse oocytes ($n = 94$) were thawed and surviving oocytes ($n = 83$) were randomized into three groups for ICSI: PVP-treated ($n = 28$); HA-treated ($n = 27$) and control ($n = 28$). After ICSI, oocyte degeneration rate was noted and percentage of embryos at the 2-cell stage was assessed as surrogate for sperm decondensation. Chi-square test and Fisher's exact test were used to compare the data; $P < 0.05$ was considered statistically significant.
Main results and the role of chance: Of 94 mouse oocytes thawed, survival rate was 88% (83/94). The degeneration rates of oocytes measured 18 hours post ICSI were comparable across the groups ($P = 0.93$; Chi-square test): 32% (9/28) in PVP group, 33% (9/27) in HA group, and 29% (8/28) in control group. The survival rate of embryos at the two-cell stage 24 hours after ICSI was comparable across the groups ($P = 1.0$; Fisher's exact test): 74% (14/19) in PVP-group, 72% (13/18) in HA-group and 75% (15/20) in control group.
Limitations, reasons for caution: Further experiments involving a larger sample size may be helpful in confirming the findings of our study. Other outcome measures previously linked to the detrimental effect of PVP were not tested.
Wider implications of the findings: Our results demonstrate no significant differences in mouse oocyte degeneration rate and, the percentage of embryos at the two-cell stage assessed as surrogate of sperm decondensation among the PVP-and the HA-bound human sperm after ICSI. The use of HA may be a physiologic replacement for the synthetic compound PVP.
Trial registration number: Not applicable.

P-021 Combination of density gradient centrifugation and magnetic-activated cell sorting significantly reduce sperm DNA fragmentation index of semen samples

H.J. Chi[1], S. Kwak[1], S. Kim[1], Y. Kim[1], J. Park[1], C. Yoo[1], K. Lee[2], I. Park[2], H. Sun[2], J. Kim[2]
[1]*Mamapapa&baby Hospital, IVF Laboratory, Ulsan, South Korea*
[2]*Mamapapa&baby Hospital, Ob/Gy, Ulsan, South Korea*

Study question: Is it possible to reduce sperm DNA fragmentation index by sequential treatment of density gradient centrifugation (DGC) and magnetic-activated cell sorting (MACS)?
Summary answer: Combination treatment of DGC and MACS showed a significant synergy effect on reducing the DFI of semen samples.
What is known already: Density gradient centrifugation is widely used to collect the sperm with progressive motility from the raw semen. Recently, an inverse correlation between sperm DNA fragmentation and progressive motility was observed in our previous studies. MACS recently has been introduced for isolation of non-apoptotic sperm because apoptosis is well known to be a major cause of sperm DNA fragmentation. Although a few of authors reported a positive effects of DGC and MACS on reducing the sperm DFI, further studies need to investigate the effect of combination of DGC and MACS on isolation of the sperm with high DNA integrity.
Study design, size, duration: This is a prospective study performed from Jan. 2015 to Aug. 2015.
Participants/materials, setting, methods: 29 normozoospermic semen samples were obtained from the volunteers. Sperm with progressive motility were isolated from raw semen by DGC, and then the motile sperm was separated into apoptotic and non-apoptotic sperm by using MACS ART Annexin V system kit. Sperm DFI was evaluated with Halosperm test.
Main results and the role of chance: Sperm DNA fragmentation index (11.6%) of non-apoptotic sperm was significantly lower than that (21.1%, $P < 0.01$) of apoptotic sperm which means a positive effect of MACS on reducing the sperm DFI. An inverse correlation between sperm DFI and progressive motility was observed in both apoptotic ($r = -0.506$, $P < 0.01$) and non-apoptotic sperm ($r = -0.508$, $P < 0.01$). Density gradient centrifugation also significantly reduced the sperm DFI (11.5%) of raw semen down-to 8.1% ($P < 0.05$). The sperm DFI (11.5%) after DGC alone was significantly re-decreased to 4% ($P < 0.05$) after combination treatment of DGC and MACS.
Limitations, reasons for caution: The limitation in the number of the semen samples involved in this study which slightly reduced the statistical analysis power.
Wider implications of the findings: This combination treatment will be a practical and efficient method to isolate the sperm with high DNA integrity for the patients who showing high sperm DFI.
Trial registration number: None.

P-022 Addition of myoinositol into sperm preparation medium improved the sperm motility and pregnancy rate of IUI cycles in asthenozoospermic patients

J.Y. Park[1], S.G. Kim[1], Y.Y. Kim[1], S.J. Kwak[1], C.S. Yoo[1], K.H. Lee[1], I.H. Park[1], H.G. Sun[1], J.D. Cho[2], H.J. Chi[1]
[1]*Infertility Center, Mamapapa&baby Ob/Gy Clinic, Ulsan, South Korea*
[2]*Infertility Center, Elle-Medi Clinic, Changwon, South Korea*

Study question: This study was performed to evaluate the effects of myoinositol (MI) on sperm motility and clinical outcomes of IUI cycles.
Summary answer: Myoinositol improved the sperm motility and pregnancy rate of IUI cycles in asthenozoospermic patients, but it didn't show any beneficial effect in normozoospermic patients.
What is known already: Percentage of spermatozoa with high mitochondrial membrane potential (MMP) levels showed a correlation with high fertilization rate because the MMP level of sperm is directly associated with motility of sperm. However the MMP level is inversely correlated with ROS level that induce a damage to the mitochondrial membrane. MI increased the percentage of spermatozoa with high MMP level in the patients with abnormal sperm parameters. Moreover, MI increased fertilization and pregnancy rates in women who failed to pregnancy due to poor oocyte quality by reducing oxidative stress in culture conditions.
Study design, size, duration: A prospective study was carried out to investigate the effects of MI on sperm motility and clinical outcomes in IUI cycles from August to December 2015. Total 376 patients (IUI cycles) were divided into two groups according to the addition of MI into sperm preparation medium; MI group ($n = 144$) and Control group ($n = 232$). Both groups were subdivided into 3 groups according to the result of semen analysis; Normozoo-, Asthenozoo-, and Oligoasthenozoo-spermic patient groups.
Participants/materials, setting, methods: Raw semen was treated with density gradient centrifugation for isolation of motile sperm, and then the motile sperm was washed twice with Ham's F-10 with or without 5mg/ml MI. An antioxidant effect of MI on the sperm motility suppressed by hydrogen peroxide was investigated to identify the enhancing effect of MI on motility.
Main results and the role of chance: The effects of various MI concentrations (0, 2, 5, 10, 20 mg/ml) on motility of raw semen was investigated. Even the treatment with low concentration of 5mg/ml significantly increased the motility (38.1%) compared to the treatment without MI (21.5%, $P < 0.01$). Unlike the raw semen, however, in the motile sperm isolated by density gradient centrifugation, the sperm motility in the MI group was not different from the motility in the control group (87.1% vs 83.5%). Between the MI and Control groups, there were no differences in the age of patients (female; 33.7 vs. 34.1, male; 35.9 vs.35.9), volume (3.4 vs. 3.3ml), count (89.5 vs. 101.8×10^6/ml), and motility (42.1 vs. 47.3%) of the raw semen. The pregnancy rates of asthenozoo- (28.8%) and oligoasthenozoo-spermic patients (33.3%) in the MI group were higher than those of control group (18.8 and 25.0%, respectively), although a statistical significance was not observed in the difference. Addition of hydrogen peroxide

significantly decreased the sperm motility in a concentration-dependent manner. The suppressive effect of hydrogen peroxide was significantly reversed by addition of MI.
Limitations, reasons for caution: The limitations of the present study included the limited number of samples tested, which slightly reduced the study's statistical power.
Wider implications of the findings: MI improved sperm motility and pregnancy rate of IUI cycles in asthenozoospermic patients. The beneficial effect of MI may be associated with antioxidant activity as well as improvement of MMP level. Therefore, MI also may be useful for IVF-ET cycles in asthenozoospermic patients.
Trial registration number: None.

P-023 PAWP expression and distribution in spermatozoa is not associated with fertilization failure

T. Freour[1], M. Barragan[2], A. Ferrer-Vaquer[2], V. Vernaeve[3], R. Vassena[2]
[1]*CHU Nantes, Médecine de la Reproduction, Nantes Cedex 01, France*
[2]*Clinica Eugin, Research Department, Barcelona, Spain*
[3]*Clinica Eugin, ART Department, Barcelona, Spain*

Study question: Is PAWP protein expression and distribution in sperm cells associated with fertilization failure in cycles with donated oocytes?
Summary answer: PAWP protein expression and distribution in sperm cells is not associated with fertilization failure in cycles with donated oocytes.
What is known already: Successful fertilization in mammals depends on sperm cell's ability to initiate intracellular Ca^{2+} oscillations in the oocyte. This phenomenon is elicited by a Sperm Oocyte Activating Factor (SOAF), whose quantitative and/or qualitative defect should result in fertilization failure. Post-Acrosomal WW domain-binding Protein (PAWP) has been proposed as a putative SOAF, but its ability to activate oocyte has been questioned in the recent literature in a rodent model of fertilization, and its implication in fertilization failure remains unknown. Identifying and studying SOAFs in the human species is particularly difficult as oocyte factors contributing to the phenotype cannot be usually excluded.
Study design, size, duration: This monocentric prospective cohort study was conducted in 2015 on 8 couples referred either for an autologous cycle with woman's own oocytes (4 couples) or for a cycle with either donor oocytes following female ovarian insufficiency (4 couples). In all cases, elective ICSI was performed, resulting in fertilization failure (<10% fertilization rate). All oocyte donors were of proven fertility. A cohort of 8 sperm donors with proven fertility was used as control.
Participants/materials, setting, methods: In each male patient and donor, PAWP protein expression was analyzed by western blot (WB; relative expression versus α-tubulin) and immunofluorescence (IF; proportion of spermatozoa with a PAWP signal in the equatorial region) with Abcam ab170115 antibody on raw frozen-thawed sperm sample used for ICSI. PAWP expression and distribution in patients and donors were compared with Mann Whitney rank test.
Main results and the role of chance: Mean fertilization rate was 5% (range [0–10%]) in patients and 68% in donors, (range [33–88%]). PAWP was present in all patients' sperm samples and in all sperm donors. Mean PAWP expression in WB was not significantly different between patients with fertilization failure (mean 1.12 ± 0.35; range [0.82–1.89]) and fertile semen donors controls (mean 1.25 ± 0.45; range [0.74–1.81]). The proportion of PAWP positive sperm cells in IF was not significantly different between patients and donors (51.2% ± 27.9 vs 65.7% ± 12.9 respectively). This result remained the same when only sperm cells with visible acrosome instead of all sperm cells where considered for PAWP staining (55.5% ± 25.2 vs 66.2% ± 12.6 in patients and donors respectively).
Limitations, reasons for caution: Although we aimed to isolate fertilization failure cases of male origin by integrating cycles with oocytes donated from young fertile donors, and elective ICSI to ensure sperm entry, we cannot exclude completely an unknown oocyte effect on the observed fertilization outcomes.
Wider implications of the findings: The results of our study do not support the hypothesis of a clear role of PAWP as SOAF in the human species. Likewise, the study of PAWP protein expression in sperm cells as a diagnostic or prognostic marker of fertilization outcomes is not supported.
Trial registration number: not applicable.

P-024 PAWP gene and protein expression in sperm cells in relation to sperm parameters and ICSI outcome in egg donation cycles

M. Barragan[1], T. Freour[1], A. Ferrer-Vaquer[1], V. Vernaeve[1], R. Vassena[1]
[1]*Clinica Eugin, Clínica Eugin, Barcelona, Spain*

Study question: Is PAWP protein and gene expression related to sperm parameters and oocyte donation cycle outcome?
Summary answer: PAWP gene and protein expression were neither correlated with semen analysis parameters, nor with oocyte donation cycle outcome.
What is known already: Post-Acrosomal WW domain-binding Protein (PAWP), a protein found in the equatorial region of mammalian spermatozoa, has been proposed as a Sperm borne Oocyte Activating Factor contributing to calcium release within the oocyte and subsequent fertilization and embryo development. However, its capability to elicit calcium oscillations individually in oocytes and its relevance as either a diagnostic or a prognostic marker of fertilization failures has been questioned in the recent literature.
Study design, size, duration: This basic research study was conducted in 2015 in 33 couples referred for oocyte donation cycle. PAWP protein and gene (when possible) expression was measured in each patient on raw frozen-thawed semen sample.
Participants/materials, setting, methods: Western blot (WB; relative expression versus α-tubulin) and immunofluorescence (IF; proportion of PAWP positive cells in equatorial region) were performed with Abcam ab170115 antibody on raw frozen-thawed sperm sample. In addition, PAWP gene expression was also measured in the same sperm samples by RT-qPCR for 20 patients presenting with cells for additional RNA extraction. PAWP gene and protein expression were then correlated with semen analysis parameters (number, motility and morphology) and oocyte donation cycle outcome.
Main results and the role of chance: PAWP protein was expressed in all patients with a high variability (mean relative expression 1.77 ± 0.8, range [0.4–3.7], mean proportion of positive cells 63.6% ± 13.9, range [37–85]). The analysis of PAWP expression with IF gave similar results in all sperm cells and in acrosome-visible (intact or reacted) cells (63.6% ± 13.9 vs 67.6% ± 12.1 respectively), confirming that PAWP localization and expression are equatorial, not acrosomal. PAWP gene was also expressed in all tested patients with a high variability (mean gene expression after normalization with geNorm algorithm 7.3 ± 8.2, range [0.2–13.7]). Gene expression levels were not significantly correlated with PAWP protein expression (R^2<0.1). Mean PAWP protein expression was comparable between normozoospermic patients and patients with abnormal sperm analysis. No significant correlation was found between PAWP gene or protein expression and sperm parameters (R^2<0.1 for every parameter) nor with fertilization rate. PAWP gene and protein expression was not significantly different according to oocyte donation clinical outcome, i.e. pregnancy achievement or not.
Limitations, reasons for caution: Analysis of PAWP expression with WB was semi-quantitative.
Wider implications of the findings: This study does not support the interest of PAWP protein and gene expression in sperm cells as a prognostic factor of ICSI cycle outcome.
Trial registration number: NA.

P-025 Effect of microsurgical varicocelectomy on semen parameters in severe male factor infertility

E. Sagara[1], K. Nagao[1], N. Oka[1], R. Obata[1], N. Aono[1], M. Ono[1], A. Tanaka[1], S. Nonaka[1], M. Machida[1], H. Kimura[1], T. Takeuchi[1], K. Kyono[1]
[1]*Kyono ART Clinic Takanawa, Department of Obstetrics and Gynecology, Tokyo, Japan*

Study question: This study was conducted to assess the effect of surgical repair of varicoceles on spermatogenesis, particularly in patients with severely compromised semen parameters.
Summary answer: Microscopic varicocelectomy provided a beneficial effect on sperm concentration and/or sperm motility consequently improving total motile sperm count as well as on sperm DNA integrity.
What is known already: Varicocele is one of the main reasons for male infertility, contributing to impaired spermatogenesis and decreased serum testosterone level. Also, it has been reported that varicocele induces sperm DNA damage. Varicocelectomy has been an effective therapeutic option in male infertility.

Study design, size, duration: Retrospective study. The subjects were separated into three groups of microsurgical varicocelectomy cases, from Nov. 2012 to Mar. 2015. Group 1: 24 cases with sperm concentration (SC) less than 5 million/ml; Group 2: 20 cases with sperm motility (SM) less than 20%, Group 3: 10 cases with sperm DNA fragmentation rate being higher than 50%.
Participants/materials, setting, methods: We compared semen parameters before microsurgical varicocelectomy and 3 months following the surgery among three groups. Sperm DNA integrity was assessed by sperm chromatin dispersion test (Halosperm®). Clinical outcome was evaluated in cases where post-surgery progress follow-up was possible.
Main results and the role of chance: In Group 1, the SC, SM and total motile sperm count (TMSC) before surgery were $2.0 \pm 1.7 \times 10^6$/ml, 31.5 ± 21.7%, and $5.4 \pm 21.7 \times 10^6$, respectively, while post surgery, they were $9.8 \pm 12.3 \times 10^6$/ml, 40.2 ± 25.2%, and $16.9 \pm 21.5 \times 10^6$. The post SC and TMSC were significantly improved ($P < 0.05$). In Group 2, the SC, SM and TMSC prior to surgery were $15.4 \pm 15.0 \times 10^6$/ml, 10.0 ± 6.7%, and $4.8 \pm 4.4 \times 10^6$, respectively. While post surgery, they were $23.8 \pm 19.3 \times 10^6$/ml, 30.5 ± 26.0%, and $29.0 \pm 37.9 \times 10^6$, respectively. The post SM and TMSC were remarkably increased ($P < 0.05$). As for Group 3, although the post SC, SM and TMSC were similar to those before the treatment, the post DNA fragmentation rate (42.1 ± 18.8%) was significantly reduced ($P < 0.01$) from that of before surgery (73.7 ± 14.7%). Among those patients, 8 females became pregnant during a follow-up period.
Limitations, reasons for caution: None.
Wider implications of the findings: Surgical repair of varicoceles contributed to improvement in the TMSC and the sperm DNA integrity. Furthermore, pregnancies were obtained with improved semen, suggesting that microsurgical varicocelectomy is an effective strategy for males with severely compromised spermatogenesis.
Trial registration number: None

P-026 Proliferation of spermatogonium GC-1 spg and GC-2 spd cells was regulated by SET protein

Q. Zhu[1], B. Zhang[1], D. Xu[1], Y. Cui[1]
[1]*Jiangsu Province Hospital, State Key Laboratory of Reproductive Medicine, Clinical Center of Reproductive Medicine, Nanjing, China*

Study question: Whether SET protein participates in the regulation of spermatogenesis
Summary answer: SETprotein participates in the regulation of spermatogenesis
What is known already: SET protein is mainly expressed in spermatogonial cells and spermatocytes, suggesting that it is involved in spermatogenesis. In this study, we find SET protein inhibite proliferation and cell cycle of GC-1 spg and GC-2 spd cells. SET selectively regulates Akt phosphorylation at Ser-473 to regulate cell proliferation.
Study design, size, duration: The cultured GC-1 spg and GC-2 spd cells were transfected with AdH1 -siRNA/SET. Proliferation, cell cycle, AKT, pAKT (S473) and pAKT (T308) were investigated.
Participants/materials, setting, methods: The expression and cellular location of SET protein was assessed by Immunofluorescence and Confocal laser scanning microscopy. Western Blotting was used to detect the expression level of SET protein before and after transfection. Cell viability was determined by CCK8 assay. Cell proliferation was tested by BrdU incorporation assay, while cell cycle were measured by flow cytometry. Expressions of AKT, pAKT (S473), pAKT (T308)were determined by Western Blotting.
Main results and the role of chance: In GC-1 spg and GC-2 spd cells, SET protein was found in both the cytoplasm and nucleus, but its location was mainly in the cytoplasm. Expression of SET Protein in the GC-1 spg and GC-2 spd cells transfected with AdH1 -siRNA/SET was significantly lowered, while the cell viability and the proliferation rate was decreased (all $P < 0.01$). Knockdown of SET protein, the percentage of S phase was decreased in both GC-1 spg and GC-2 spd cells. An increase of percentage of G2/M phase in GC-1 spg and percentage of G0/G1 and G2/M phase in GC-2 spd cells were observed ($P < 0.05$). Down-regulated SET expression for 48h, the expressions of pAKT (S473) was decreased but not pAKT (T308) ($P < 0.05$).
Limitations, reasons for caution: More animal experiments are needed to support our study.
Wider implications of the findings: SET may be a potential therapeutic target in oligo-astheno-teratospermia for future clinical application.
Trial registration number: NO.

P-027 Simple effective vitrification of a small number of human spermatozoa using Rapid-i carriers: a follow-up study

M. Murakami[1], S. Mizumoto[2], K. Tanaka[2], H. Otsubo[2], A. Egashira[2], T. Kuramoto[3]
[1]*Kuramoto Women's Clinic, Research Laboratory, Fukuoka, Japan*
[2]*Kuramoto Women's Clinic, IVF Laboratory, Fukuoka, Japan*
[3]*Kuramoto Women's Clinic, President, Fukuoka, Japan*

Study question: To determine the efficacy of our technique for vitrifying a small number of sperm, from 35 severe oligosperimic/azoospermic patients, followed by ICSI with warmed sperm.
Summary answer: The procedure yielded high post-warm sperm recovery rates, normal fertilization, and good quality (GQ) embryos, resulting in six successful pregnancies after ET of these embryos.
What is known already: Despite interest in low sperm count cryopreservation for men with severe male factor infertility, little is available regarding the ideal carrier or technique that can be used universally. Several commercial devices have been applied for cryopreserving such sperm in miniscule fluid volumes to facilitate recovery, but the sample size was small, and reports of subsequent successful delivery are limited to case reports (Desai et al., 2012; Endo et al., 2012). We previously described a novel, simple method for vitrifying a limited number of human sperm using the closed system Rapid-i (ESHRE 2011) and subsequently implemented the technique at our clinic.
Study design, size, duration: Vitrification of a small number of sperm was performed for 28 men with severe oligospermia/azoospermia following testicular biopsy (Group A) and for 7 men with severe oligospermic semen samples (Group B) from November 2011–December 2015. ICSI treatment was performed with the vitrified/warmed sperm (52 cycles). The resultant 2PN oocytes/GQ embryos were vitrified by day 6. Data on ET of the warmed embryos performed by the end of December 2015 were analysed.
Participants/materials, setting, methods: Vitrification: 1–14 spermatozoa were aspirated into an ICSI pipette and deposited into 1.5 µL cryoprotective solution (2:1 mixture K-SISC:K-SISM buffers; Cook) on a Rapid-i carrier strip (Vitrolife), which was placed in LN_2 vapour (2 min), inserted into a pre-cooled RapidStraw, ultrasonically sealed, and plunged into LN_2. Warming: the cryopreserved strip was placed in 2 µL cryoprotective solution. Spermatozoa were recovered using an ICSI pipette and placed in 2 µL modified HTF medium for ICSI treatment.
Main results and the role of chance: In Groups A and B, 770 sperm (motile, 86.3%) and 155 sperm (motile, 100%) were vitrified in 140 and 36 Rapid-i carriers, respectively (5–81 sperm/man). The vitrified/warmed sperm of Groups A and B underwent 42 and 10 cycles, respectively, of ISCI. During ICSI, 485 sperm (85 carriers) and 100 sperm (23 carriers) were warmed, and the recovery rates were 87.6% and 97.0% in Groups A and B, respectively ($P < 0.01$). Motile sperm rates/recovered sperm were 53.9% and 41.2% in Groups A and B, respectively. Fertilization rates/ICSI with the recovered sperm were 99/247 (40.1%) and 22/44 (50.0%) in Groups A and B, respectively. The numbers of vitrified 2PN oocytes, GQ day 2/3 embryos, and GQ day 5/6 blastocysts were 35, 21, and 1 in Group A and 5, 3, and 1 in Group B. Groups A and B underwent 21 and 4 vitrified ET cycles, respectively. All warmed 2PN oocytes and embryos survived. Mean numbers of embryos transferred, clinical pregnancy rates/vitrified ET, and miscarriage rates/pregnancy were 1.38 ± 0.11, 8/21, and 3/8, respectively, in Group A, and 1.5 ± 0.29, 1/4, and 0/1 in Group B. Five and one singleton babies were live-born in Groups A and B, respectively.
Limitations, reasons for caution: Our Rapid-i method is far superior to the conventional (e.g., vial) methods for single sperm cryopreservation, as it helps circumvent a laborious and time-consuming search for individual sperm. However, long-term follow-up studies for more patients with very low sperm counts in their semen/testicular specimens are warranted to validate the efficacy.
Wider implications of the findings: Our new vitrification system should be valuable for severe male factor infertility. For example, effective sperm storage by this method prior to IVF cycles can avoid the complications and expense associated with repeated surgical sperm retrievals and the risk of finding no sperm on the day of oocyte retrieval.
Trial registration number: N/A.

P-028 Connexin 43 regenerates meiosis and toxicant-induced blood-testis barrier disruption in the rat testes

W. Lee[1], N. Li[1], Y. Cheng[1]
[1]University of Hong Kong, School of Biological Sciences, Pokfulam, Hong Kong

Study question: We sought to examine if the gap junction protein connexin 43 (Cx43) would reseal disrupted blood–testis barrier (BTB) and reinitiate spermatogenesis in adjudin-treated rats.
Summary answer: It was found that overexpression of Cx43 indeed reboots meiosis and reseals BTB disruption, even though it fails to support round spermatids to enter spermiogenesis.
What is known already: We have shown that treatment of adult rats with an acute high-dose of adjudin [1-(2,4-dichlorobenzyl)-1H-indazole-3-carbohydrazide], a male contraceptive under investigation, induces irreversible BTB disruption. In these animals, the population of undifferentiated spermatogonia and spermatogonial stem cells remains largely unaffected, yet these spermatogonia fail to differentiate into spermatocytes. Interestingly, it has been found that Sertoli cell-specific deletion of the gap junction (GJ) protein Cx43 in mice leads to spermatogenesis failure and BTB in these Sertoli cell-specific Cx43 knockout mice also displays significant defects. Collectively, these findings illustrate the likely involvement of GJ in BTB function and its significant role in spermatogenesis.
Study design, size, duration: We expand our earlier study using the acute adjudin animal model to investigate if an overexpression of Cx43 in these rats would rescue spermatogenesis in particular meiosis and if the overexpression of Cx43 in these rats would reseal the disrupted BTB. If it did, we also sought to understand the underlying molecular mechanism (s) by which Cx43 regulate BTB function.
Participants/materials, setting, methods: A single acute dose of adjudin at 125 mg/kg body weight by oral gavage caused sterility in adult rats in which >98% of the tubules were devoid of germ cells except for the population of spermatogonia, which remained relatively unaffected. A full-length Cx43 cloned into mammalian expression vector pCI-neo was used to transfect testes of adjudin-treated rats versus empty vector.
Main results and the role of chance: Overexpression of Cx43 in the testis *in vivo* at 12, 12.5, and 13 wk in rats ($n = 4$ at each time point) vs. rats transfected with empty pCI-neo vector was found to induce resumption of meiosis. Most importantly, it was noted that round spermatids were detected in a significant number of tubules in testes overexpressed with Cx43 vs. adjudin-treated rats overexpressed with empty vector alone or rats treated with adjudin alone. However, elongating and elongated spermatids remained undetected in Cx43-overexpressed testes, illustrating spermiogenesis remained arrested. Immunofluorescent staining indicated that Cx43 in the overexpressed testes was localized prominently at the BTB and became properly organized. It was also noted that the resumption of meiosis was accompanied by reorganization of F-actin, anchoring junction proteins (N-cadherin and γ-catenin), and tight junction proteins (occludin and ZO-1) at the BTB. These studies were demonstrated by immunofluorescent and immunoblot analyses. By the use of a BTB integrity functional *in vivo* assay, we next examined whether the disrupted BTB induced by adjudin was resealed following overexpression of Cx43 in the testis. It was noted that the number of tubules in which the BTB displayed signs of being resealed was >80% in term with the transfection efficiency.
Limitations, reasons for caution: In summary, we have demonstrated that overexpression of Cx43 in the testis can reseal the adjudin-induced BTB disruption by conferring proper localization of anchoring and tight junction proteins to the BTB microenvironment. This also repairs spermatogenesis, at least through meiosis.
Wider implications of the findings: These findings suggest that toxicant-induced BTB dysfunction and male infertility including humans induced by other toxicants, such as cadmium, phthalates, and perfluorooctanesulfonate (PFOS), can possibly be therapeutically managed by overexpressing Cx43 because these toxicants were shown to exert similar effects both in rodents and humans in our recent studies.
Trial registration number: N.A.

P-029 Investigation the effects of chronic mobile phone radiation and melatonin used for protection purpose on the semen morphology

G. Take Kaplanoglu[1], M. Ozgen[1], I. Kaplanoglu[2], D. Erdoğan[1], C.M. Seymen[1]
[1]Gazi University Faculty of Medicine, Histology and Embryology, Ankara, Turkey
[2]Etlik Zubeyde Hanım Women's Health Center, ART Center, Ankara, Turkey

Study question: What is the possible protective effects of melatonin on the semen morphology in the case of exposure to chronic mobile phone radiation?
Summary answer: Melatonin could be used potentially for inhibiting the mobile phone radiation, but it is not sufficient to prevent all of the spermium abnormalities.
What is known already: The mobile phone radiation causes some effects on the number, motility, viability and structure of spermia, and these criterias are very important for male fertility.
Study design, size, duration: 24 male rats were divided into 4 equal groups. There was no application performed to control group. The second group was injected by 10 mg/kg melatonin subcutaneously. The third group was exposed to 2100 MHz radiation for 30 minutes. The fourth group was injected by melatonin subcutaneously 40 minutes before the exposure to radiation for 30 minutes. All the groups were treated for 90 days respectively.
Participants/materials, setting, methods: 24 male Wistar albino rats were used for this study. By the end of the experiment, left caudal epididymis and ductus deferens tissues were taken and moved into Pure Sperm Wash (Nidacon) solution and dissected. Spermiogram, Spermac stain and Transmission Electron Microscobic examinations and statistical analyses were used. Perinuclear ring of the manchette and the posterior portion of the nucleus measurement (ARC) was performed for the heads of the spermia for all groups.
Main results and the role of chance: The light microscobic evaluations showed that the number of total spermiums, total motile spermia and active motile spermia were decreased in the other groups when compared to the control group. However, this reduction was statistically significant only in the radiation and radiation + melatonin treated groups. The number of spermia with normal morphology was also decreased significantly in the radiation and the radiation + melatonin treated groups. ARC measurements of the radiation and the radiation + melatonin treated groups showed a significant angular increase compared to the control group ($p < 0.05$). Evaluations of fhe findings obtained from the electron microscopy showed that the structures in the heads, the necks and the tails of the spermia in the melatonin treated group protected their normal pattern as the control group. The deformed regions in the acrosomes, derangement in some parts of the membranes, fussion of the nucleus content of acrosomes and degenerations in outer dense fibers were seen in the radiation treated group. The radiation + melatonin treated group had the acrosome and the nucleus with normal morphology; however, there were some separations in the membrane.
Limitations, reasons for caution: Melatonin injections have given a burning sensation to the animals so researchers must be careful for the reaction of subjects during the administrations. And also researchers must be protect themselves during the radiation applications.
Wider implications of the findings: No morphological and ultrastructural studies have been done for protective effects of melatonin in case of exposure to chronic mobile phone radiation on semen until this study and we found that melatonin can be used for inhibiting the radiation, but it is not sufficient to prevent all of the abnormalities.
Trial registration number: None.

P-030 Determination of an inducer optimized to induction of sperm capacitation in the mice

S. Baek[1], M.H. Park[1], J.E. Park[1], H. Lee[1], S.T. Lee[2], J.I. Yun[3]
[1]College of Animal Life Science, Department of Animal Life Science, Chuncheon, South Korea
[2]College of Animal Life Science, Department of Animal Life Science and Division of Applied Animal Science, Chuncheon, South Korea
[3]College of Animal Life Science, Division of Animal Resource Science, Chuncheon, South Korea

Study question: What is type and concentration of an inducer showing the best capacitation rate among diverse sperm capacication inducers in the mouse sperms?
Summary answer: 2.7mM calcium was the most effective capacitation inducer among diverse sperm capacitation inducers,
What is known already: Acquisition of sperm capacitation in the female reproductive tract after ejaculation is an essential step in the fertilization with oocytes. Accordingly, during *in-vitro* fertilization, induction of capacitation in the retrieved sperms should be required necessarily for successful fertilization. To date, many candidate substances have been considered as capacitation inducers

in-vitro. However, there were no noticeable reports about the comparison of efficiency inducing sperm capacitation among diverse capacitation inducers.
Study design, size, duration: We tried to determine an inducer showing the best capacitation rate in the mouse sperms through comparative analysis.
Participants/materials, setting, methods: Different concentration of bovine serum albumin (BSA; 0.15, 0.30 and 0.45% (w/v)), calcium (0.9, 1.8 and 2.7 mM), progesterone (7.5, 15 and 30 μM), heparin (25, 50 and 75 μmol/ml), lysophosphatidylcholine (Lyso-PC; 50, 100 and 200 μM) as candidate capacitation inducers were adjusted to sperms collected in epididymis, and then ratio of sperms experiencing acrosome reaction observed in sperms acquiring capacitation was accessed using coomassie G-250 blue staining.
Main results and the role of chance: Although there were no significant differences among different concentration groups, 0.3% (w/v) BSA, 15 μM progesterone, 50 μmol/ml heparin and 50 μM Lyso-PC showed numerically the best induction of acrosome reaction in sperms. Moreover, sperms experiencing capacitation by 2.7 mM calcium showed significantly the highest percentage of acrosome reaction, compared to those by 0.9 and 1.8 mM calcium. Subsequently, in comparison of the ratio of sperms acquiring capacitation by each inducer showing the best potential in the induction of acrosome reaction, significantly the highest percentage of sperms with acrosome reaction was detected in the use of 2.7 mM calcium inducer.
Limitations, reasons for caution: The results of this study were derived from only mouse. Therefore, studies on determining type and concentration of an inducer showing the best capacitation rate among diverse sperm capacication inducers in the human and other species sperms should be conducted in the future.
Wider implications of the findings: This will greatly contribute to improvement of IVF success rate in the level of experimental animals.
Trial registration number: –

P-031 Pollution exposure and high DNA fragmentation index in human sperms: a case-control study

G. Ruvolo[1], M.C. Roccheri[2], L. Carrillo[3], A. Pane[3], G. Lo Bosco[4], R. Chiappetta[5], D. Carone[5], F.R. Prusciano[6], M. Manno[3], E. Cittadini[3], L. Bosco[2]
[1]*Centro Di Medicina della Riproduzione, Palermo, Italy*
[2]*University, Dip. Scienze e Tecnologie Biologiche- Chimiche e Farmaceutiche. Università degli Studi di Palermo, Palermo, Italy*
[3]*Centro di Biologia della Riproduzione, Centro di Biologia della Riproduzione, Palermo, Italy*
[4]*University, Dip di Matematica e Informatica- Università degli Studi di Palermo, Palermo, Italy*
[5]*Centro di Riproduzione e Andrologia, Centro di Riproduzione e Andrologia, Taranto, Italy*
[6]*Laboratorio Prusciano, Laboratorio Prusciano, Taranto, Italy*

Study question: Could pollution exposure play a key role on sperm quality, in terms of DNA fragmentation index (DFI)?
Summary answer: Patients exposed to high level of pollution show an higher percentage of sperm DNA fragmentation index in contrast with patient from control group.
What is known already: Taranto area is characterized by a number of steel factories and petrochemical industries. Data about the detrimental effects of environmental pollution are alarming. Pollution coming from the industrial plants causes health and fertility risks, mainly due to the exposure to several pollutant (PM10, heavy metals, etc).

Toxic substances can affect DNA directly or indirectly, through oxidative stress, impairing sperm quality: high levels of sperm DNA fragmentation index has been summoned as possible cause of male infertility; it is known, in effect, that a spermatic DFI less than 15% is physiologic, while above 30% is related to fertility issues.
Study design, size, duration: Case-control study: valuation of DFI in patients exposed to different level of environmental pollutants.

A. Patients from the city of Taranto leaving far from industries
B. Patients working in local steel factories in Taranto
C. Patients from Palermo (control group)

Duration of the study: 24 months, from January 2010 to December 2012.

DFI assessed by *in situ* TUNEL assay. The fields of fixed semen samples were analysed, by fluorescence and light microscopy.
Participants/materials, setting, methods: Three different groups of patients (tot. number of pts 152), afferent to an assisted reproduction clinic in Taranto: Group A) workers of local steel factories (pt. No: 28) and B) Taranto residents (pt. No: 61) and a Control group C) (pt. No: 63) afferent to an assisted reproduction clinic in Palermo with supposed fertility issues.
Main results and the role of chance: Our study analyzed sperm samples from three patients groups: A) workers of local steel factories; B) Taranto residents; C) Controls.

We observed a highly statistically significant increase of spermatic DNA fragmentation Index (DFI) in the "factory workers" group, constantly exposed to environmental pollutants for professional reasons" compared with control (DFI 31% *vs* 16.8% $P \leq 2.685 * 10^{-6}$) as well as in comparison with the Taranto resident (DFI 31% *vs* 25% $P \leq 2.9 * 10^{-3}$). We have also observed a statistically significant difference between Taranto resident and control group (DFI 25% vs 16.8% $P \leq 3.681*10^{-6}$).
Limitations, reasons for caution: The limitation of this study is that it is a retrospective study and the size of cohort of patients.
Wider implications of the findings: Our study supports the hypothesis that the level of dioxin exposition might be positively correlated with the sperm DFI.

Interrupting the sperms damaging source might bring back the DFI level to normal values. So, moving away from the damaging source, patients from A and B groups could restore spermatogenesis.
Trial registration number: The trial is an observational study and no registration is needed.

P-032 Relationship between leucospermia and sperm DNA damage

P. Costur Filiz[1], A. Saribacak[2], E. Yalcinkaya[3], E. Caliskan[1], S. Filiz[4]
[1]*VM Medical Park Kocaeli Hospital, Obstetrics & Gynecology, Kocaeli, Turkey*
[2]*VM Medical Park Kocaeli Hospital, Urology, Kocaeli, Turkey*
[3]*Private Adatip Hospital, IVF Unit, Sakarya, Turkey*
[4]*Kocaeli University Faculty of Medicine, IVF Unit, Kocaeli, Turkey*

Study question: Is there any relationship between leucospermia and sperm DNA damage?
Summary answer: There is a powerfull correlation between leucospermia and DNA damage.
What is known already: 15% of couples who are trying to achive a clinical pregnancy and had no pregnancy at least 12 months had an infertiliy problem. 50% of infertility is related to male factor. Some of these problems are curable and protectable that makes the diagnosis and treatment of male infertility is more valuable. One of the male factor of infertility is urogenital infections. Urogenital infections can effect sperm quality and so pregnancy.
Study design, size, duration: This prospective study was conducted in Andrology clinic of VM Medical Park Kocaeli Hospital during July to December 2015. A total of 10 men who failed to have a child despite 1 year of attempt were included in the study. 5 of them had leucospermia and the other 5 had no leucospermia. The sperm analysis were performed based on the World Health Organization (WHO) 2010 criteria.
Participants/materials, setting, methods: In this study only who had leucospermia and who had normal sperm parameters were included. Peroxidase test was performed to discriminate leucospermia with immature germ cells and leucocyte like cells. The cellular painting between yellow to brown showed the peroxidase positive leucocyte, pink cellular painting showed other cells (immature germ cells). Sperm DNA damage was determined with Halo sperm test which is a sperm chromatin dispertion (SCD) test.
Main results and the role of chance: Mean age of the control group and leucospermia group was 33.2 and 31.5 years, and total sperm count was 83.5×10^6/ml and 78.7 ×/ml, respectively. There were no statistically differences between ages and total sperm counts. Sperm DNA fragmantation index (DFI) was 8% in control semen and 47.5% in leucospermic semen which showed statistically difference (p value 0.001).
Limitations, reasons for caution: In this study, only leucospermic men and who had normal semen parameters were included. The men who had oligozoospermia, azoospermia, or endocrine disorders were excluded.
Wider implications of the findings: It has been showed that sperm DNA damage was significantly higher in couples who had unsuccessfull IUI. One of the main factors in male infertility etiology is urogenital infections. According to

WHO, ≥ 1×10^6/ml leucocyte in semen is abnormal. Leucospermia has toxic effects on sperm and may cause infertility.
Trial registration number: This is not a clinic trial.

P-033 Human prolactin inducible protein in seminal plasma as a marker of azoospermia

M. Jeseta[1], J. Žáková[1], P. Ventruba[1], I. Crha[1], L. Chalupová[2], M. Hložánková[2], E. Lousová[1]
[1]*Faculty of Medicine, Masaryk University Brno and Faculty Hospital Brno, Gynecology and Obstetrics Clinic, Brno, Czech Republic*
[2]*BioVendor - Laboratory Medicine A.S, Development of ELISA sets, Brno, Czech Republic*

Study question: Is it possible to use concentration of prolactin inducible protein in seminal plasma as a marker of azoospermia ?
Summary answer: Our results showed that the seminal plasma samples from azoospermic donors was significantly reduced levels of protein PIP compared to healthy donors.
What is known already: Prolactin inducible protein (PIP) is expressed in most organs that contribute to human body fluids. PIP binds to many proteins and play important roles in many important biological processes such as fertility or immunoregulation. PIP is represented in high concentration in seminal plasma, where protect the spermatozoa from the damage by IgG. Recently, in seminal plasma was isolated complex of PIP, with human serum albumin. Albumin has been known to preserve the motility of sperm, therefore, this native albumin-PIP complex in human seminal plasma may suggest another important role of PIP, which can directly be correlated with male fertility/infertility.
Study design, size, duration: We developed a novel enzyme immunoassay for quantitative measurement of human PIP suitable for detection of PIP in seminal plasma. During 1 year we measured PIP in seminal plasma from donors with different diagnoses (normozoospermia 24 patients, azoospermia 13 patients, asthenospermia 19 patients, oligospermia 23 patients and after vasectomy 2 patients).
Participants/materials, setting, methods: We assembled sandwich ELISA for the quantitative measurement of huma PIP in seminal plasma This ELISA test is based on two sheep specific polyclonal anti-human PIP antibodies. The Standard used in this kit is native PIP protein isolated from human seminal plasma. Before PIP analyzes we performed evaluation of spermiogram in each donor. In this study were only men between 23–45 years old.
Main results and the role of chance: In the seminal plasma samples from azoospermic patients was determined significantly lower concentrations of PIP (709.02 µg/ml) compared with a seminal plasma samples from normozoospermic donors (1366.09 µg/ml), asthenozoospermic donors (1660.84.09 µg/ml) and also oligozoospermic donors (1378.87 µg/ml) ($P < 0.05$). Indeed concentration of PIP in donors after vasectomy were similar (1544.98 µg/ml) as in control normospermic donors (for low number of samples we cannot perform correct statistical evaluation).
Limitations, reasons for caution: For future development of this diagnostic method is necessary analyse more samples from men after vasectomy. Higher number of samples from this group is necessary for correct evaluation and final decision regarding obstructive or nonobstructive azoospermy.
Wider implications of the findings: On the basis of these results we can conclude that samples from azoospermic donors was significantly reduced levels of protein PIP compared to healthy donors. ELISA for the quantitative measurement of human PIP in seminal plasma could be used as a promising non-invasive method for the diagnosis of azoospermia.
Trial registration number: without trial registration number.

P-034 Physical activity is correlated with sperm quality in sperm donors

F. Quintana Ferraz[1], J. Irazusta[2], D. Vaamonde[3], J. De los Bueis Fernandez[4], I. Peñalba[1], R. Matorras Weining[5]
[1]*IVI Bilbao, Andrology Laboratory, Vizcaya, Spain*
[2]*UPV, Professor of Physiology in UPV/EHU Basque Country, Leioa, Spain*
[3]*University of Cordoba, Human Embryology and Anatomy Sciences Dept., Córdoba, Spain*
[4]*Cruces Hospital, Obstetrics and Gynecology Unit, Barakaldo, Spain*
[5]*IVI Bilbao, Research Coordinator in IVI Bilbao. Reproduction Unit., Vizcaya, Spain*

Study question: Ascertain the influence of physical activity in sperm quality
Summary answer: Higher levels of intense physical activity was associated with better semen parameters
What is known already: The literature presents conflicting results describing the absence of relationship, beneficial or negative effect on the relationship between physical activity and semen quality and other markers of testicular function. The ideal level of physical activity is unknown from the point of view of the seminal quality. Therefore from a practical point of view, there are no arguments when advising males within couples with fertility problems to change their physical activity
Study design, size, duration: Prospective observational non randomized in order to determine influence of one variable on a given outcome
4 cohort groups of physical activity are established, according to their score in IPAQ: **Very high,** total minimum of physical activity of al least 3000 MET week: 26 donors
High, minimum of physical activity between 1500–3000 MET week: 46 donors
Moderate: minimum of physical activity between 600–1500 MET week: 9 donors
Low: until < 600 MET week: 4 donors
Participants/materials, setting, methods: 85 Candidates for sperm donors < 35 years old in the donation program at IVI Bilbao during 2015–2016
International Physical Activity Questionnaire (IPAQ) was offered before sperm donation. Energy requirements defined in METs being multiples of the metabolic rate that quantifying the phisical activity assigned according each activity

Semen parameters of the donors to study by means of a spermiogram were evaluated according to WHO 2010, without knowing IPAQ questionnaire data
ANOVA and linear regression analysis were performed
Main results and the role of chance: Ejaculated volume did not differ significantly between the 4 groups although it was slightly lower in the group of low activity: (2.6 ± 1.60, 2.8 ± 0.93, 3.4 ± 1.53, 3.5 ± 1.6).
Concerning sperm concentration/ml, it was higher in the group of intense activity without statistical significance. (52 ± 41.94, 40 ± 28.82, 34.71 ± 54, 53 ± 39.7) was not statistically significant.

Something similar happened to the **total number of spermatozoa**, groups higher in high and very high again without statistical significance. (120 ± 89.81, 110 ± 78.13, 115.02 ± 170, 170 ± 142.31)

Concerning the **total number of progressive** mobile spermatozoa, there is a higher average of progressive ones (51 ± 36.19, 49.94 ± 62, 81 ± 63.12, 100 ± 89.28)

Among the total concentration of sperm and the highest values of IPAQ a certain trend in the linear regression analysis were observed ($r = 0.016$, $p = 0.24$) despite the p value, which doesn't become significantly statistical

A similar pattern was observed with the total progressive mobile spermatozoa when physical activity increased, expressing a high IPAQ value ($r = 0.045$, $p = 0.05$)

Physical activity was not related with the sperm morphology
Limitations, reasons for caution: The small size of the population sample goes against the correction of the confounding factors. The lack of significant differences between the averages which is likely due to the small sample size and be unbalanced groups. The results may not be the same in older populations. IPAQ is universally accepted questionnaire.
Wider implications of the findings: In this study, the intense physical activity range not only had no adverse effects on semen quality, but also was associated with better semen parameters.

While more studies are needed, one could speculate with infertile male suitability of increasing their physical activity
Trial registration number: NCT02683057.

P-035 Clinical pregnancy rates comparing different sources of spermatozoa

K. David[1], R. Azambuja[1], L. Okada[1], V. Reig[1], A. Tagliani-Ribeiro[1], L. Proença[1], S. Flach[1], C. Telöken[1], F. Badalotti[1], R. Petracco[1,2], J. Michelon[1,2], M. Badalotti[1,2], A. Petracco[1,2]
[1]*Fertilitat, Centro de Medicina Reprodutiva, Porto Alegre, Brazil*
[2]*Faculdade de Medicina, PUCRS, Porto Alegre, Brazil*

Study question: Compare pregnancy and fertilization rates among the different sources of spermatozoa (ejaculate, epididymis, and testicle).
Summary answer: Our results confirm that there is no difference in pregnancy and fertilization rates when comparing the different sources of spermatozoa (ejaculate, epididymis, and testicle).

What is known already: It is known that the spermatozoon is considered mature after contacting the ducts of the epididymis, before ejaculation. However, several studies have shown that spermatozoa collected directly from the testicle and the epididymis can fertilize and produce completely normal embryos. Meantime there is an ongoing debate whether the source of sperm cells has influence on the outcome of ICSI cycles.
Study design, size, duration: Retrospective cohort study between 2000 and 2015.
Participants/materials, setting, methods: There were performed 6508 cycles of ICSI. The couples were divided into three groups: epididymis, testicle and ejaculated. Each one with 282, 282, and 5944 cycles, respectively. Eighteen hours after insemination by ICSI, fertilization was verified. All the embryos were kept in culture until transfer at the cleavage or blastocyst stage. Twenty one days after the transfer, the clinical pregnancy was confirmed by ultrasound. Fertilization and pregnancy rates were compared using the chi-square test.
Main results and the role of chance: A total of 45258 eggs were inseminated, 2335 were inseminated with sperm from the epididymis; 2673 oocytes with testicular sperm and 30896 inseminated with spermatozoa from ejaculate. The fertilization rate was statistically higher in patients who used ejaculated spermatozoa (76.8%), followed by the group in the epididymis (63%), and testis group provided the lower fertilization rate (57.6%) (p <0.05). Pregnancy rates were similar in the 3 groups; 49% (epididymis), 45.1% (ejaculate) and 43.1% (testicle), with no statistical difference (p.0.05). As well as the clinical pregnancy rate 40.3% (epididymis), 39.1% (ejaculate) and 34.7% (testicle) also did not show statistical significance. Although the fertilization rate is higher in the ejaculated group, pregnancy rates were not different between then. Thus, the source of the sperm does not influence the outcome of IVF.
Limitations, reasons for caution: Although there were a very different number of cycles among the groups, this did not affect the results found in this study.
Wider implications of the findings: The source of spermatozoa does not affect the pregnancy rate outcome.
Trial registration number: Not necessary.

P-036 The testicular histopathology as a predictive factor of sperm retrieval in patients with non-obstructive azoospermia (NOA)

F. Scarselli[1], A.M. Lo Bascio[1], S. Muzzì[1], M.C. Greco[1], K. Litwica[1], A. Caragia[1], G. Nastri[1], V. Zazzaro[1], V. Casciani[1], E. Cursio[1], A. Ruberti[1], L. Gnessi[2], G. Franco[3], M.G. Minasi[1], E. Greco[1]
[1]*European Hospital, Reproductive Medicine, Rome, Italy*
[2]*Sapienza University, Department of Experimental Medicine, Rome, Italy*
[3]*Sapienza University, Department of Urology, Rome, Italy*

Study question: The purpose was to investigate the sperm retrieval rate and sperm recovery time after testicular biopsy, and clinical outcomes according to five different testicular histopathologies.
Summary answer: Testicular histopathology is predictive of research time needed for sperm retrieval. No difference was found in clinical outcomes in ICSI cycles performed with testicular sperm.
What is known already: Azoospermia occurs in 10–15% of infertile male population. Non-obstructive azoospermia (NOA) is caused by testicular failures and represents 60% of azoospermia. It is due to testicular or pre-testicular damages, such as hypothalamus pituitary dysfunctions. Surgical retrieval of spermatozoa in order to perform an ICSI cycle, is the only possibility of fathering a child in patients suffering for NOA. Some studies show that testicular histology is the best predictor of success in sperm retrieval from testicular biopsy, such as Testicular Sperm Extraction (TESE).
Study design, size, duration: This retrospective study was performed from March 2005 to November 2015 on 518 patients. Patients were divided in five different groups, based on different testicular histopathology: Sertoli-cell-only (A), maturation arrest (B), severe hypo-spermatogenesis (C), normal spermatogenesis (D), Sclerohyalinosis (E). Sperm recovery time (SRT), fertilization rate (FR), clinical pregnancy (CPR) and live birth rates (LBR) for each enrolled groups, were analyzed. Statistical analyses were performed using student T-test and Fisher's exact test (P value < 0.05).
Participants/materials, setting, methods: If spermatozoa were not retrieved in one testis, the biopsy was performed on the other one. In each surgery, a small tissue sample was histologically analyzed. For each Group the same observation time, from few minutes to almost 12 hours, was applied. Recovered spermatozoa were used for fresh ICSI of partner's oocytes or cryopreserved for future use. There were no differences in male and female mean ages among the five groups.
Main results and the role of chance: Patients who underwent conventional TESE were 518: 200, 94, 73, 140, 11 in groups A-B-C-D-E, respectively. Spermatozoa were recovered in 348 patients (67.2%): 64 (32%), 77 (81.9%), 63 (86.3%), 135 (96.4%), 9 (81.8%) in groups A-B-C-D-E, respectively. Statistical difference in sperm retrieval rate, was observed in group A compared to all other groups ($p \leq 0.0001$) and in group D compared with groups B, C, E ($p \leq 0.002$). For each group, the mean of SRT was considered: 3.4, 2.7, 2.5, 1.0, 3.3 hours in groups A-B-C-D-E, respectively. Statistical significant difference in SRT was found only among group-D compared to all the other groups ($p \leq 0.02$). A total of 336 (A-64, B-77, C-63, D-123, E-9) patients with positive spermatozoa retrieval performed an ICSI cycle, 119 using fresh and 217 frozen spermatozoa. Injected oocytes were 2027. FR was 58.3% (224/384), 54.3% (266/490), 61.5% (221/359), 67.3% (504/749), 48.9% (22/45) in groups A-B-C-D-E, respectively and a statistical difference was found in group-D compared with A, E and B ($p \leq 0.01$) and in group-B compared with C ($p = 0.03$). CPR was 36.9% (17/46), 32.8% (20/61), 30.6% (15/49), 34.1% (31/91), 25% (1/4) in groups A-B-C-D-E, respectively (NS). LBR was 14.3% (15/105), 10.6% (15/142), 9.2% (11/120), 19.4% (41/211), 10% (1/10) in groups A-B-C-D-E, respectively (NS).
Limitations, reasons for caution: Clinical data are not complete since many patients with positive spermatozoa retrieval didn't undergo an ICSI cycle. Sperm recovery time is strictly related to the number of biologists involved in the research and to the laboratory equipment. Performing a multiple-TESE or a micro-dissection TESE could shorten sperm recovery time.
Wider implications of the findings: Sperm retrieval research time could be a limiting factor for ICSI procedure, related to in-vitro oocyte ageing. Testicular histopathology could give valuable information with regard to the likelihood of retrieving sperm in NOA patients. More severe is the pathology and a longer time is necessary to retrieve spermatozoa.
Trial registration number: Not applicable.

P-037 Pathological threshold of human sperm DNA oxidation, an increase value for infertility diagnostics

S. Vorilhon[1,2], F. Brugnon[1,2], A. Kocer[2], S. Dollet[2], C. Bourgne[3], M. Berger[3], L. Janny[1,2], B. Pereira[4], J. Drevet[2], H. Pons-Rejraji[1,2]

[2]*GReD Clermont University, UMR-CNRS 6293-INSERM U1103, Clermont-Ferrand, France*
[3]*Clermont Ferrand CHU Estaing Hospital, Laboratory of Biological Hematology, Clermont-Ferrand, France*
[4]*CHU Clermont-Ferrand, DRCI- 'Délégation Recherche Clinique et Innovation', Clermont-Ferrand, France*

Study question: What is the pathological threshold of human sperm DNA oxidation concerning men infertility diagnosis? What is its real impact on human sperm quality?
Summary answer: Our findings determined a pathological threshold of human sperm DNA oxidation related with sperm parameters associating intensity mean of fluorescence and percentages of oxidized spermatozoa.
What is known already: Oxidative stress plays a major role in male infertility by inducing sperm DNA damage. Sperm nuclear integrity is essential to conduct normal embryonic development and paternal genome transmission to offspring. Therefore it is essential to provide a test permitting to measure sperm DNA alterations.

8-OHdG is the major adduct found in human sperm due to oxidative stress. Nevertheless, there is no standardized and consensual protocol to measure 8-OHdG in human sperm in clinical practice. We previously validated an immuno-detection protocol for sperm 8-OHdG biomarker and measured its accuracy, reliability, sensibility and specificity in comparison with a commercial kit "OxyDNA assay®".
Study design, size, duration: In this prospective study, sperm DNA oxidation level of 80 patients (35 ± 1 years) were measured during 13 months. Sperm DNA oxidation level was simultaneously measured using the commercial "OxyDNA assay®" kit and our validated 8-OHdG immuno-detection protocol. DNA oxidation level obtained with both methods was confronted with semen parameters and patients characteristics.

Participants/materials, setting, methods: Forty patients were normozoospermic, 40 presented abnormal sperm parameters (leuco-, necro-, astheno and teratozoospermia). Sperm DNA oxidation was assayed with a previously validated immuno-detection protocol using anti-8-OHdG primary antibody and Alexa 488-conjugated secondary antibody. Sperm 8-OHdG measured with "OxyDNA assay®" and immuno-detection were detected by flow cytometry (FCM) computing quantification and qualification of sperm DNA oxidation using fluorescent spermatozoa percentage and oxidation intensity mean of fluorescence.

Main results and the role of chance: Using immuno-detection protocol, we measured significant difference in 8-OHdG spermatozoa percentage or/and in intensity mean of fluorescence for all measured sperm parameters, i.e., necrozoospermia ($n = 8$, $p < 0.05$), asthenozoospermia ($n = 12$, $p < 0.01$), teratozoospermia ($n = 27$, $p < 0.05$) and leucozoospermia ($n = 14$, $p < 0.001$) patients in comparison with respective normal groups.

Overweight patients ($n = 20$, 1478 ± 373, $p < 0.01$) showed also a significant higher mean of fluorescence *versus (vs.)* normal weight group ($n = 14$, mean: 379 ± 75).

Significant correlations were observed between sperm DNA oxidation fluorescence intensity and body mass index ($r = 0.6$, $p < 0.001$), sperm concentration ($r = 0.30$, $p < 0.05$), round cells concentration ($r = 0.26$, $p < 0.05$) and the polynucler neutrophil concentration ($r = 0.5$, $p < 0.001$).

Using OxyDNA assay®, only teratozoospermia group presented a significant lower percentage of 8-OHdG spermatozoa ($p < 0.01$) vs. normal group.

The validated immuno-detection protocol allowed to determinate a human sperm DNA 8-OHdG pathological threshold associating intensity mean of fluorescence and percentage of oxidized spermatozoa. Patient having higher values (sperm percentage and fluorescence intensity) than the determinated threshold presented mainly leucospermia or/and asthenozoospermia, confirming the diagnostic value of the biomarker.

The distribution of marked sperm cells values using OxyDNA assay® didn't show any threshold using either oxidated sperm percentage or fluorescence intensity.

Limitations, reasons for caution: Oligozoospermia population was not evaluated in the study.

Wider implications of the findings: The present study is the first to determine a pathological threshold concerning human sperm DNA oxidation, related with sperm parameters notably leucozoospermia and asthenozoospermia.

This 8-OHdG immuno-detection protocol, preliminary validated for clinical practice, will improve male infertility diagnosis and patient support notably with an adapted and effective antioxidants oral supplementation.

Trial registration number: None.

P-038 The influence of high values of sperm DNA fragmentation on the quality and genotype of the embryos

T. Kodyleva[1], J. Kiseleva[1], I. Ushakova[1], O. Golubeva[1], T. Volodyaeva[1], A. Abubakirov[1], N. Mishieva[1]
[1]*Federal State Budget Institution "Research Center for Obstetrics- Gynecology and, Ministry of Healthcare of the Russian Federation, Moscow, Russia C.I.S.*

Study question: Whether if the high values of sperm DNA fragmentation effect quality and genotypes of the embryos in PGS programs.

Summary answer: The positive correlation was found between the sperm DNA fragmentation and the high frequencies of aneuploidy and deletions in the embryonic genome.

What is known already: Many authors agree that early spontaneous abortions might be associated with the high level of DNA damage (DNA fragmentation). FISH analysis of several chromosomes has shown that patients with high values of sperm DNA fragmentation have a high frequency of chromosomal abnormalities in spermatozoa's genomes. We find this problem of high interest and believe that it needs in-depth study using the contemporary methods of whole-genome embryo screening.

Study design, size, duration: The retrospective analysis of 170 couples, undergoing the IVF treatment with the evaluation of functional semen parameters (concentration, motility, morphology), and sperm DNA fragmentation. The rates of fertilization and blastocyst formation were evaluated. The frequencies of autosomal monosomies and trisomies and disomies in sex chromosomes, as well as the number of deletions and translocations in the embryonic genomes, were evaluated using the whole-genome screening by CGH.

Participants/materials, setting, methods: ICSI+PGS program, fertilization and embryo culture according to the manufacturers recommendations of ORIGIO (Denmark), sperm DNA fragmentation was evaluated using a TUNEL assay (the normal level of DNA fragmentation is < 15%), array CGH (Agilent, USA) was used for 24-chromosome embryonic genome analysis.

Main results and the role of chance: Our results show that there are lower rates of blastocyst formation (24% vs. 55%, $p < 0.05$) in the group with high values of sperm DNA fragmentation in comparison with the group with normal values of this parameter. PGS has shown the significantly lower number of embryos with normal genotype (suitable for transfer) (42.9 vs. 58.4 $p < 0.0095$) and the increase of frequencies of deletions and large translocations in embryonic genomes (40.95 vs. 6.14 $p < 0.0095$) for the couples with high values of DNA fragmentation which is caused by the transmission of genetic damages from the nuclei in a spermatozoa to the genome of an embryo. Higher frequencies of trisomies (21.04 vs. 19.43 $p < 0.005$) and autosomal monosomies (18.69 vs. 17.59 $p < 0.05$) were found in our group of study. Damaged or abnormal spermatozoa very often carry an extra sex chromosome, which leads to the birth of a child with the Klinefelter syndrome (47, XYY; 48, XXXY etc.). In the group with high values of DNA sperm fragmentation, we found higher frequencies of disomies in sex chromosomes in comparison with the group with normal values of this parameter (11.58 vs. 7.35 $p < 0.0095$).

Limitations, reasons for caution: Our study didn't include a large number of couples. It might be reasonable to carry on a study in which values of sperm DNA fragmentation before and after antioxidative treatment are compared as we expect to find better results of the genetic screening after treatment.

Wider implications of the findings: Our study shows the correlation between the high values of sperm DNA fragmentation and deletions in the embryonic genome as well as autosomal aneuploidies and disomies in sex chromosomes. Nevertheless, we highly recommend to undergo PGS for the couples with high values of sperm DNA fragmentation.

Trial registration number: N/A.

P-039 Toll like receptors signaling pathway PCR array in recurrent implantaion failure patient with high and low sperm DNA damage

Z. Zandieh[1,2], M. Golestan[2], S. Aghajanpour[2], M. Ashrafi[2], R. Aflatoonian[2]
[1]*Iran University of Medical Sciences, School of Medicine, Anatomy, Tehran, Iran*
[2]*Royan Institute for Reproductive Biomedicine, Department of Endocrinology and Female Infertility at Reproductive Biomedicine Research Center, Tehran, Iran*

Study question: What are the differences between Toll like receptor signalling pathway PCR array in recurrent implantation failure (RIF) patients with high sperm DNA damage and low sperm DNA damage?

Summary answer: TLRs, especially TLR5, its signalling pathways and inflammatory cytokines have higher expression in RIF couples with high DF, compared with RIF ones with normal DF.

What is known already: TLRs are the major compartment of innate immune system. It is well established that microbial PAMPs are ligands for TLRs. However, it is becoming clearer that certain locally produced endogenous substances can also stimulate TLRs. Also, TLRs play a role in pathogenesis of unexplained infertile couples with high DF (DNA fragmentation) and Sperm DNA damage plays an important role in immunological interaction of sperm with female reproductive tract.

Study design, size, duration: 30 Fresh semen samples were obtained from RIF couples in two groups.1. fiftheen samples with DNA fragmentation more than 30% (by SCSA assay) and 2. fiftheen with less than 5%. All these semen samples, after washing were co-incubated with human fallopian tube cell line (OE-E6/E7) in triplicate for 24 hours.

Participants/materials, setting, methods: TLRs genes and protein expression in OE-E6/E7 cell line was investigated By RT-PCR and Immunostaining respectively and compared with human fallopian tube tissue. After co-incubation of sperm in both group with fallopian tube cell line, the profile of Toll like receptors signalling pathways gene expression were evaluated by TLR PCR array kit in OE-E6/E7 cells.

Main results and the role of chance: TLR1-6 gene and protein were expressed in OE-E6/E7, like fallopian tube tissue. The mean relative expression of TLRs, especiallyTLR5 were higher significantly in response to sperm with high DNA

fragmentation in compared to sperm with low DNA fragmentation ($P<0.05$). Also, MYD88 dependent pathway had higher expression compared with MYD 88-independent pathway. Besides, the vast majority of adaptors, effectors and member of NFkB, Jak/stat and cytokine mediated signaling pathway were intermediately to highly expressed in RIF patient with high DF than low one.

Limitations, reasons for caution: The results need to be confirmed in more cases.

Wider implications of the findings: DAMP of TLRs causes TLRs signalling activation. No DAMP for TLR5 have been recognized yet, but several studies showed the role of TLR5 in some disease without a role for its specific PAMP. So, DNA damage should be considered in treatment of RIF due to high production of inflammation.

Trial registration number: N/A.

P-040 Does the number of veins ligated during microsurgical subinguinal varicocelectomy influence semen and hormone outcome?

A. Majzoub[1], M. Arafa[1], H. El Bardisi[1], S. Al Said[1], D. Durairajanayagam[1], A. Agarwal[1]
[1]*Hamad Medical Corporation, Urology, Doha, Qatar*

Study question: The study of factors predicting semen improvement after varicocele ligation is motivating. in this study we ask whether the number of veins ligated during surgery play any significant role.

Summary answer: A significant improvement in semen parameters occurs after microsurgical varicocelectomy, this improvement does not seem to be related to the extent of vein ligation.

What is known already: The subject has been evaluated previously in 2 studies showing a superior outcome in semen parameters with higher number of vein ligation. However, both studies were small sized and the surgical method was not uniform in one of them. Newer varicocele ultrasound grading systems consider the presence of a venous plexus of veins and the sum of diameters of all detected veins in grading. Although the number of veins witnessed during surgery can vary greatly irrespective of the clinical grade, their value in the pathophysiology and/or the detrimental effects of varicocele on testicular function is not known.

Study design, size, duration: This is a retrospective study of 682 records of patients undergoing left microsurgical varicocelectomy between 2007 and 2014. Patients presenting with infertility were included in this study. While the exclusion criteria were patients who underwent surgery for an indication other than infertility, patients with prior history of varicocele ligation, presence of abnormal genetics as cause of infertility, history of mumps orcitis and history of medical treatment before varicocelectomy.

Participants/materials, setting, methods: A total of 378 records were included. Semen and hormone test results done initially were compared to those performed 9 months after surgery. Patients were divided into 2 groups according to their initial semen results; abnormal (sperm count < 20 million/ml and/or total motility <50% and/or abnormal morphology >70%) and normal groups. Patients were also subdivided depending on the number of veins ligated during surgery into 3 subgroups; < 5, 5–10 and > 10 veins.

Main results and the role of chance: Overall, sperm count, total motility and progressive motility were significantly increased in 62%, 60.3% and 53.3% of patients postoperatively (p=0.001). No significant differences in hormone levels were detected. 332 patients had an abnormal semen analysis while the remaining 46 patients had a normal result. Sperm count, total motility and progressive motility were significantly increased after varicocelectomy, only in patients with abnormal initial semen analysis (p=0.001). Less than 5 veins, 5–10 veins and >10 veins were ligated in 23%, 28.3% and 48.7% of patients, respectively. A correlation between preoperative semen and hormone levels with the number of veins ligated intraoperatively did not reveal any statistically significant deference. Moreover, the extent of vein ligation did not have any statistically significant effect on the percentage improvement in semen and hormone levels between both groups.

Limitations, reasons for caution: Sperm chromatin integrity was not assessed in this study and can be considered as a limitation due to its vital relation with varicocele. Furthermore, no comparison was performed between ultrasound and intraoperative findings, since in most patients the ultrasound sis not have details about the number of veins detected.

Wider implications of the findings: This study disagrees with previous smaller reports, which suggested an influence for the number of ligated veins on surgery outcome. Varicocele imaging with ultrasonography is an addition to the clinician's armamentarium, however it does not replace physical examination in his clinical judgments.

Trial registration number: (NA) This is a retrospective study.

P-041 Spermatozoa with both abnormal chromatin condensation and large nuclear vacuoles seem to have a negative influence on clinical outcomes, in oocytes-donation cycles with repeated failures

E. Iovine[1], A.M. Lobascio[1], F. Scarselli[1], R. Polese[1], V. Casciani[1], T. Riccio[1], S. Muzzì[1], G. Nastri[1], A. Ruberti[1], G. Franco[2], A. Greco[1], C. Arrivi[1], M.T. Varricchio[1], M.G. Minasi[1], E. Greco[1]
[1]*European Hospital, Center for Reproductive Medicine, Rome, Italy*
[2]*Umberto I, Department of Urology - University "La Sapienza", Rome, Italy*

Study question: Find a correlation between live birth rate and sperm quality, valuated according to MSOME (Motile sperm organelle morphology examination) criteria, in oocytes-donation (OD) cycles.

Summary answer: We suppose a negative effect of spermatozoa with both large nuclear vacuoles (type IV) and abnormal chromatin condensation, in clinical outcomes, in oocytes-donation cycles.

What is known already: During spermiogenesis, the somatic histones are substituted by protamines for a normal nuclear chromatin condensation. Aniline blue selectively targets lysine-rich histones showing blue nuclei typical of spermatozoa with abnormal condensation. An association between male infertility and the anomalous chromatin condensation, are reported. Also morphological abnormalities of sperm head linked to the number and to the dimension of nuclear vacuoles, are well-known. In fact, there are evidences that confirm the relationship between the high-magnification sperm selection and both the number of blastocysts obtained and the clinical outcomes.

Study design, size, duration: Fresh semen samples of sixteen patients, of whom spermatozoa were beforehand used for oocytes-donation cycles with repeated *in vitro* failures, in our and in other laboratories, were successively analyzed, for their nuclear vacuoles according to MSOME criteria. Same samples were used for aniline blue staining and FISH (Fluorescence In Situ Hybridization) analysis. Samples were collected from March to December 2015. The man mean age was 43.3 ± 6.2. Statistical analyses were performed using student-test (P value <0.05).

Participants/materials, setting, methods: Samples, not used for ICSI, were examined for seminal parameters according to WHO-2010 criteria. Sperm morphology was evaluated allowing to MSOME criteria identifying four classes: type I-II with none or one small vacuoles and normal head shape; type III with plus three vacuoles and normal head shape; type IV with large vacuoles and abnormal head shape. Aniline blue (v.n. <30) and FISH analysis (13, 15, 16, 17, 18, 21, 22, X, Y chromosomes) were performed.

Main results and the role of chance: The sixteen semen samples analyzed (concentration 40.1 ± 18.3 M/ml and progressive motility 44.4 ± 16μm/sec), appear to have normal ploidy for the nine investigated chromosomes by FISH analysis. For each patient, 100 spermatozoa for MSOME and 100 for aniline blue, were analyzed. Total sperm examined, using MSOME criteria, were divided as follow: 588 type I-II, 412 type III, 600 type IV. In nine patients, 321 spermatozoa showed positivity to aniline blue staining.

Analyzing data, we find a positive correlation between semen samples with more type IV spermatozoa and the aniline blue positivity ($P < 0.0001$). At the same time there is a negative correlation between type I-II sperm number and the aniline blue positivity ($P = 0.001$). Finally, a statistical significance relationship between the type III sperm and the aniline blue ($P = 0.0145$), was detected.

Generally, the OD cycles with worst clinical outcomes (embryo degenerations, implantation failures, abortions) were performed with semen sample successively resulted with more vacuoles in spermatozoa (type IV) and showing blue nuclei typical of an abnormal chromatin condensation.

Limitations, reasons for caution: The main limitation of this study is the low number of samples, due to the impossibility, in some cases, to recover the fresh semen samples after the OD cycles failures. More samples should be analyzed, in the future, to reinforce our conclusions.

Wider implications of the findings: Our data show that the sperm selection, with high magnification microscopy, could be useful to improve the ICSI successful in OD cycles with repeated failures in clinical outcomes.

Trial registration number: Not applicable.

P-042 Human seminal plasma of different men induce different power of uterine contractility in a uterus perfusion model

I. Hoffmann[1], L. Lotz[1], S. Findeklee[1], M.W. Beckmann[1], R. Dittrich[1]
[1]University Erlangen, Ob/Gyn, Erlangen, Germany

Study question: Does human seminal plasma of different men induce different contraction strength of the uterus?
Summary answer: Application of individual seminal plasma into the porcine uterus cause different reaction of uteri regarding the contractility (power, frequency, AUC). Data suggest a dose-dependent effect.
What is known already: A sufficient contractility of the uterus plays an important role for successful conception. Several substances as oxytocin, estradiol or prostaglandins are known to support uterine contractility. The fact that these substances are ingredients of the seminal plasma stresses its relevance for the reproductive function. Examinations in animals as well as in humans showed seminal plasma`s impact for conception. However seminal plasma composition and reciprocity of the substances seem to be very complex and not completely understood yet. No studies about the dose-dependent effect of seminal plasma application into the whole uterus have been published.
Study design, size, duration: The aim of this experimental in-vitro study was to evaluate the influence of human seminal plasma on their contractility by using an extracorporal perfused pig uteri. Ejaculate of 36 men with normozoospermia were taken from the laboratory of the university hospital Erlangen. The ejaculates were injected into the perfused uterus of 54 pigs to analyze whether individual dose-dependent effect of seminal plasma on the uterine motility exists by repetitive intraluminal bolus application of different volumes.
Participants/materials, setting, methods: The uteri were stored in a special nutrition solution and perfusion was managed with the aid of a 24 G canula inserted into both Arteriae uterinae. Uterine pressure as the area under the curve (AUC) was measured by a precision pressure catheter with two measure points near to the ovaries (IUP 1) and near to the cervix (IUP 2) at four time points (t0: minute 0–60; t1: minute 61–105; t2: minute 106–150; t3: minute 151–195).
Main results and the role of chance: Injection of 0.3, 0.6 and 1.2 ml seminal plasma increased uterine pressure significantly. It was not significantly higher at IUP 2 compared with IUP 1. Contraction frequency improved after injection of 0.3 and 0.6 ml seminal plasma. The ovarian and the cervical measure point showed no significant difference concerning maximal and average pressure amplitude after application of 0.3 ml seminal plasma, but revealed significantly higher values at IUP 2 after administration of 0.6 and 1.2 ml seminal plasma. The seminal plasma application into the porcine uterus significantly increases contractility in form of AUC, contraction frequency as well as average and maximal values of the contraction amplitude. The data suggest a dose-dependent effect. The direct comparison of the integrals of intrauterine pressure over time after administration of seminal plasma of different men showed a high variation between 3769 and 2132 mmHg/h.
Limitations, reasons for caution: Physical disturbance variables potentially influencing the results were limited as much as possible. For preventing an increase in uterine contractility because of the temperature seminal plasma was warmed up to the nutrition solution temperature. With a slow uniform injection a steady seminal plasma distribution and a low pressure were reached.
Wider implications of the findings: The results demonstrate the importance of physiologic seminal plasma composition and introduce new potential options in diagnostic and treatment for couples with an unfulfilled wish for a child. Further investigations about the exact seminal plasma composition and the interaction of the ingredients are necessary.
Trial registration number: None.

P-043 Calretinin increases androgen production in testicular Leydig cells

X. Wendan[1], C. Yugui[1], Z. Bei[1], Z. Qian[1]
[1]Clinical Center of Reproductive Medicine-First Affiliated Hospital, State Key Laboratory of Reproductive Medicine, Nanjing, China

Study question: In the present study, we explored the effect of calretinin (CALB2) on the regulation of androgen production in testicular Leydig cells and its potential mechanism associated with Ca^{2+} pathway.
Summary answer: CALB2 plays a positive role in the acceleration of androgen production in Leydig cells by the Ca^{2+} pathway, besides PKC and PKA pathways.
What is known already: The Ca^{2+}-binding protein CALB2 is well known as the Ca^{2+}-buffering function, primarily expressed in specific neurons, while it can also function as the Ca^{2+} sensor. And it emerges as a multi-functional protein also associated with development, i.e., cell proliferation, differentiation and cell death recently. Ca^{2+}, as the second messenger, participates in hormonal synthesis which could be regulated by PKA and PKC signals. Previously we observed CALB2 was also expressed in testicular Leydig cells and had a positive correlation with androgen levels, suggesting CALB2 could participate in regulating steroidogenesis.
Study design, size, duration: The change of androgen production was detected in the overexpressed and downexpressed-CALB2 Leydig cells. Then these cells were treated by PKC inhibitors (Chelergthrin), PKC and PKA inhibitors (Daphnetin) singularly or combining with hCG, in order to clarify the steroidogenensis regulated by CALB2.
Participants/materials, setting, methods: The cultured R2C and MLTC-1 were transfected by LV-SiRNA-Calb2 and LV-Calb2, respectively. The transfected MLTC-1 were treated with 0.1 IU/mL hCG for 4 h. All medium was collected for measuring androgen via radioimmunaossay, Ca^{2+} levels were detected by the confocal microscopy with calcium fluorescent probes X-Rhod-1,and Western blotting was used to examine CALB2 expression. After transfected MLTC-1 were treated by Chelergthrin, Daphnetin, and calcium releasing agents (Clopiazonic) with or without 0.1IU/mL hCG for 4h, androgen was measured.
Main results and the role of chance: Steroidogenesis was significantly increased in the hCG treated cells, while expression of calretinin increased ($P < 0.01$). Progesterone production in the R2C cells with LV-SiRNA-Calb2 was decreased ($P < 0.05$), and testosterone production in the MLTC-1 cells with LV-Calb2 was significantly increased ($P < 0.05$). In the LV-Calb2 transfected MLTC-1 cells with or without HCG, the cytoplasmic Ca^{2+} was up-regulated compared with the corresponding vector groups ($P < 0.01$). However the cytoplasmic Ca^{2+} was decreased ($P < 0.05$) in the R2C cells with LV-SiRNA-Calb2. In the LV-Calb2 transfected MLTC-1 cells with or without HCG, testosterone production was significantly induced by clopiazonic ($P < 0.01$), while daphnetin and Chelergthrin had no impact on testosterone production compared with the vectors ($P > 0.05$).
Limitations, reasons for caution: From our study, we know CALB2 enhances Ca^{2+} to promote steroidogenesis in Leydig cells. However, overload of Ca^{2+} may injury Leydig cells, so that we should quantify Ca^{2+} in fear of Ca^{2+} overload.
Wider implications of the findings: This study demonstrates that Calretinin is involved in the regulation of testicular androgen synthesis, so that it enhances our knowledge on the intracellular signaling mechanisms of testosterone synthsis, and provides us a theoretical basis and clinical understanding for male reproductive endocrine disorders and the late-onset hypogonadism.
Trial registration number: –

P-044 Clinical outcome in intracytoplamic sperm injection (ICSI) cycles using testicular sperm in post chemotherapy non-obstructive azoospermia (NOA)

T. Ishikawa[1], S. Mizuta[1], K. Yamaguchi[1], Y. Takaya[1], R. Nishiyama[1], K. Kitaya[1], H. Matsubayashi[1]
[1]Reproduction Clinic Osaka, Andrology, Osaka, Japan

Study question: What are sperm retrieval rates (SRR) by microdissection testicular sperm extraction (micro TESE), fertilization rate, and embryonic development among post chemotherapy NOA couples?
Summary answer: The SRR in post chemotherapy NOA was higher than that of patients with other uneplained NOA patients, and better fertilization and embryonic development were achieved.
What is known already: The survival rates for pediatric and adolescent patients with various types of malignancies have dramatically improved with advances in chemotherapeutic treatments. In male cancer survivors, the restoration of fertility and achievement of paternity have become important concerns. The recent success of micro TESE combined with ICSI for patients with NOA indicates that ART (assisted reproductive technologies) offer a potential new treatment option for affected couples and so that this procedure provides hope for men of reproductive age who have not undergone sperm cryopreservation before chemotherapy.
Study design, size, duration: We performed a retrospective study based on a reproduction center in Japan and evaluated 26 post chemotherapy NOA patinets (including 6 patients with bone marrow transplantation (BMT)) and 250 NOA

patinets with 46XY without past history (unexplained NOA; not including after orchidopexy, Klinefelter syndrome, cryptozoospermia, mumps orchitis, etc) who underwent micro TESE by a single surgeon (T.I.) between September 2013 and December 2015.

Participants/materials, setting, methods: The cancer types included testicular cancer, colon cancer, Hodgkin's lymphoma, non-Hodgkin's lymphoma, leukemia, neuroblastoma, and osteosarcoma. The age at micro TESE and chemotherapy was 34.6 ± 9.0 and 16.9 ± 7.9 years, respectively, and the mean wives age at ICSI was 34.0 years. Two pronuclei (2PN) oocytes, blastocysts development, good-quality blastocysts (Grade >3BB by the Gardner score), biochemical and clinical pregnancies rates were examined. Statistical analysis was performed using unpaired t-tests and chi-squared tests.

Main results and the role of chance: None of the patients had undergone cryopreservation of their sperm before chemotherapy. SRR in post chemotherapy NOA (13/26 = 50.0%) was higher than unexplained NOA (73/250 = 29.2%) patients ($p < 0.05$) in whom micro-TESE was performed. Three of 6 post BMT patients were retrieved spermatozoa. Two of 3 patients even showed 46XX (transplantation from women). The 13 patients who failed to obtain sperm could not find any germ cells in their testicular samples during micro TESE and histopathological findings (Sertoli cell only syndrome). With respect of type of cancer, there was no predictor for SRR and no significant differences in the pregnancy and live birth rates. In sperm retrieved post chemotherapy NOA, age at chemotherapy end was older (22.0 ± 8.3 years) than failure group (11.8 ± 7.7 years) ($p < 0.01$). 2PN oocytes, blastocysts development, and good-quality blastocysts rates were 64.9%, 50.6%, and 51.3% in post chemotherapy NOA and 60.1%, 44.5%, and 41.9% in unexplained NOA. Biochemical pregnancy and clinical pregnancy rates per embryo transfer (ET) were 57.1% (12/21) and 47.6% (10/21) in post chemotherapy NOA, and 32.8% (44/134) and 25.4% (34/134) in unexplained NOA, respectively. Clinical pregnancy rate per patients was 75.0% (9/12) in post chemotherapy NOA and 58.5% (31/53) in unexplained NOA.

Limitations, reasons for caution: The participants are limited to the NOA but not cryptozoospermic patients. No hormonal treatment was performed before micro TESE. There was a lack of standardization with respect to the chemotherapeutic regimen. The safety and screening for cancer and congenital malformations among these children has not been fully investigated.

Wider implications of the findings: The patients with post chemotherapy NOA no longer should be considered sterile without performing micro TESE-ICSI. It is useful to obtain reliable embryonic information from NOA patients and to encourage micro TESE for post chemotherapy NOA patients even with severe dysregulation of spermatogenesis.

Trial registration number: N/A.

P-045 The application of 3-methyladenine with lithium chloride increases the detrimental effects of lithium chloride on sperm number and motility

İ. Aydın[1], M. Ergüven[2], E. Aktaş[3], A. Kadıoğlu[4], F. Bener[5], A. Archibong[6], A. Bilir[6]

[5]*İstanbul İn vitro Fertilization and Women Health Center, İn Vitro Fertilization Unit, İstanbul, Turkey*

[6]*Zirve University, Emine-Bahaeddin Nakiboğlu Faculty of Medicine, Department of Histology and Embryology, Gaziantep, Turkey*

Study question: Does 3-methyladenine (3-MA) prevent detrimental effects of lithium chloride (LiCl) on sperm number and motility at normospermic males?

Summary answer: The application of 3-MA with LiCl slightly increased the detrimental effects of lithium chloride on sperm number and motility at normospermic males.

What is known already: Chemical LiCl with its' anti-physicotic and anti-neoplastic effects is accepted as a drug and it has been being used used in clinic for 60 years. The detrimental effect of LiCl on male infetility through the inhibition of sperm motility and viablility is known already. LiCl was declared either autophagy inducer and inhibitor at several reports. 3-MA, an autophagy inhibitor, is commonly studied in cancer for inducing sensitivity and overcoming resistance. In infertility era, a few study can be found and the most relevant one to infertility subject showed that 3-MA has no effect on paternal mitochondria removal at the fertilization.

Study design, size, duration: This study was performed with 40 semen samples collected from normospermic males at İstanbul University, İstanbul Faculty of Medicine, Department of Urology, Section of Andrology between March 2013–January 2014.

Participants/materials, setting, methods: Sperms obtained by the liquefaction of semen of normopsermic males aged between 20 and 35 were divided into four groups as control, LiCl (10 μM), 3-MA (10 μM) and the combination group. Sperms were incubated with the drugs for 1 h at 37°C and then they are evaluated by sperm number and motility (Light microscopy), sperm viability and apoptosis indeces (Flow cytometry), phosphoinositide 3-kinase (PI3-K)/Vps34 protein (Immunohistochemistry, IHC) and ultrastructure (Transmission electron microscopy, TEM).

Main results and the role of chance: Sperm number was decreased by the combination group in comparison to control group and singly applied chemicals (93×10^4; $p > 0.05$). IHC evaluation showed that PI3-K/Vps34 levels were also reduced by the combination group (20%; $p < 0.001$). Viability index was similar to control group and 3-MA group, however it was lower than LiCl group (35.432%; $p > 0.05$). It increased total apoptotic sperm cell rate slightly (54%; $p > 0.05$). TEM evaluation showed that the combination group led to the increase in vacuolisation and apoptotic cell morphology and the decrease in autophagic vacuoles.

Limitations, reasons for caution: Defects were found healthy and normospermic accepted males under TEM evaluation. They are discarded from experiment. Low sample numbers are restrictive to find out exact results for this applications.

Wider implications of the findings: Yet, the effect of LiCl with 3-MA haven't been being tested in male fertility. This study showed that they acted both through the inhibition of autophagy. LiCl with 3-MA will not be new infertility treatment modality for males who suffered from cancer or physcotic disorder or both.

Trial registration number: This study was approved by İstanbul University, İstanbul Faculty of Medicine Clinical Research Ethical Committee at February 19, 2013 and the number is 197.

P-046 Testicular endocrine patterns in young boys operated for cryptorchidism

T. Almont[1], R. Mieusset[1], S. Hamdi[1], P. Thonneau[1]

[1]*EA 3694, Human Fertility Research Group, Toulouse University Hospital, Reproductive Medicine, Toulouse, France*

Study question: Are hormonal markers of the testicles (Testosterone, inhibin B and Anti-Mullerian Hormon or AMH) in cryptorchid boys are significantly different than in non-cryptorchid boys?

Summary answer: Cryptorchid boys have simultaneous significantly decreased serum testosterone, AMH and inhibin B levels, suggesting a functional defect of both Leydig and Sertoli cells.

What is known already: Cryptorchidism is the most common male congenital malformation, with an increasing incidence within the last decades in industrialised countries. Cryptorchidism is also a major risk factor for infertility and for testis cancer (Toppari, 2001; McGlynn, 2012). Many studies have compared hormonal markers of the testicles (Testosterone, inhibin B and Anti-Mullerian Hormon or AMH) in cryptorchid and non-cryptorchid boys. Nevertheless, the results remain contradictory showing no difference in older studies (Christiansen, 2002; Barthold, 2004; Suomi, 2006), while more recent studies show a significant reduction of these hormones in children with cryptorchidiscryptorchidism (Guibourdenche, 2003; Pierik, 2009; Matuszczak, 2012; Thorup, 2015).

Study design, size, duration: We performed a hospital-based cross-sectional study. During one year, we identified from surgery appointment records, boys with unilateral or bilateral cryptorchidism undergoing orchiopessy (excluding any illness or other urogenital malformations) and boys undergoing dental care, minor osteoarticular (talipes, hallux valgus) or dermal surgery (naevi). Informed parental consent was obtained. Blood samples were taken during the

surgical procedure for biological (cholesterol and triglycerides) and hormone assays (testosterone, inhibin B and AMH).

Participants/materials, setting, methods: Analyses were performed in the Biochemistry department of Toulouse University Hospital.

Cholesterol and triglycerides concentrations were determined enzymatically with an Olympus analyzer (Beckman Coulter, Roissy, France).

Testosterone was assessed through an RIA kit (Cis-Bio International, Gif-sur-Yvette, France).

AMH was assayed by an enzyme-linked immunoassay (ELISA) kit provided by DSL-Beckman Coulter (Webster, TX, USA).

Inhibin B was measured by ELISA with a kit supplied by OBI-DSL (Oxford, UK).

Both AMH and Inhibin B were assayed in duplicate according to manufacturer's protocols.

Main results and the role of chance: Two groups of 27 boys were included, different for age at surgery: 26.6 versus 24.2 months ($p = 0.172$).

All serum levels were lower in cryptorchid than in control boys. Testosterone levels, measured in 10 controls and 10 cases, were 18.10 ng/100 mL ± 4.07 and 11.60 ng/100 mL ± 1.26, respectively ($p < 0.001$). AMH levels were 86.63 ng/mL in cryptorchid boys and 134.56 ng/mL in controls ($p = 0.003$), while inhibin B levels were 96.89 pg/mL and 133.44 pg/mL, respectively ($p = 0.007$).

AMH and inhibin B were markedly lower in the bilateral cryptorchidism subgroup, being 50% lower than in the controls (both $p = 0.003$).

Limitations, reasons for caution: Weakness of the study relates to the absence of INSL3 assay, an additional marker of Leydig cells dysfunction, which could reinforce our results on testosterone secretion in both groups. INSL3 is involved in the trans-abdominal phase of testis descent. Unfortunately, the assay was not available at the time of study.

Wider implications of the findings: Decreased serum testosterone, AMH and inhibin B levels, suggest a functional defect of both Leydig and Sertoli cells. The Sertoli cell defect appeared more pronounced in bilateral cryptorchid boys. It could be interesting to assess the impact on the future fertility of these boys.

Trial registration number: We have obtained the study agreement number 907152 from the French data protection Authority (CNIL).

P-047 Hydrogen molecule treatment enhancesincreases ATP production in human spermatozoa

K. Nakata[1], K. Yoshida[2], M. Yoshida[3], N. Yamashita[1]

[1]Yamashita shonan yume clinic, Reproductive Medicine Reserch Center, Kanagawa, Japan

[2]Toin University of Yokohama, Biomedical Engineering Center, Kanagawa, Japan

[3]The University of Tokyo, Misaki Marine Biological Station- Graduate School of Science, Kanagawa, Japan

Study question: Why does hydrogen molecule treatment enhance ATP in human spermatozoa?

Summary answer: H_2 treatment rescued inhibition of complexes I and III of the mitochondrial electron transport chain. H_2 treatment increases ATP production in spermatozoa.

What is known already: H_2 treatment remarkably improved the rate of forward motility of human spermatozoa, whereas N_2 treatment did not. H_2 treatment also increased the mitochondrial membrane potential of human sperm. Less motile frozen-thawed sperm from patients improved the rate of forward motility after being cultured in a medium containing 75% hydrogen molecules.

Study design, size, duration: Frozen-thawed sperm suspension from 132 normospermic patients were divided into seven groups: control group was H_2 noncontained medium; H_2 treated group was 75% H_2-saturated medium; the other groups were antimycine A (A), rotenone (R) contained each control mediums, or 75% H_2-saturated mediums; and pentoxyphiline (P) group contained control medium.

Participants/materials, setting, methods: Normospermic suspensions were frozen on the collected day. Forty-two sperm suspensions treated A (200 μM), 45 sperm suspensions treated R (200 μM) and 45 sperm suspensions treated P (2 mg/ml). Sperm ATP was measured with an luminometer. Sperm concentration and motility were measured with Makler chamber and Sperm Class Analyser (SCA).

Main results and the role of chance: In terms of sperm ATP amount, 75% of H_2-saturated medium showed the best results compared with those of A (H2 + A vs. C + A: 305.58 ± 204.89 vs. 186.65 ± 111.26, $n = 30$, $P < 0.001$), R (H2 + R vs. C + R: 297.37 ± 157.58 vs. 171.11 ± 77.36, $n = 30$, $P < 0.001$), P (H2 vs. P: 547.01 ± 324.89 vs. 358.84 ± 190.12, $n = 45$, $P < 0.001$), control (H2 vs. control: 437.06 ± 291.47 vs. 306.92 ± 200.01, $n = 105$, $P < 0.001$), respectively (pmol/10^6 sperm: data are shown as mean ± SD). On measuring sperm motility parameters with SCA, C + A treated sperm were significantly lower than H + A treated sperm in VCL, VSL, VAP, ALH, and BCF ($P < 0.05$, $n = 12$). C + R treated sperm were significantly lower than H + R treated sperm in VCL and ALH ($P < 0.05$, $n = 15$).

Limitations, reasons for caution: This is a basic study on a relatively small sample size with limited conditions. The confirmation using larger samples under various conditions may be required. Furthermore, we need to check the safety of H_2 treated sperm use in ART.

Wider implications of the findings: The findings of this study indicate that H_2 treatment increases the intracellular ATP of the oligoasthenoteratozoospermic patients' sperm. Possibly, men with severe sperm dysfunction could select IVF instead of ICSI by using H_2 treatment. It may also be useful in the selection of good quality sperms for ICSI.

Trial registration number: Nothing.

P-048 Patients with Sertoli cell-only syndrome combining with seminiferous tubule hyalinization have higher sperm retrieval rate when micro-TESE was performed

J. Zhang[1]

[1]The Sixth Affiliated Hospital, Sun Yat-sen University, Reproductive Center, Guangzhou, Guangdong, China

Study question: Could seminiferous tubule hyalinization predict a different sperm retrieval rate (SRR) when non-obstructive azoospermia (NOA) patients with Sertoli cell-only syndrome (SCO) undergo microdissection testicular sperm extraction (micro-TESE)?

Summary answer: Patients with SCO combining with seminiferous tubule hyalinization had higher SRR comparing with those not combining with seminiferous tubule hyalinization.

What is known already: More intratubular germ cells with active spermatogenesis within seminiferous tubule cause the tubule to appear larger, more opaque and whiter than tubules without sperm production, therefore micro-TESE can find out the small isolated areas of sperm production according to the microscopic findings. SRR has been achieved in up to 22.5–42.9% of patients with SCO, however, testicular volumes and serum level of FSH, LH, inhibin B and testosterone is just indicative of the testicular function as a whole and may not reflect focal areas of spermatogenesis that are found during micro-TESE, and is not reliable in predicting SRR.

Study design, size, duration: This is a retrospective study. From Jan. to Dec.2015, fifty NOA patients underwent micro-TESE and were diagnosed histologically with SCO. They were subclassified into patients with seminiferous tubule hyalinization or without seminiferous tubule hyalinization.

Participants/materials, setting, methods: Micro-TESE was performed at x20 magnification under the operating microscope. Seminiferous tubules were removed and immediately placed within a sperm buffer. Then the tubules were dissected and examined immediately by an embryologist under a phase microscope at x200 magnification. The hyalinization group and non-hyalinization group were compared in age, testicular volumes, FSH, LH, inhibin B, testosterone, SRR and microscopic findings of testicular tubules during operation.

Main results and the role of chance: 34 patients (68%) were diagnosed with SCO combining with seminiferous tubule hyalinization, while 16 patients (32%) without hyalinization. No significant difference was observed in age (35.2 ± 6.7 vs. 33.3 ± 5.1), FSH (32.6 ± 12.8 vs. 27.8 ± 9.3), LH (14.7 ± 6.1 vs. 12.1 ± 5.8), testosterone (3.1 ± 0.9 vs. 3.5 ± 1.2) and inhibin B (15.7 ± 10.4 vs. 28.3 ± 8.3) levels between hyalinization and non-hyalinization group (All P>0.05). However, testicular volume in hyalinization group was lower than non-hyalinization group (4.1 ± 2.3 vs. 5.3 ± 3.7, P<0.05). Spermatozoa were successfully retrieved from 16 patients (32%), SRR of hyalinization group was higher than non-hyalinization group (41.2% vs. 12.5%, P<0.05). 15 patients (30%) showed heterogeneous thickness of seminiferous tubule and 12 of them were found to have testicular sperm (80%). Patients in hyalinization group had more opportunity to show heterogeneous tubule than non-hyalinization group (35.3% vs. 18.8%, P>0.05).

Limitations, reasons for caution: In our study, although patients with SCO combining with seminiferous tubule hyalinization had more opportunity to show heterogeneous testicular tubule than those without hyalinization, more cases should be included because the difference was not significant. And it is unclear that whether the hyalinization precedes or follows the spermatogenic disorder.
Wider implications of the findings: Based on our results, regarding higher SRR, micro-TESE should be recommended to NOA patient with SCO especially for those combining with seminiferous tubule hyalinization. Considering micro-TESE would not provide an advantage if seminiferous tubules show homogeneous thickness, needle biopsy should be performed previously to minimized testicular damage.
Trial registration number: (This is a retrospective study).

P-049 Interleukin-18 and apoptosis of mice Leydig cell during lipopolysaccharide-induced acute inflammatory condition

T. Inoue[1,2,3], M. Ishikawa[1,2], M. Uemura[1], H. Yamashita[1], Y. Koga[1], A. Nakao[2], J. Kotani[2], M. Usami[1]
[1]*Kobe University Graduate School of Health Sciences, Department of Biophysics, Kobe, Japan*
[2]*Hyogo College of Medicine, Department of Emergency Disaster and Critical Care Medicine, Nishinomiya, Japan*
[3]*Miyazaki Ladies Clinic, Reproductive Medical Laboratory, Osaka, Japan*

Study question: Dose Leydig cell-derived interleukin (IL)-18 induce apoptosis of Leydig cell during lipopolysaccharide (LPS)-induced acute inflammation?
Summary answer: LPS induced Leydig cell apoptosis via death-receptor pathway without increased IL-18.
What is known already: In mouse testes, IL-18 is produced from germ cells, Leydig cells, and resident macrophages and may regulate testicular function via autocrine/paracrine signaling under physiologic conditions. IL-18 is an important cytokine to maintain the homeostasis of testicular cells. However, we reported high dose of IL-18 induced germ cell apoptosis on mice endotoxemia. (Inoue et al., 2015). Bamias et al. (2012) reported the role of IL-18 depends on which cells secrete it. In intestine, endothelial cell-derived IL-18 induced epithelial reconstitution, but lymphocyte-derived IL-18 induced epithelial injury. The amount of IL-18 may be a key determinant of the role of IL-18.
Study design, size, duration: Recombinant interleukin-18 (rIL-18) stimulation: TM3 cells were stimulated with 0.1, 1, 10, and 100 ng/mL rIL-18 and were sampled at 12 hours. LPS stimulation: Mouse Leydig cell line TM3 and macrophage cell line RAW264.7 cells were stimulated with 200 or 1,000 ng/mL LPS and were sampled at 0, 1, 6, 12, 24 and 48 hours. Vehicle: TM3 or RAW264.7 cells were incubated medium only.
Participants/materials, setting, methods: Cells were harvested on 6-well microplate (4×10^5 cells) with DMEM-F12 medium for 48 hours at 37°C, 5% CO_2. Cell viabilities were determined by trypan blue staining. Cleaved caspase-3 and tBID was measured by western blotting to evaluate apoptosis and the pathways. Expressions of Tnf-α, Il-6, Il-18 and Fas mRNA were analyzed using reverse transcriptional real-time PCR. Statistical analysis was performed using a Tukey–Kramer's post hoc test (statistically significant; $p < 0.05$ compared with vehicle).
Main results and the role of chance: High dose (10 and 100 ng/mL) of rIL-18-stimulation induced cleaved caspase-3 expression in TM3 at 12 hours. In LPS-stimulation, expressions of Tnf-α and Il-6 were significantly increased at 1 hours ($p < 0.01$), and decreased to baseline within 6 hours. LPS had no influence on the cell viabilities on TM3 and RAW264.7. Cleaved caspase-3 expressions were increased at 6 hours, and it kept until 48 hours. Expression of Fas was increased at 12 hours ($p < 0.05$), but it of tBID could not be detected. Expression of Il-18 in TM3 were significantly low at 6 and 12 hours ($p < 0.05$, $p < 0.05$, respectively). The expression of Il-18 in RAW264.7 were significantly increased at 6 hours ($p < 0.01$) and kept high level until 24 hours. These results suggested that IL-18 was produced mainly by macrophages during LPS-stimulation. In this study, rIL-18 induced Leydig cell apoptosis. LPS also induced Leydig cell apoptosis via death-receptor pathway, but LPS did not increase IL-18 in Leydig cell. Macrophages increased IL-18 expression by LPS stimulation. We speculated macrophage-derived IL-18 may be a main reason of over-expression of IL-18, which leads Leydig cell apoptosis, during endotoxemia.
Limitations, reasons for caution: The limitation of this study is the cell-cell interactions could not be evaluated. Future studies are planned to investigate the effect of IL-18 on cell-cell interaction by co-culture system.
Wider implications of the findings: Our results suggested that the high dose of IL-18 induced of Leydig cell apoptosis. The high dose of IL-18 may derive from macrophages. Prevent overexpressed IL-18 from macrophages could be a new therapeutic target to prevent orchitis during endotoxemia.
Trial registration number: Not applicable.

P-050 Assessment of sperm motility in oligoasthenospermic men, treated with metabolic and essential nutrients, in a randomized, double blind, placebo study

S. Micic[1], N. Lalic[1], N. Bojanic[2], D. Djordjevic[2], A. Virmani[3], A. Agarwal[4]
[1]*Uromedica Polyclinic, Andrology Department, Belgrade, Serbia*
[2]*Clinical Center of Serbia, Urologic Clinic, Belgrade, Serbia*
[3]*Sigma-tau-nl, Inovation-Reserach and Devekopment at Sigma-tau Health Scinece, Utrecht, The Netherlands*
[4]*American Center for reproductive Medicine, Andrology Center, Cleveland, USA*

Study question: The aim of the study was the assessment of sperm motility, especially progressive motility, after 3 and 6 months therapy of men with oligoasthenozoospermia.
Summary answer: Study showed significant improvement in progressive motility after 6 months therapy with metabolic and essential nutrients in men with initial low progressive motility.
What is known already: Spermatozoa have high-energy requirements for maturation, capacitation and motility. Indeed many factors affecting their motility act through decreasing energy availability mainly by disrupting mitochondrial function. Many nutrients and metabolic compounds affect mitochondrial function. The compounds L-carnitine (L-C) and acetyl-L-carnitine (ALC) play a pivotal role in transport of long-chain fatty acids into the mitochondrial matrix, where they are used to generate energy. Both L-C and ALC also have important roles in the post-gonadal maturation of spermatozoa. Studies have reported either no effect or that treatment with combined high dose L-C and ALC significantly increases sperm concentration and forward motility.
Study design, size, duration: This study was randomized, double blind, placebo controlled and it examined the effect of test formulation, Proxeed Plus, L-C 2g and ALC 1g, as well as vitamins and minerals, in men with oligo- or asthenoteratozoospermia. The protocol was 2 months "wash out" and 6 months therapy (125 patients) or placebo (50 patients) and 2 months follow up (T-2, T0, T+3,T+6). The control group (placebo) 50 patients were administered in a similar way with the placebo.
Participants/materials, setting, methods: Men visiting the Andrology center, aged between 18 and 50 years and with history of difficulty conceiving > 12 months were randomized to receive treatment or placebo in a double blind protocol**.** Subjects with endocrine disorders, autoimmune disease, azoospermia, cystic fibrosis, testicular cancer etc., were excluded. Compliance was assessed at visits. Analysis of ejaculate was done according to WHO 5th guideline, and progressive sperm motility (A+B grade of rapid, progressive) was done manually.
Main results and the role of chance: There was a statistically significant difference with $p = 0.34$, by Kruskal-Wallis test, in the values of progressive sperm motility in three different time period: T0=22.50% (11.50 ± 38.00), T3=22% (11.00 ± 40.00) and T6=28.50% (16.75 ± 40.25).

Then we correlated all 3 groups between each other, with Friedman tests, and analysis showed a statistically significant difference between T0 =22.50% (11.50 ± 38.00) and T6= 28.50% (16.75 ± 40.25) with $p < 0.05$. In placebo group we couldn't find significant improvement, in progressive sperm motility, before 20.14 (10.39 ± 28.11) and after 6 months period (23.44 (14.65 ± 30.16) with $p < 0.082$.
Limitations, reasons for caution: In this randomized, placebo study we used a manual method of evaluating the rapid and progressive movement of the cells, and this can have a some possible impact of assessment of motility. But experienced biologist and technician has done all this analysis
Wider implications of the findings: Results of this randomized study agreeing with with other non-randomized studies with smaller sample size. We underline

the importance of duration of therapy (3 and 6 months) with metabolic and essential nutrients: this means that after 6 months therapy we can expect significantly higher percentage progressive sperm motility.
Trial registration number: Protocol PXP-001-B.

P-051 Outcome of testicular sperm extraction in 52 spinal cord injured-men

K. Suzuki[1], T. Iwahata[1], Y. Shimomura[1], T. Kobayashi[1], T. Shin[1], A. Miyata[2], H. Okada[1]
[1]Dokkyo Medical University Koshigaya Hospital, Urology, Koshigaya, Japan
[2]Dokkyo Medical University Koshigaya Hospital, Reproduction Center, Koshigaya, Japan

Study question: What are the outcomes of testicular sperm extraction in spinal cord injured-men?
Summary answer: TESE is one of the most useful technique for sperm retrieval in spinal cord injury patient.
What is known already: In men with spinal cord injury (SCI) the ejaculated sperm usually exhibits poor motility and viability. Under these circumstances, IUI with ejaculated sperm in men with SCI commonly is not offered so far. Recently, it is said testicular sperm is optimal for intracytoplasmic injection (ICSI) in men with SCI.
Study design, size, duration: This study is retrospective analysis for spinal cord injury-men who enforced TESE from April, 2008 to December, 2015.
Participants/materials, setting, methods: A total of 52 male patients with ejaculatory disorder due to SCI who underwent TESE for various reasons were included in this study. We investigated the sperm retrieval rates (SRRs) and pregnancy rates (PRs) from the medical records. Data on the age, testicular volume, the hormonal status (lutenizing hormone, follicle stimulating hormone (FSH), testosterone), and the period from SCI injury were also obtained and analyzed to detect any associations with the presence of spermatogenesis.
Main results and the role of chance: SRRs and PRs were 89% and 62%, respectively. A univariate analysis revealed a statistically significant relationship between serum FSH level ($P < 0.001$), serum LH level ($P < 0.005$), the period from SCI injury ($P < 0.005$) and spermatogenesis presence. A logistic regression model, however, revealed a statistically significant relationship only between serum FSH level and spermatogenesis presence ($P < 0.0001$). No association was found between the period from SCI injury and the presence of spermatogenesis.
Limitations, reasons for caution: Study data were obtained retrospectively, which might have affected the quality of the data. Furthermore, the sample size was too small to draw definite conclusions from the results. We need to accumulate additional data from similar cases.
Wider implications of the findings: None.
Trial registration number: None.

P-052 Taste receptors genes variability related to male infertility: expression of gustducin and transducin G proteins α-subunits in human sperm

L. Crifasi[1], P. Piomboni[2], D. Campa[3], M. Gori[2], A. Luddi[2], V. De Leo[2], R. Barale[4]
[1]San Cipirello, Italy
[2]University, Department of Molecular and Developmental Medicine, Siena, Italy
[3]Department of Biology, Section of Genetics, Pisa, Italy
[4]Section of Genetics, Department of Biology, Pisa, Italy

Study question: Association of TAS2Rs/TAS1R (taste receptors) and GNAT3 (alpha transducing 3) genetic variants with male infertility and localization of α-gustducin and α-transducin in human spermatozoa before and after *in vitro* capacitation.
Summary answer: Genetic variants in taste related genes and sperm parameters are correlated. Human sperm expresses taste receptors with a different localization in basal versus capacitated sperm.
What is known already: Several studies in mammals have demonstrated the expression of α-gustducin and α-transducin, G proteins coupled with taste receptors, during mouse spermatogenesis and a segmental distribution along the flagellum of mouse, rat, bull, and boar spermatozoa, suggesting a functional role in processing intracellular signals controlling sperm motility. It has been reported that taste sensitivity varies among individuals and that it is associated with polymorphisms in the taste receptor genes. The high frequency of human genetic variations of genes involved in taste perception results in a large variability from super-taster subjects to totally "non-taster" patients, that might be influence sperm functionality too.
Study design, size, duration: For this study, a total of 314 males patients undergoing spermiogram evaluation during infertility diagnosis at the Centre of Couple Sterility, Siena University Hospital (Italy), were enrolled starting from October 2014 to October 2015.
Participants/materials, setting, methods: The patients enrolled were characterized for main sperm parameters, according to WHO (2010) guidelines: concentration, morphology, progressive and total motility, and their genomic DNA was isolated both from buccal swab. All subjects were then genotyped for 24 single nucleotide polymorphisms (SNPs) in TAS2Rs/TAS1R and GNAT3 genes. The genotyping was performed using the KASPar SNP genotyping system. Ejaculated spermatozoa were analyzed by Western blot and immunofluorescence analysis before and after *in vitro* capacitation.
Main results and the role of chance: Association between the SNPs and the main sperm parameters was tested through chi^2 test. We found a statistically significant association between *sperm concentration* and *progressive motility* with TAS1R1 rs12080675 SNP ($p = 0.04$; $p = 0.01$). Also TAS2R49 rs7135018 SNP ($p = 0.01$) was associated with *sperm concentration*. *Progressive and total motility* resulted correlated with both TAS1R1 rs11587438 SNP ($p = 0.001$) and TAS2R14 rs11610105 ($p = 0.014$). A statistically significant association was also between *total motility* and TAS2R44 rs10845293 ($p = 0.015$), TAS2R49 rs7301234 ($p = 0.008$) the TAS2R50 rs1376251 SNPs ($p = 0.004$). Based on immunoblot and immunofluorescence analyses, both G proteins are present in human sperm; α-gustducin was detectable in both the acrosome and the proximal region of the tail, whereas α-transducin signal was confined only to the proximal region of the tail, with a different intensity among individual sperm cells. After capacitation, both G proteins change their localization: this phenomenon may be relevant for the next stages, such as acrosomal reaction, zona pellucida penetration and finally motility iperactivation.
Limitations, reasons for caution: The polymorphism TAS2R49 rs7135018 has a low frequency in the population and therefore a larger study needs to be carried out in order to validate the findings.
Wider implications of the findings: Further studies might contribute in further understanding the genetic components of male infertility and the possible role of these G proteins in sperm physiology.
Trial registration number: None.

P-053 Evaluation and introduction into service of Male Factor Infertility assays, in the provision of Y-chromosomal micro-deletion screening for the West of Scotland

J.M. Rice[1], J. Doherty[1], T. Bradley[1], C. Morrissey[2], N. Williams[1]
[1]West of Scotland Genetic Services, Molecular Diagnostics Laboratory, Glasgow, United Kingdom
[2]Elucigene Diagnostics, Citylabs, Manchester, United Kingdom

Study question: To evaluate the suitability of two newly developed assays for the detection and determination of the extent of Y-chromosomal micro-deletions in routine diagnostic practice
Summary answer: We document our experience of Elucigene Diagnostics Male Factor Infertility kits (MFI) that are suitable for diagnostic service provision and compliant with EMQN guidelines
What is known already: Chromosome micro-deletions of the Azoospermia factor regions (AZF) on the Y chromosome have long been implicated in male infertility. There are several commercial Y-chromosomal micro-deletion analysis kits available, however recent EMQN best practice guidelines recommend that the extent of any deletion detected is determined (using extension analysis) for the fullest clinical representation and utility. Elucigene Diagnostics have produced a workflow (MFI) to detect AZF deletions and then ascertain their extent. In addition the MFI kit can indicate of the presence of a sex chromosome aneuploidy, itself a cause of male infertility.
Study design, size, duration: Retrospective testing of Y micro-deletion positive samples from our diagnostic service male infertility cohort and parallel analysis of prospective samples referred during (Oct-Dec 2015). Further data will be collected throughout 2016 as the assays are phased into service delivery.

Participants/materials, setting, methods: Blood samples from male patients referred from local (Greater Glasgow and Clyde NHS region, Scotland, UK) Assisted Conception Units, in male infertility cases for routine genetic analysis including karyotype analysis.
Main results and the role of chance: Our study comprises retrospective and prospective testing AZF deletion cases (known positives or new referrals) and then ongoing service delivery using the Elucigene Diagnostics Male Factor Infertility assays. Our testing remit includes the use of both Male Factor Infertility and Male Factor Infertility-Y-Plus to fully resolve any deletions detected. In total we analysed 34 retrospective cases and 35 new referrals with the MFI kit.

Secondary analysis was performed using Elucigene Diagnostics MFI-Y-Plus assay to assess the extent of those deletions found with the MFI assay. We analysed a total of 8 cases with deletions which reflected a range of AZFa, AZFb+partial AZFc and AZFc deletions.

Our results showed complete concordance with previous or parallel analysis using an alternative Y-chromosome micro-deletion kit and additionally we were able to define the extents of those deletions. This included the ability to discriminate between two AZFb+partial AZFc deletion cases which were previously typed as identical, but differed with the presence or absence of marker sY105.

Implementation of these kits proved to be simple, with single tube set up for both assays and clear and intuitive analysis using Soft Genetics Genemarker™. Adoption of this workflow has facilitated improvements to our Infertility service.
Limitations, reasons for caution: Due to the nature of our referrals no new deletions or sex chromosome aneuploidy were detected during the prospective validation period (Oct-Dec 2015). While the markers present are sufficient to indicate the presence of a sex chromosome aneuploidy, we recommend additional analysis by sexing QF-PCR for confirmation.
Wider implications of the findings: A solution to the difficulties of introducing extension analysis for the Molecular Diagnostic community of accredited service laboratories in the UK and beyond.
Trial registration number: Not applicable.

P-054 Mitochondrial DNA copy number in spermatozoa as a predictor of successful IVF

L. de Wit[1], J. Rhemrev[2], J.W. Lens[3], R. Menkveld[4]
[1]*The Hague, The Netherlands*
[2]*Bronovo Hospital, Department of Obstetrics and Gynaecology, The Hague, The Netherlands*
[3]*VU medical centre, IVF Centre, Department of Obstetrics and Gynaecology, Amsterdam, The Netherlands*
[4]*Tygerberg Academic Hospital and university of Stellenbosch, Department of Obstetrics and Gynaecology, Tygerberg, South Africa*

Study question: Is there an association between mitochondrial DNA (mtDNA) copy number in spermatozoa and IVF outcome?
Summary answer: No significant correlation was found in the studied IVF group between the number of mtDNA copies and fertilization rate or pregnancy outcome.
What is known already: Sperm mitochondria provide energy via adenosine triphosphate (ATP) production and affect apoptosis (programmed cell death). Abnormal mitochondria may therefore effect sperm motility and are associated with reduced spermatozoa production. Several studies reported mutations in mtDNA associated with asthenozoospermia or a negative impact on male fertility. Deletions in mtDNA and decreased sperm motility have also been described. Studies evaluating the relationship between abnormal semen parameters and mtDN copy numbers found that an increased mtDNA copy number could result in parameters such as a higher percentage of non-progressive motile spermatozoa and thus influence the fertilizing capacity of spermatozoa.
Study design, size, duration: Prospective observational cohort study. Semen samples were collected from 104 men of couples undergoing IVF treatment in the IVF centre of a university medical centre.
Participants/materials, setting, methods: Participants of the study were males from couples undergoing IVF treatment in a university hospital. The threshold for inclusion was ejaculates with a minimal post-wash sperm count of $>10^6$ spermatozoa. Semen analyses were performed based on the WHO (1992/1999) guidelines. The method for mtDNA measurement used was based on the commercially available Retina Mitox DNA test (Primagen – Amsterdam, the Netherlands) consisting of DNA extraction, DNA amplification and mtDNA measurement.
Main results and the role of chance: To examine the correlation between the number of mtDNA copies and the fertilization rate in the IVF group, the Spearman's Rho Correlation coefficient for non-paramentric data was used. No significant correlation was found, $r = 0.068$, $p = 0.494$. The mean (SD) fertilization of oocytes in the study group was 66.7% (28.3). The correlation between mtDNA copy number and pregnancy outcome was also non-significant, $r = -0.45$, $p = 0.654$. The overall pregnancy rate was 32.4%.

Data concerning fertilization were non-dichotomous. A cut-off value was visually determined for fertilization rates, in order to use the dichotomous ROC curve. The cut-off value was 21%. The "area under the curve" (AUC) was used as a measurement of accuracy of the test, which was 0.611. The small AUC indicates that the number of mtDNA copies has no predictive or prognostic value for fertilization rates in IVF treatment.

The ROC curve was also used for studying the predictive value of mtDNA copy number for the outcome of pregnancy, but yielded similar results, indicating that mtDNA copy number in sperm cells does not have a predictive value for pregnancy outcome in assisted reproductive treatment.
Limitations, reasons for caution: A limitation is the fact that one needs at least 10^6 total progressive motile spermcells post-wash to adequately run the Retina Mitox DNA assay. Therefore males with less than 10^6 post-wash spermatozoa were excluded from the analyses.
Wider implications of the findings: Based on this study mitochondrial DNA in spermatozoa has no prognostic value in assisted reproductive therapies regarding fertilization rate or pregnancy outcome.
Trial registration number: No clinical trial.

P-055 Study of the protection of zinc and alpha-tocopherol on human sperm parameters, lipid peroxidation, apoptosis and DNA fragmentation with Mobile Phone Radiation treated *in vitro*

M.H. Bahadori[1]
[1]*Gilan University of Medical Sciences, Rasht, Iran*

Study question: What is the role of zinc and alpha-tocopherol to protect human sperm irradiated with mobile phone?
Summary answer: its seems zinc and alpha-tocopherol decrease the harmful effect of mobile phone exposure on human sperm.
What is known already: Cell phones have become an essential part of daily life but, the health risks related with their usage are often overlooked. However, possible consequences of the cellular phone usage on human sperm parameters have not been investigated adequately. This study was performed to evaluate the possible protective effect of zinc and alpha-tocopherol, against sperms exposed to the cell phone radiation.
Study design, size, duration: Semen samples were obtained from 18 fertile males presenting to the infertility clinic between 25–41 age years during 1 Feb 2013 t0 1Feb 2014. Following liquefaction, sperm parameter was performed based on WHO standard criteria (2010), and then each sample was divided equally into 5 parts: control (sample not exposed), exposed (sample exposed to cell phone), exposed+15µM zinc, exposed+5µM alpha-tocopherol, and exposed+15µM zinc+5µM alpha-tocopherol groups. Irradiation was done by cell phone for 10 minutes continuously.
Participants/materials, setting, methods: In all groups, sperm analysis was performed for their viability, morphology and motility. Morphology test was conducted using giemsa dye, viability test with trypan blue staining protocol and DNA fragmentation with halo test. Apoptosis detection was carried out by means of TUNEL kit, lipid peroxidation via MDA kit and total antioxidant capacity with TAC kit. Data were analyzed by one-way ANOVA followed by Tukey's test using SPSS version 16 software.
Main results and the role of chance: Our result indicated that exposure group showed a significant decrease in the rapid progressive, slow progressive sperm movement and viability compare to control groups. It also increases the no – motility category of sperm movement and abnormal sperm significantly ($p < 0.05$). In comparison with the fresh and exposed groups, there was a significant decrease in the total antioxidant capacity but increased the lipid peroxidation, DNA fragmentation and apoptosis ($p < 0.05$).

Also alpha- tocopherol (5 mM) and zinc (15 µM) increases rapid progressive, slow progressive and viability of sperm and decreased abnormal sperm in mobile phone exposed group significantly. Moreover, zinc and

alpha-tocopherol only and combined together, induced significant increases the total antioxidant capacity and decreased lipid peroxidation, DNA fragmentation and apoptotic sperm in mobile phone exposed group ($p < 0.05$). Furthermore, there was not a significant difference in morphology between five groups.

Limitations, reasons for caution: This is an in-vitro study because of we used just human fertile men just presenting to our infertility center and the number of case low during study.

Wider implications of the findings: We concluded Radiofrequency electromagnetic waves emitted from cell phones may lead significant decrease sperm parameter**.** The addition of zinc and alpha- tocopherol only and combined together in the semen could be useful to prevent human semen parameters after mobile phone radiation.

Trial registration number: The results of this study indicated that master of science thesis in guilan university of medical sciences with No: 100.

P-056 Is there an association between the different HOST-induced tail swelling patterns and sperm quality?

S. Daoud[1], N. Chakroun-Feki[1], A. Sellami[1], K. Chaabene[2], L. Ammar-Keskes[1], T. Rebai[1]

[1]Medical School of Sfax, Histology-Embryology Laboratory and Research Unit, Sfax, Tunisia

[2]Hedi Chaker academic Hospital, Gynaecology and Obstetrics Department, Sfax, Tunisia

Study question: We aimed to investigate whether the degree of sperm tail swelling observed during hypo-osmotic swelling test (HOST) may predict sperm quality in infertile men.

Summary answer: Our results show that the pattern of sperm tail swelling seems to be strongly linked to sperm functional integrity.

What is known already: Based on the sperm reaction (swelling) under hypo-osmotic conditions, HOST was developed to evaluate sperm membrane integrity. The usefulness of this test to identify viable immotile sperm in testicular or ejaculated preparations during intracytoplasmic sperm injection (ICSI) is widely approved. However, little is known about the significance of the different patterns of sperm tail swelling under hypo osmotic stress.

Study design, size, duration: The study was performed on semen samples collected from 37 men attending our center for couple infertility investigation.

Participants/materials, setting, methods: Semen analyses and HOST were performed according to the World Health Organization (WHO) guidelines. Sperm chromatin status was evaluated by a modified version of the Diff-Quik staining assay and expressed by the percentage of abnormal dark nuclear staining sperm (DQ-D).

Main results and the role of chance: The mean HOST value for the study group was 66.5 ± 10%, and was positively correlated with sperm motility ($r = +0.34$; $p = 0.03$) and vitality ($r = +0.34$; $p = 0.04$). There was a negative association between the mean HOST value and the percentage of DQ-D sperm ($r = -0.36$; $p = 0.03$). The mean percentage of HOST-induced tail-swelling grade "b" was significantly associated with higher sperm motility, vitality, concentration, and improved sperm morphology. Grade "d" was positively correlated with sperm motility and morphology, and grade "f" with sperm concentration and morphology.

Limitations, reasons for caution: The distribution of HOST categories with relevance to semen quality subgroups need to be elucidated.

Wider implications of the findings: HOST is a useful tool for rapid, low-cost semen quality evaluation. According to our results, HOST grades "b", "d" and "e" were most associated with better sperm parameters, suggesting their preferential use during routine sperm selection for ICSI.

Trial registration number: No trial registration number.

P-057 Cigarette smoking and semen quality: a new meta-analysis examining the effect of the 2010 world health organization laboratory methods for the examination of human semen

R. Sharma[1], A. Harlev[2], A. Agarwal[3], S.C. Esteves[4]

[1]Saint Joseph's University, Department of Health Services, Philadelphia, PA, USA

[2]Soroka University Medical Center, Obstetrics and Gynecology, Beer - Sheva, Israel

[3]Cleveland Clinic, American Center for Reproductive Medicine, Cleveland, OH, USA

[4]ANDROFERT, Andrology and Human Reproduction Clinic, Campinas, Brazil

Study question: To assess the impact of smoking on semen parameters according to the updated World Health Organization (WHO) methods for laboratory evaluation of human semen.

Summary answer: Cigarette smoking negatively affect sperm parameters. Sperm count and motility remained similar when WHO 2010 and earlier criteria were used but equivocal for sperm morphology.

What is known already: Approximately 37% of men of reproductive age smoke cigarettes, with Europe having the highest tobacco use among all the WHO regions. Smoking cigarettes has been associated with a deterioration of sperm quality, including motility, concentration and morphology, which are the parameters most frequently used in clinical settings to assess fertility. However, the evidence is not unequivocal, and some studies have found no effect on sperm quality. Given the high prevalence of smoking and the new WHO laboratory criteria for the examination of human semen, the role of cigarette exposure on semen parameters needs a new look.

Study design, size, duration: We conducted a systematic search using MEDLINE/Pubmed, SJU discover and Google Scholar to identify all relevant studies published from 2010 to 2015 (August) after release of the latest WHO methods for laboratory evaluation of human semen. Participants were from fertility/urological clinics and andrology laboratories. The outcome measures were semen volume, sperm concentration, motility and morphology which are the parameters commonly used in clinical settings to assess fertility.

Participants/materials, setting, methods: Participants were males aged 13 years and older regardless of population size and origin. Each semen parameter was evaluated separately and independently. Infertile smokers were compared to matched smokers from the general population. Subgroup analyzes included the comparison of infertile smokers and infertile non-smokers, WHO criteria for laboratory examination of human semen 2010 edition versus previous editions, and impact assessment of the number/amount of cigarettes consumed per day on semen parameters.

Main results and the role of chance: We used twenty studies in the meta-analysis, involving 5,865 subjects. Exposure to cigarette smoking was associated with reduced sperm count (mean difference -9.72×106/mL, [95% CI −13.32, −6.12], $P < 0.001$), motility (mean difference −3.48% [95% CI −5.53, −1.44], $P < 0.001$) and morphology (mean difference −1.37%, [95% CI −2.63, −0.11], $P = 0.03$), but not with semen volume (mean difference −0.15 mL, [95% CI −0.35, 0.05], $P = 0.14$). Subgroup analyses indicated that effect size was higher in infertile men than the general population and in moderate (10–20 cigarettes a day) and heavy smokers (>20 cigarettes a day) than mild (<10 cigarettes a day) smokers. The recent changes in the WHO methods (5th edition) for laboratory evaluation of human semen did not seem to influence the observed negative effect of an association between smoking and sperm count and motility, but results on semen volume and morphology were equivocal.

Limitations, reasons for caution: The meta-analysis did not include any randomized trials since a randomized trial to assess the impact of smoking is not practical. We conducted a thorough bias evaluation of the included studies.

Wider implications of the findings: Pooled results from studies evaluated suggest that cigarette smoking negatively affects sperm quality. The full clinical implications of the WHO 2010 criteria on the association between cigarette smoking and human semen quality deserves further investigation.

Trial registration number: As a meta-analysis the study did not require registration.

P-058 Clinical experience with personalized treatment of male infertility by FSH based on FSH receptor gene polymorphisms

I. Cernakova[1], L. Reismullerova[2], M. Grossova[2], R. Petrovic[1], M. Fischerova[1], J. Valky[2]

[1]Reprogen- S.R.O., Department of genetics, Bratislava, Slovakia

[2]Iscare, Reprofit- A.S., IVF Center, Bratislava, Slovakia

Study question: Can the low-dose FSH treatment of oligoastheno (terato) zoospermia men based on FSHR gene polymorphisms improve semen analysis parameters and pregnancy rate?

Summary answer: The low-dose administration of FSH in oligoastheno (terato) zoospermic men has a positive impact on parameters of semen analysis and pregnancy rate.

What is known already: Follicle-stimulating hormone (FSH) stimulates proliferation of Sertoli cells and it is an essential hormone for induction and maintenance of normal spermatogenesis. FSH acts through binding to a specific receptor (FSHR) encoded by FSHR gene. The two most common polymorphisms in the coding region occur at nucleotide position 919 and 2039 in exon 10, which cause amino acid exchange from threonine (Thr) to alanine (Ala) at codon 307 and from asparagine (Asn) to serine (Ser) at codon 680. These polymorphisms can be risk factors for sperm production. The part of oligoastheno(terato)zoospermic men can benefit from FSH treatment based on their genotype.
Study design, size, duration: Prospective evaluation of the response of low-dose FSH treatment in terms of sperm production and pregnancy rate on the basis of Ala307Thr-Asn680Ser polymorphisms in the FSHR gene in OAT men with normal hormonal profile in 2012–2015 years with the goal to overcome the side-effects and to bring to the patients a low-cost treatment of male infertility.
Participants/materials, setting, methods: We examined 72 Slovak men with presented severe form oligoastheno(teratooospermia with unsuccessful previous IVF cycles. All of them had normal hormone profile, normal karyotype, no cystic fibrosis gene mutation and no Y-chromosome microdeletion. The patients after chemo-/radiotherapy were excluded. We tested FSHR gene exon 10 polymorfisms (rs6165, c.919A>G and rs6166, c.2039A>G) by DNA sequencing. Men with at least one Asn680Ser allele were treated by 75 IU FSH, administrated 3-times one injection weekly.
Main results and the role of chance: DNA analysis revealed 65 men (90.3%) with at least one Asn680Ser allele presented. All of them were treated by low-dose FSH. Semen analysis was done before and 3 months after therapy. The improvement of its parameters was observed after treatment (sperm concentration 3.8 mil/ml vs. 10.8 mil/ml, motility 2.0 mil/ml vs. 5.2 mil/ml, 3% vs. 8% of normal sperm morphology). 16 couples (24.6%) were pregnant 4–8 months after treatment, 10 of them by IVF methods and 5 couples had spontanneous pregnancy. Seven men with standard haplotype (presence of two normal alleles for both polymorphisms in exon 10) were additionaly tested for polymorphisms in the promotor of FSHR gene (rs1394205, −29G>A) and in the promotor of beta-subunit FSH gene (FSHB: rs10835638, −211G>T) by DNA sequencing. This additional examination revealed that 3 of them (3/7, 42.8%) could have profit based on FSH treatment and the chance to have child.
Limitations, reasons for caution: The low-dose and low-cost FSH therapy can be appropriate in selected oligozoospermic men with normal FSH level. The occurence of a higher number of the men with two Ser680 alleles could be affected by method of selection. Moreover, a part of patients can benefit after additional evaluation of FSHR/FSHB promotor polymorphisms.
Wider implications of the findings: We choosed a low-dose FSH administration of normogonadotrophic men with decreased semen parameters to overcome possible side-effect of treatment. According to our preliminary experience and publicated data FSHB and FSHR promotor polymorphisms should be taken into account, including the severity of impairment of spermatogenesis and the genotype of the patients.
Trial registration number: Not applicable.

P-059 The influence of hyperbaric oxygenation (HBO) and antioxidant therapy (AT) on spermatogenesis in course of preparation for assisted reproduction technique (ART)

Y. Shtyrya[1], E. Korshunova[2], M. Korshunov[3], L. Kindarova[4]
[1]*Russian-German Centre of Reproduction and Clinical Embryology "Generation NEXT", Moskva, Russia C.I.S.*
[2]*National Medical Research Centre of Radiology, Department of Oncoandrology, Moscow, Russia C.I.S.*
[3]*Russian-German Centre of Reproduction and Clinical Embryology "Generation NEXT", Andrology, Moskva, Russia C.I.S.*
[4]*Russian-German Centre of Reproduction and Clinical Embryology "Generation NEXT", IVF, Moskva, Russia C.I.S.*

Study question: Our study was focused on the comparison of solo AT, HBO effects and combine therapy (CT) in the correction of severe forms of pathospermia.
Summary answer: Merged effect of CT is supreme to the effect of solo AT and HBO on spermatogenesis in the course of preparation in IVF/ICSI cycles.
What is known already: Dramatic idiopathic spermatogenesis changes are known to decrease ART success rate. Oxygen deficiency, piling up of byproducts of anaerobic metabolism can cause disturbances in tissue metabolism, mitochondrial deficiency, imbalance of spermatogenesis of hormonal regulation, and, as a consequence severe forms of pathospermia.

Several studies have shown that empirical AT may improve sperm quality, ART outcome and increase pregnancy rates. There are few studies showing positive effects of hyperbaric oxygenation (HBO) on spermatogenesis.
Study design, size, duration: Data was collected from May 2013 to July 2015. Only the couples with idiopathic male factor of infertility were considered. We analyzed 56 ART failure (IVF/ICSI) cases. Patients were randomly divided into 3 groups. First 16 men – AT (E vitamin, L-carnitin, selenium) for 8 weeks, second 19 men - HBO (12 consecutive sessions, 1,6 ATM for 50 min), third 21 men - HBO and AT (CT). After the therapy the couples underwent subsequent IVF-ICSI.
Participants/materials, setting, methods: The mean men age was 31.6 ± 5.2 years. All of patients had dramatic idiopathic changes in sperm (oligoasthenoteratozoospermia). None of them had any urological and genetic abnormalities. Semen analysis (WHO 2010), DNA fragmentation index (DFI) (Halosperm©), semen oxidative stress reaction (ROS) were performed before and after the treatment. The fertilization rate, blastocyst formation rate, biochemical and clinical pregnancy rates per IVF/ICSI cycle were measured.
Main results and the role of chance: There was no significance difference in parameters in groups before the therapy. The results after the treatment: 1 group – mean sperm concentration increased by 13.9%, sperm motility (a+b) increased by 20.7%,% normal morphology increased by 16.7%, sperm vitality - by 18%, DFI decreased by 6.6% ($p < 0.05$), ROS decreased by 24.1%.

2 group - mean concentration increased by 14.6%, motility increased by 38.6% ($p < 0.05$),% normal morphology increased by 55.6% ($p< 0.05$), sperm vitality - by 24.5% ($p< 0.05$), DFI decreased by 1.6% ($p< 0.05$), ROS increased by 168% ($p< 0.001$).

3 group - mean concentration increased by 20.3% ($p < 0.05$), sperm motility – by 83.3% ($p < 0.001$), percentage of normal sperm increased by 100% ($p < 0.001$), sperm vitality increased by 34.8% ($p< 0.001$), DFI decreased by 5.6% ($p < 0.05$), ROS increased by 142.9% ($p < 0.001$). There was a significant negative correlation between DFI and sperm motility in all groups ($p < 0.05$).

For the couples in 3 groups who underwent ICSI blastocyst formation rate improved to 45% ($p = 0.05$), 46% ($p < 0.05$) 52% ($p < 0.001$) in groups 1, 2 & 3 respectively. Biochemical pregnancy rates were 62.5% [10/16], 63.2% [12/19], 76.1% [16/21] in groups 1, 2, 3 respectively. Clinical pregnancy rates were 43.7% [7/16], 47.3% [9/19], 57.1% [12/21] in groups 1, 2, 3 respectively.
Limitations, reasons for caution: There were no registered side effects of the proposed therapy. Further studies with larger population are needed.
Wider implications of the findings: Merged effect CT is supreme to the effect of solo AT and HBO on semen quality. Despite rising ROS we did not marked increasing sperm DFI. CT significantly improves IVF/ICSI outcome. HBO is proven to be safe and might be used for pathospermia correction in course of preparation for ART.
Trial registration number: N/A.

P-060 Outcome of ICSI with testicular spermatozoa obtained through microscopically assisted testicular sperm extraction in relation to the ovarian response

M. Karacan[1], M. Ulug[1], A. Arvas[1], A. Usta[2], E. Erdem[3], Z. Cebi[1], T. Camlibel[1]
[1]*Ota Jinemed Hospital, Reproductive Endocrinology and Infertility Clinic, Istanbul, Turkey*
[2]*Balikesir University Faculty of Medicine, Obstetrics and Gynecology, Balikesir, Turkey*
[3]*Ota Jinemed Hospital, Andrology Department, Istanbul, Turkey*

Study question: To determine whether the outcome of ICSI with testicular spermatozoa obtained microscopically assisted testicular sperm extraction (m-TESE) is dependent on the number of MII oocytes.
Summary answer: The number of the mature oocytes is an important prognostic factor in ICSI with testicular spermatozoa obtained from azoospermic men.
What is known already: Retrieval of healthy oocytes is a key component of assisted reproductive treatment for infertile couples. Intracytoplasmic sperm injection (ICSI) has been commonly used for couples with male infertility since its first successful introduction in 1992 and reliable pregnancy rates were achieved by using testicular spermatozoa from patient with azoospermia.

Study design, size, duration: A retrospective cohort of women 40 years old who underwent ICSI treatment with testicular spermatozoa were included from 2006 to 2013.
Participants/materials, setting, methods: Women were enrolled only for one cycle. ICSI was performed with motile testicular spermatozoa obtained from 89 men with obstructive azoospermia and 251 men with nonobstructive azoospermia. GnRH antagonist protocol was used for ovulation induction. Simple linear regression was carried out between the number of MII oocytes and the live birth rate. Receiver operator characteristic (ROC) curves were formed to detect a cut-off number of MII oocytes below which live birth rate was significantly decreased.
Main results and the role of chance: The live birth rate was significantly higher in ICSI-mTESE cycles with ≥7 MII oocytes than that with <7 oocytes (30.6% vs. 14.3%, respectively, $r = 0.12$, $p = 0.02$). LBRs were the lowest in cycles with one or two MII oocytes available (9% and 9%, respectively), but these rates were not statistically different than cycles with 3,4,5 and 6 MII oocytes (14.8%, 16.6%, 17.8%, 23%, respectively, $p>0.05$). Embryo transfer was not achieved in 37 cycles with <7 oocytes (37/167, 22.1%) and 18 cycles with ≥7 oocytes (18/173, 10.4%) because of the absence embryos available following ICSI ($p < 0.01$).
Limitations, reasons for caution: The limitations of the present study were the retrospective design and relatively small number of ICSI cycles with testicular spermatozoa.
Wider implications of the findings: Our current findings imply that obtaining low numbers of oocytes is associated with impaired pregnancy rate in ICSI with m-tese cycles.
Trial registration number: Instutional Ethics committe number: 2016-012.

P-061 stress preconditioning of human sperm for cryopreservation: a new strategy to improve frozen-thawed sperm quality

M. Hezavehi[1], H. Mohseni Kouchesfahani[1], G. Hosseini Salekdeh[2], P. Eftekhari-Yazdi[3], M. Sharafi[4], A. Shahverdi[3]
[1]Kharazmi University- Postal Code 15719-14911-Tehran- Iran, Department of Developmental Biology, Faculty of Biological Sciences, Tehran, Iran
[2]Royan Institute for Stem Cell Biology and Technology-ACECR- Tehran- Iran, Department of Molecular Systems Biology, Cell Science Research Center, Tehran, Iran
[3]Royan Institute for Reproductive Biomedicine- ACECR- Tehran- Iran., Department of Embryology, Reproductive Biomedicine Research Center, Tehran, Iran
[4]Tarbiat Modares University- Tehran- Iran, Department of Poultry Sciences, Faculty of Agriculture, Tehran, Iran

Study question: pre-freezing sublethal stress Can improve sperm function after freezing. What is the optimum level of Nitric Oxide for preconditioning of sperm before cryopreservation?
Summary answer: Motility, viability and the rate of apoptotic sperm were significantly improved using 0.01 µM Nitric Oxide after freezing.
What is known already: In recent years, controllable sublethal stress due to increasing of general resistance to further stresses have been applied for oocyte, embryo and sperm. Regard the various physiological effects of Nitric oxide, it can be a novel stressor for human sperm cryopreservation. low concentrations of NO can induce biosynthesis kinetics of stress-related proteins (Heat Shock Protein, Intracellular antioxidants including glutathione). Stress-induced proteins reduce activation of the apoptotic cascade, thereby protect cells against oxidative stress. This response is regulated at transcriptional, translational or posttranslational levels.
Study design, size, duration: Semen samples were collected from normozoospermic men ($n = 42$) for assessment of oxidative stress markers (ROS-TAC score). Then, twenty six samples which had not the oxidative stress were selected for experiment.
After processing sperm with PureSperm gradient, each sample was divided into 7aliquots according to the following groups: fresh, groups exposed to 0, 0.01, 0.1, 1, 10 and 100 µM Sodium Nitroprusside (NO donor) for 1 h at 37°C (5% CO2) before cryopreservation.
Participants/materials, setting, methods: The optimum concentration of NO was determined by evaluation of motility and velocity parameters using Computer assisted semen analysis (CASA),apoptosis status (Active caspase detection by flow cytometry), DNA fragmentation (SCSA by flow cytometry) after freezing-thawing.
Main results and the role of chance: Data were analyzed using SPSS and Statistical differences among various group means were determined by ANOVA and Tuckey's post hoc test. the values of $P < 0.05$ were considered to be statistically Significant.

In comparison with the fresh spermatozoa, there was a significant decrease in the viability, motility, velocity parameters and increase in Caspase+/PI- and DNA Fragmentation in the cryopreserved spermatozoa ($P < 0.001$).

Moreover, 0.01 µM NO produced the higher significant percentage of total and progressive motility (62.23 and 44.935% vs 49.43, 34.02% respectively) in compared to group without any treatment (N0-0).

Furthermore, significantly improves average path velocity (VAP), velocity straight linear velocity (VSL) (50.73 and 37.3 vs 64.04 and 48.1 µm/s respectively).

The percentage of caspase 3 activity significantly reduced in the NO-0.01 when compared to the other groups ($p < 0.01$). Also, NO-10 and NO-100 produced the higher percentage of dead spermatozoa (44.8 and 52.9% respectively) compared to the other groups. For DNA fragmentation there was no significant different in NO-0.01 group compared to group without any treatment.(N0-0).
Limitations, reasons for caution: proteins associated with stress and information about the molecular background of elevated stress tolerance induced by NO could be assessed in this experiment. But due to insufficient sperm cells, we couldn't do Proteomic analysis at the same time.
Wider implications of the findings: This approach may improve the efficacy of most of the assisted reproductive techniques such as fertilizing ability, and developmental competence of embryos and gametes.

This approach may result in considerable improvement from a wide range of procedures (*in vitro* fertilization, cryopreservation, etc.) in assisted reproductive techniques.
Trial registration number: N/A.

P-062 How long should we keep ejaculatory abstinence (EA) before intrauterine insemination (IUI)?

J.W. Kim[1], K.H. Lee[1], I.H. Park[1], H.G. Sun[1], H.J. Chi[1], S.G. Kim[1], Y.Y. Kim[1], S.J. Kwak[1], J.Y. Park[1], C.S. Yoo[1]
[1]Infertility Clinic, Mamapapa&baby, Obstetrics & Gynecology, Ulsan, South Korea

Study question: Is ejaculatory abstinence before IUI essential factor for pregnancy?
Summary answer: The period of ejaculatory abstinence before IUI is not related with pregnancy rates.
What is known already: The total number of motile sperm inseminated has been cited as the most predictive index of conception in IUI cycles. Intercourse on the day of hCG administration might cause concern about a lower recovery of total motile sperm. However, optimal period of ejaculatory abstinence before IUI is not yet established.
Study design, size, duration: Retrospective analysis of 804 IUI cycles performed between April and December in 2015. The period of ejaculatory abstinence before IUI, semen analysis parameters of the ejaculate (pre-wash) and the insemination specimen (post-wash) for IUI, and pregnancy rate following ovulation induction and IUI were recorded.
Participants/materials, setting, methods: The whole ejaculate was prepared for insemination using a technique of density gradient separation with centrifugation. Ejaculatory period before IUI was divided into 3groups (0–2 days, 3–5days, >5 days).
Main results and the role of chance: In each group, age, semen volume, sperm motility (pre-wash) and liquefaction time did not show significant differences. Although the longer EA period, the more total motile sperm count (pre-wash) was observed (88.2, 137.2, 194.7(*10^6/ml), $p < 0.05$), but there were no significant differences in post-wash total motile sperm count (8.3, 10.9, 11.7 (*10^6/ml), $p > 0.05$). Total pregnancy rate was 19.4% (144/804). There were no significant differences among three groups in the pregnancy rate (22.5% (14/80), 18.7% (53/310), 19.3% (77/414); $p > 0.05$).
Limitations, reasons for caution: To identify the period of EA, we asked for questionnaire survey to patients. So, there could be recall bias. Prospective randomized studies with larger sample size will be required to confirm our conclusions.
Wider implications of the findings: There were few studies about relation between pregnancy rate and period of EA before IUI. Our result shows that period

of EA before IUI does not affect pregnancy rate. Therefore, we can advise that abstinence before IUI and the interval of intercourse seldom affect pregnancy outcome.
Trial registration number: None.

P-063 Effect of the chemotherapy cyclophosphamide and busulfan on the levels of pre-meiotic markers and testicular growth factors of sexually immature and mature mice

M. Huleihel[1], A. Stepanovsky[2], B.C. Amano[2], O. Karpel[2], R. Levy[2], E. Lunenfeld[3]
[1]*Ben-Gurion University of the Negev, The Shraga Segal Department of Microbiology & Immunology and The Center of Advanced Research and Education in Reproduction CARER, Beer - Sheva, Israel*
[2]*Ben-Gurion University of the Negev, The Shraga Segal Department of Microbiology & Immunology, Beer - Sheva, Israel*
[3]*Ben-Gurion University of the Negev, Division of Obstetrics and Gynecology and The Center of Advanced Research and Education in Reproduction CARER, Beer - Sheva, Israel*

Study question: What is the effect of the chemotherapy cyclophosphamide and busulfan on the levels of pre-meiotic markers and testicular growth factors of immature and mature mice?
Summary answer: They decrease the levels of the examined pre-meiotic markers and in parallel increased the levels of the testicular growth factors.
What is known already: Spermatogonial stem cells (SSCs) proliferate and differentiate to sperm is under the regulation of Sertoli cells and other testicular somatic cells. These effects are performed through the production of different growth factors such as glial cell-derived neurotrophic factor (GDNF), stem cell factor (SCF), leukemia inhibitory factor (LIF) (by Sertoli and peritubular cells) and colony stimulating factor-1 (CSF-1) (by Leydig cells). Cyclophosphamide (CP) and busulfan (Bu) are chemotherapy that affect proliferating cells, including spermatogonial cells in the testis, and may cause azoospermia. The effect of CP and Bu on the activity of testicular somatic of immature mice was not study yet.
Study design, size, duration: Mice were injected intraperitoneal (i.p) with 100 mg/kg CP (for immature) or 200 mg/kg (mature) and saline for the CT group, once a week during 3 weeks. The Bu group was injected (i.p) with a single dose of 45 mg/kg Bu or DMASO (1:1 water) for the CT group. Mice were sacrificed every week after the last injection for 5–12 weeks.
Participants/materials, setting, methods: Seven days-old and 8-weeks-old ICR mice were divided into two groups: CP or Bu groups and control group (CT); n = 9–12mice/time point. Testes weights were performed and later on homogenized for protein evaluation and RNA extraction. Homogenates were examined for protein levels of the above factors by specific ELISA and for RNA expression by qPCR analysis.
Main results and the role of chance: Our results show an increase in the production (at the level of protein and RNA) of all the examined growth factors GDNF, SCF (originate from Sertoli cells) and CSF-1 (originate from Leydig cells) mainly within the first three weeks after the last injection in the CP or Bu groups compared to the CT groups. Thereafter, their levels were similar between CP and CT group or Bu and CT group. The increased levels of those growth factors were in parallel to decrease in the expression levels of the examined pre-meiotic markers (vasa, sall4 and GFRa). The effect of CP and Bu on the production of growth factors was similar in both immature and mature mice.
Limitations, reasons for caution: The study was performed in mouse model and the correlation with human should be considered.
Wider implications of the findings: This is the first study that shows effect of CP/Bu on testicular somatic cell activity in immature and mature mice and the negative correlation with the expression of pre-meiotic markers. Our results emphasize the crucial cross talk between somatic cells and spermatogonial cells during gonadal cytotoxicity to cure spermatogenesis.
Trial registration number: NA.

P-064 BrdUTP/anti-BrdUTP TUNEL labeling system fails to detect DNA fragmentation in highly condensed chromatin of dead/apoptotic spermatozoa

S. Forte[1], M. Muratori[2], M. De Geyter[1], C. De Geyter[1]
[1]*University Hospital Basel, Clinic of Gynecological Endocrinology and Reproductive Medicine, Basel, Switzerland*
[2]*University of Florence, Department of Experimental, Clinical and Biomedical Sciences- DeNothe Center of Excellence, Florence, Italy*

Study question: Is antibody-based TUNEL (Terminal deoxynucleotidyl transferase dUTP Nick End Labeling) adequate to analyse spermatozoa DNA fragmentation (SDF) in the assessment of male infertility?
Summary answer: The labeling system BrdUTP/anti-BrdUTP greatly underestimates the value of DNA fragmentation in dead and apoptotic spermatozoa.
What is known already: Although many studies reported adverse effects of SDF on the outcome of assisted reproduction technology, there are still considerable discrepancies between SDF values and the correlation between SDF thresholds and male infertility. These uncertainties are one of the reasons why several Societies (ASRM, ESHRE) still do not recommend SDF to be introduced into clinical practice. The TUNEL assay is one of the most commonly used methods for SDF quantification. The labeling system BrdUTP/anti-BrdUTP is described as giving rise to brighter signals in flow cytometry because of a more readily incorporation of BrdUTP into the DNA of apoptotic cells.
Study design, size, duration: This study was part of the validation of the TUNEL assay coupled to flow cytometry analysis in the Clinic of Gynecological Endocrinology and Reproductive Medicine, University Hospital, University of Basel, Switzerland and involved the TUNEL analysis of 20 semen samples of fertile and infertile men (WHO 2010 reference values) attending the Clinic of Gynecological Endocrinology and Reproductive Medicine between July 2015 to January 2016.
Participants/materials, setting, methods: In this work, TUNEL assays with different labeling systems were tested. Br-dUTP/anti-BrdUTP system was analyzed with the ApoBrdU DNA Fragmentation Assay Kit (BioVision Inc.) and the fluorescein- labeled nucleotide system with In Situ Cell Death Detection Kit, Fluorescein (Roche). The influence of chromatin condensation was proved by decondensation of spermatozoa DNA followed by TUNEL. The efficiency of labeling in different populations of spermatozoa was obtained with sorting and TUNEL.
Main results and the role of chance: We demonstrated that BrdUTP/anti-BrdUTP labeling system largely underestimates DNA damage in semen analysis. Compared to the Roche kit, which directly labels the nucleotide, BrdUTP/anti-BrdUTP stained as low as 3% of the spermatozoa stained with the Roche kit. We found that the differences in efficiency of the labeling depend on the condition of the spermatozoa: BrdUTP/anti-BrdUTP staining of dead/apoptotic spermatozoa is very low but staining of living spermatozoa is identical in both methods. We conclude that the difference in the staining efficiency is due to the sterical hindrance effect of the antibody against BrdUTP. The antibody is too large to access the highly condensed form of dead/apoptotic spermatozoa chromatin. After decondensation of dead spermatozoa DNA, BrdUTP/anti-BrdUTP proved to be able to fully detect the DNA breaks. The use of labeled antibodies revealed to be inadequate for detection of SDF. Nevertheless, in both systems, and depending on the semen sample, there is a considerable percentage of unstained dead spermatozoa, confirming the results of Mitchell et al. describing that TUNEL results underestimate SDF due to chromatin condensation. The relationship of TUNEL staining efficiency on spermatozoa/chromatin state was, to our best knowledge, never reported so far.
Limitations, reasons for caution: Although there are several companies selling TUNEL kits with the system BrdUTP/anti-BrdUTP, only BioVision kit was tested. We assumed that the other kits with the same labeling system will present identical limitations in spermatozoa staining.
Wider implications of the findings: This work has shed some light on the problem of TUNEL discrepancies between different laboratories contributing to the standardization of protocols. Our findings on TUNEL efficiencies dependence on the spermatozoa state emphasize the need to carefully interpret TUNEL results comparison between semen samples and processed samples (>90% spermatozoa alive).
Trial registration number: NA.

P-065 The effect of varicocelectomy on semen parameters and pregnancy rate in infertile male with clinical varicocele

M. Mitsunami[1], N. Watanabe[1], K. Yamasaki[1,2], M. Uchida[3,4], S. Andou[3,4], A. Joraku[3], K. Uchida[4], S. Takamizawa[3], K. Yanagida[3], T. Fujiwara[1], O. Tsutsumi[1], T. Iwamoto[1,3]
[1]*Sanno Hospital, Center for Human Reproduction and Gynecologic Endoscopy, Tokyo, Japan*

[2]Tsukuba Gakuen Hospital, Department of Urology, Ibaraki, Japan
[3]International University of Health and Welfare Hospital, Center for Infertility and IVF, Tochigi, Japan
[4]International University of Health and Welfare Hospital, Department of Urology, Tochigi, Japan

Study question: Can varicocele repair contribute to improve semen parameters and pregnancy rate compared with medication or observation in infertile males with clinical varicocele?
Summary answer: There is a possibility that varicocelectomy (microsurgical sub-inguinal varicocelectomy at unilateral side or laparoscopic varicocelectomy at both sides) can improve pregnancy rate rather than semen parameters.
What is known already: Clinically palpable varicoceles have been clearly associated with infertility. Some studies show an improvement in semen parameters and fertility after repair of varicoceles.
Study design, size, duration: This was a retrospective study that included 321 infertile male patients with varicocele (Grade 1–3) with semen parameters of normozoospermia, oligozoospermina and/or asthenozoospermia in 2 hospitals from September 2007 to August 2015.
Participants/materials, setting, methods: Surgery group was 134 patients who underwent varicocelectomy, non-Surgery group was 187 patients who took medication or observation. Patients were assessed by clinical evaluation, semen analysis (before treatment and at 2, 4, 6, 9, 12 months following) and pregnancy results by medical records and questionnaires. Patients who had not come to hospital more than 6 months without any information and did not answer the questionnaire have been excluded from pregnancy rate analysis.
Main results and the role of chance: The semen parameters have not improved with the Surgery group compared with the non-Surgery group. Pregnancy rate is 32.5% (27/83) for patients in the Surgery group and 18.8% (19/101) in the non-Surgery group. Pregnancy rate increased with operation treatment ($p < 0.05$). In the Surgery group, 7 patients conceived naturally, 6 patients by intrauterine insemination (IUI) and 13 patients by *in vitro* fertilization/intracytoplasmic sperm injection (IVF/ICSI) while 4 patients had miscarriages. As for the non-Surgery group, 6 patients conceived naturally, 2 patients by IUI, 11 patients by IVF/ICSI while 5 patients had miscarriages.
Limitations, reasons for caution: This was a small retrospective study. Female factors were not considered but there was no significant difference in their age between 2 groups.
Wider implications of the findings: Varicoceletomy can improve the quality of sperms which are not reflected in semen analysis. Therefore it can increase pregnancy rate and contribute to a decrease in the number of patients who need assisted reproductive technology.
Trial registration number: None.

P-066 The effect of prolonged sexual abstinence period in male on fertilization and pregnancy outcomes in fresh embryo transfer after intracytoplasmic sperm injection

J.W. Lee[1], J.H. Cha[1], S.H. Shin[1], Y.J. Kim[1], S.K. Lee[1], H.J. Cha[1], J.H. Kim[1], J.H. Ahn[1], H.Y. Kim[1], K.A. Pak[1], J.S. Yoon[1], S.Y. Park[1]
[1]Agaon Fertility Clinic, IVF Center, Seoul, South Korea

Study question: Does prolonged sexual abstinence period in male affect fertilization and pregnancy outcomes in fresh embryo transfer after intracytoplasmic sperm injection (ICSI)?
Summary answer: Our study showed that prolonged sexual abstinence period in male does not influence on fertilization and pregnancy outcomes in fresh embryo transfer after ICSI.
What is known already: A short or long sexual abstinence period is associated with incorrect semen analysis results, along with intrauterine insemination using sperm of short abstinence period is correlated with higher pregnancy rates. Previously reported more than eight days abstinence period has increased sperm DNA fragmentation; however, the World Health Organization (WHO) recommended that abstinence period that surpasses 8 days is not related to increased the proportion of aneuploidy embryos.
Study design, size, duration: A retrospective cohort study in 322 ICSI cycles was conducted between January 2013 and November 2015 at Agaon Fertility Clinic. We compared rates of fertilization, top-quality embryos, and pregnancy outcomes between the two groups.
Participants/materials, setting, methods: Participants were divided into two groups: G-A (2–7 days, $n = 225$) and G-B (≥8 days, $n = 97$). The sexual abstinence period was identified before collecting semen samples. The semen analysis was performed according to the manual guideline of the WHO (2010). The cycles with poor responder, advanced maternal age (≥38 years), frozen sperm, oligoasthenoteratozoospermia, and surgically retrieved sperm were excluded.
Main results and the role of chance: There were no significant differences between G-A and G-B regarding the patients' characteristics, the female age (33.8 ± 1.8 vs. 33.7 ± 2.5, $p = 0.0710$), the male age (36.0 ± 4.0 vs. 36.6 ± 3.8, $p = 0.186$), the number of retrieved oocytes (11.6 ± 5.1 vs. 11.1 ± 4.5, $p = 0.377$), the number of transferred embryos (2.3 ± 0.7 vs. 2.3 ± 0.6, $p = 0.998$), fertilization rate (75.9% vs. 79.2%, $p = 0.077$) and the rate of top-quality embryos on day 3 (12.5% vs. 12.5%, $p = 0.965$), respectively. The biochemical pregnancy (43.1% vs. 45.4%, $p = 0.709$), clinical pregnancy (36.9% vs. 35.1%, $p = 0.753$), and ongoing pregnancy (33.8% vs. 29.9%, $p = 0.496$) rates per cycle did not significantly differ in both G-A and G-B.
Limitations, reasons for caution: The number of analyzed G-B cycles was relatively small compared with the G-A. We were not limited after the sexual abstinence period of more than 8 days and male age. Further studies are required large data samples of this size.
Wider implications of the findings: Although both a strong correlation between sexual abstinence period and sperm parameter, we haven't established a connection among fertilization, pregnancy outcomes and prolonged sexual abstinence period in fresh embryo transfer after ICSI. The reason might be because a viable sperm with normal morphology and progressive motility were selected during ICSI.
Trial registration number: Not applicable.

P-067 Dynamic transcriptional profiles of human testis-specific actin capping protein β3 and its possible implication of male infertility

T. Soda[1], Y. Miyagawa[1], N. Ueda[1], K. Takezawa[1], S. Fukuhara[1], H. Kiuchi[1], T. HIromitsu[2], N. Nonomura[1]
[1]Osaka University, Urology, Suita, Japan
[2]Nagasaki International University, Faculty of Pharmaceutical Sciences, Nagasaki, Japan

Study question: Does actin capping protein (CP) β3 play an important role in male infertility?
Summary answer: Human CPβ3 is supposed to be essential, as is expressed in testis dynamically changing its localization during spermatogenesis and possibly has implication of male infertility.
What is known already: Testis-specific α subunit of CP named CPα3 was identified in human testis previously. CPα3 was localized in the tail and postacrosomal region of sperm head. N-ethyl-N-nitrosourea (ENU)-induced mutation in CPα3 gene in mouse was shown to induce malformation of sperm head and to be responsible for male infertility. On other hand, CPβ3 which is supposed to be a heterodimeric counterpart of CPα3 has been described in mouse or bovine in several literatures. However, human CPβ3 has been neither characterized nor reported about the association with male infertility.
Study design, size, duration: To confirm the existence of CPβ3 in human testis, fresh semen samples from fertile male were observed. To investigate the protein expression during spermatogenesis, ten human cryopreserved samples were observed retrospectively, which were obtained by testicular sperm extraction from men diagnosed as obstructive azoospermia. To compare the protein expression of fertile and infertile male, cryopreserved sperm were investigated retrospectively. This study was approved by the ethical committee and informed consent was obtained from each volunteer.
Participants/materials, setting, methods: The tissue specific expression of CPβ3 was investigated by RT-PCR and Western blot analysis. The relationship between CPα3 and CPβ3 was analyzed by coimmunoprecipitation (Co-IP) assay with a use of recombinant protein tagged with EGFP or mRFP. The transcriptional profiles of CPα3 and CPβ3 during spermatogenesis were examined by immunohistochemical analysis using human spermatogenic cells. The expression patterns of CPα3 and CPβ3 in sperm from infertile male were observed and compared by immunohistochemical analysis.
Main results and the role of chance: RT-PCR showed that mRNA of human CPβ3 was expressed exclusively in testis. Western blot analysis successfully detected human CPβ3 with anti-bovine CPβ3 antibody. Co-IP assay with recombinant protein showed that CPα3 and CPβ3 form a protein complex.

In each step of cells during spermatogenesis, the localization of CPβ3 dynamically changed. In spermatogonia, CPβ3 showed slight signal in cytoplasm. Mainly from spermatocytes, the expression of CPβ3 was conspicuous and the localization of CPβ3 dynamically migrated from cytoplasm to acrosome or postacrosomal region of sperm head. On the other hand, the localization of CPα3 was completely identical to that of CPβ3 in every step of spermatogenic cells. In mature spermatozoa, both CPα3 and CPβ3 were accumulated at postacrosomal region and slightly at midpiece of tail. While the localization of CPα3 and CPβ3 was homogeneous in most of the spermatozoa in fertile male, heterogeneous or lack of staining of CPα3 and CPβ3 were identified in infertile male. The complex of CPα3 and CPβ3 seemed to play an important role in spermatogenesis and possibly have association with male infertility.
Limitations, reasons for caution: Because of the difficulty of collecting fresh samples of human testis, we used cryopreserved samples of TESE. To examine the interaction of spermatogenic cells or localization in seminiferous tubules, fresh testis sample of healthy male is better to be used ideally.
Wider implications of the findings: The altered expression of CPα3 and CPβ3 can be not only a cause of male infertility but also a prognostic factor for the result of assisted reproductive technologies (ART). They can be a useful biomarker to diagnose infertile males who are not azoospermia but have difficulties in ART.
Trial registration number: NA.

P-068 Venous blood gases of varicocele veins: correlation with testicular blood flow and semen quality in varicocele patients

K.U. Rehman[1], M.Q. Zaman[2], H. Zaneb[3], A. Numan[4], A. Qureshi[4], H. Rehman[2]
[1]Lahore Institute of Fertility & Endocrinology, Androurology, Lahore, Pakistan
[2]Univeristy of Veterinary and Animal Sciences, Physiology, Lahore, Pakistan
[3]University of Veterinary and Animal Sciences, Anatomy, Lahore, Pakistan
[4]Services Institute of Medical Sciences, Neurology, Lahore, Pakistan

Study question: Changes in blood gas patterns of varicocele veins may affect testicular blood flow and semen quality.
Summary answer: Internal spermatic veins of patients had higher pO2, sO2, lower pH and HCO3 as compared to peripheral veins. External spermatic veins were less affected.
What is known already: Varicocele is known to be associated with infertility and sperm disorders. There are limited numbers of studies where venous blood gases of the varicocele veins of testes were determined.
Study design, size, duration: Consecutive varicocele patients (aged 20–45 years), undergoing left microsurgical varicocelectomy, were included in the study during January 2013 to August 2015.
Participants/materials, setting, methods: Twenty-seven varicocele patients, were included in the study. The pH, partial pressure of oxygen (pO_2), oxygen saturation (sO_2), partial pressure of carbon dioxide (pCO_2) and bicarbonate (HCO_3) levels of varicocele veins were determined in Internal spermatic, external spermatic and peripheral veins, while semen quality parameters were determined before surgical intervention. Peak systolic velocity (PSV) and resistive index (RI) of sub capsular and Intra parenchymal branches of the testicular artery were measured using scrotal CDUS.
Main results and the role of chance: Results revealed that the pH was lower ($p < 0.001$) in the internal spermatic vein ($p < 0.01$) compared with the external spermatic and peripheral veins. The pO_2 and sO_2were higher ($p < 0.001$) in the internal spermatic vein ($p < 0.01$) compared with peripheral vein. However, HCO_3 content was lower ($p < 0.05$) in both varicocele veins compared with the peripheral vein. Whereas, the pCO2 was similar ($p > 0.05$) in all three veins. The pO_2 of internal spermatic vein had negative correlation ($r = -0.42$; $p < 0.05$) with PSV of the intra parenchymal arteries. No such correlation was observed for external spermatic vein or peripheral vein. There were non-significant weak correlations between various parameters of VBG of both varicocele veins with semen quality parameters in varicocle individuals. In conclusion, internal spermatic veins had higher oxygen level and lower pH and bicarbonate levels whereas external spermatic veins had similar pattern of blood gases to the peripheral veins in the varicocele patients.
Limitations, reasons for caution: Further studies are required to confirm our findings.
Wider implications of the findings: The apparent difference of VBG analysis between varicocele veins and peripheral veins may be due to the presence of arterio venous communications or some other mechanism that needs further investigation.
Trial registration number: This is not a clinical trial.

P-069 Differential chromatin incorporation of CREM, ACT and BRDT testis-specific transcription factors in normal and impaired human spermatogenesis

R. Favaedi[1], F. Kohandani[1,2], M.A. Sadighi Gilani[3,4], M. Shahhoseini[1]
[1]Department of Genetics, Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Iran
[2]Biology Department, Faculty of Sciences, Yazd university, Yazd, Iran
[3]Department of Andrology, Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Iran
[4]Department of Urology, Shariati Hospital, Tehran University of Medical Sciences, Tehran, Iran

Study question: What is the potential epigenetic role of transcription regulators (CREM, ACT and BRDT) in spermatogenesis impairment and male infertility?
Summary answer: Decreased expression of CREM, ACT and BRDT transcription factors parallel to decreased incorporation of them into promoters of spermatogenesis-specific genes were correlated with spermatogenesis impairment.
What is known already: During spermatogenesis chromatin of sperm undergoes extensive epigenetic remodeling to be compacted and packaged. Several studies have shown that impairment in this process is associated with infertility in men. Some genes such as cAMP response element modulator (CREM) and Bromodomain testis-specific protein (BRDT) are master regulators for expression of famous chromatin condensing factors of spermatogenesis, transition proteins (TNPs) and protamines (PRMs).
Study design, size, duration: Through ART procedure, testes tissue samples were collected from azoospermic infertile men referred to Royan Institute. Consent was obtained from each patient according local ethical approval. Based on pathological features, tissue samples divided into following three groups: complete maturation arrest, Sertoli cell only syndrome, and hypospermatogenesis as positive control (at least 30 samples in each group).
Participants/materials, setting, methods: Relative expression of CREM, ACT (activator of CREM in testis) and BRDT were evaluated by qRT-PCR. Also, ChIP-real time PCR was performed to evaluate the incorporation of CREM, ACT and BRDT transcription factors into regulatory regions of TNPs and PRMs genes.
Main results and the role of chance: Relative expression profile of CREM, ACT and BRDT showed significant decrease in complete maturation arrest and Sertoli cell only syndrome groups compared to hypospermatogenesis group ($p < 0.05$) as well as TNPs and PRMs. The results of expression confirmed by ChIP data revealed decreased incorporation of CREM, ACT and BRDT as transcription regulators of spermatogenesis into regulatory regions of TNPs and PRMs in both groups with spermatogenesis impairment vs. positive control ($p < 0.05$).
Limitations, reasons for caution: The study population could be expanded and the interaction between other transcription factors/regulators is required to be investigated.
Wider implications of the findings: The findings of this study imply significant association between altered levels of transcription regulators of spermatogenesis with impairment of spermatogenesis and male infertility.
Trial registration number: NA.

P-070 IVF outcomes and morphokinetics of embryos originating from testicular spermatozoa of men with follicle stimulating hormone receptor (FSHR) gene polymorphism

O. Somova[1], O. Feskov[1], I. Zhylkova[2], A. Ivanova[3], N. Chumakova[1], O. Tishchenko[1], V. Feskov[1], O. Zozulina[1]
[1]Centre of Human Reproduction Sana-Med Clinic of Professor Feskov A., ART Department, Kharkiv, Ukraine
[2]Centre of Human Reproduction Sana-Med Clinic of Professor Feskov A., Genetic Department, Kharkiv, Ukraine
[3]Centre of Human Reproduction Sana-Med Clinic of Professor Feskov A., Andrology Department, Kharkiv, Ukraine

Study question: Does the polymorphism in FSHR gene affect the IVF success rates and early development of embryos obtained after oocyte fertilization by testicular sperm?
Summary answer: Significant differences in embryo morphokinetics, IVF outcomes were observed in dependence on peculiarities of sperm finding but not on the presence of FSHR alternative alleles.
What is known already: The data concerning the effect of FSHR gene polymorphism on male infertility are controversial. Some studies have shown associations of genetic disturbances in FSHR with azoospermia, sperm aneuploidy, spermatogenesis impairment and serum FSH level, while other researches have not demonstrated any correlation between alternative variants of FSHR and sperm abnormalities or FSH concentration. Moreover, no results regarding possible influence of FSHR gene polymorphism on embryo morphokinetics in case of oocyte fertilization by testicular spermatozoa of men with azoospermia have been reported to date.
Study design, size, duration: Retrospective study (2012–2015) of morphokinetics of 576 embryos obtained after testicular (n = 54) or donor ejaculated (n = 24) sperm injections in oocytes of fertile women or women with tubal factor infertility (31.6 ± 3.9 years old) was conducted. Fertilization, blastulation and pregnancy rates, percent of embryo abnormal cleavage rate were assessed. Testicular spermatozoa were extracted during TESA/TESE in case of obstructive azoospermia (OA) or microTESE in case of non-obstructive azoospermia (NOA).
Participants/materials, setting, methods: The three groups of patients were compared: 1) men with azoospermia and normal FSHR genotype (n = 33); 2) men with azoospermia and FSHR gene polymorphism (n = 21); 3) sperm donors (control, n = 24). Embryo morphokinetic parameters (2pn fading, 2–8 cell divisions, intervals between divisions, direct and reverse cleavage, blastocyst formation) were analyzed using time-lapse monitoring system (PrimoVision). Thr307Ala and Asp680Ser FSHR polymorphisms were determined by Taqman assays on the ABI PRISM 7500 real-time PCR system.
Main results and the role of chance: Among 21 patients with azoospermia and FSHR gene polymorphism 17 men were the carriers of polymorphism in the both alleles of FSHR. The fertilization rate (79.6 vs 81.0%), percent of the top quality embryos (60.6 vs 42.9%), blastocysts formation (50.1 vs 47.2%) and clinical pregnancy rate (36.0 vs 30.8%) did not statistically differ between the groups 1 and 2. However, these parameters were significantly lower, than in control (91.1, 81.0, 67.6 and 48.8%, respectively, $p < 0.05$). The morphokinetic parameters also were similar in the both groups with azoospermia. With that period of pronucleus faiding, synchrony in division from 3 to 4 cells (s2) and time of division to 8 cells were longer, but time of division to 3, 5 cells and duration of the 2nd cell cycle (cc2) were shorter comparing with the control ($p < 0.05$). Direct cleavage to more than 2 cells was significantly higher in groups 1 and 2 (33.0 and 29.3%) vs control (16.3%, $p < 0.05$).
Limitations, reasons for caution: The study included only those patients who have been found at least a few motile sperm during TESA/TESE or microTESE (the spermatozoa were found in 54 men from 70). We did not analyze embryos separately for OA and NOA.
Wider implications of the findings: In the present study no spermatozoa were found in 12 carriers of polymorphism in FSHR gene (75% from all cases of sperm absence). The futher investigations of association between the treatment failures with alternative alleles in FSHR gene should be continued to develop the necessary therapy for stimulation of spermatogenesis.
Trial registration number: No registration number.

P-071 Exploring the role of the nuclear receptor coactivators in murine Sertoli cell

M. Teletin[1,2], N. Vernet[1], B. Feret[1], M. Klopfenstein[1], M. Mark[1], N.B. Ghyselinck[1]
[1]*IGBMC- Institut de génétique et de biologie moléculaire et cellulaire, Functional Genomics & Cancer Dpt, Strasbourg, France*
[2]*CECOS CMCO, Medecine et Biologie de la Reproduction, CHU de Strasbourg, France*

Study question: What is the role of nuclear receptors (NR) coactivators Ncoa1 and Ncoa2 in Sertoli cells?
Summary answer: Ncoa1 and Ncoa2 are instrumental to the maintenance of spermatogenesis by acting in Sertoli cells.
What is known already: Genetic analyses in mouse have shown that NR coactivators Ncoa1 and Ncoa2 have individually redundant functions in male reproduction function. These results were obtained by classical gene knock-out study. However, compound Ncoa1-/- Ncoa2-/- double null mutants die at birth precluding any study of the effects of Ncoa1/Ncoa2 simultaneous ablation in the adult male testes.
Study design, size, duration: To study the role of Ncoa1 and Ncoa2in Sertoli cells, mice expressing the Cre transgene expressed under the control of the anti-Müllerian hormone (Amh) promoter were crossed with mice bearing loxP-flanked alleles for both Ncoa1 and Ncoa2. The Amh-Cre transgene yields an efficient excision of loxP-flanked genes in all Sertoli cells as early as embryonic day 15.5.
Participants/materials, setting, methods: To study the role of Ncoa1 and Ncoa2in Sertoli cells, mice expressing the Cre transgene expressed under the control of the anti-Müllerian hormone (Amh) promoter were crossed with mice bearing loxP-flanked alleles for both Ncoa1 and Ncoa2. The Amh-Cre transgene yields an efficient excision of loxP-flanked genes in all Sertoli cells as early as embryonic day 15.5.
Main results and the role of chance: Invalidation both Ncoa1 and Ncoa2 in murine Sertoli cells is responsible for a massive desquamation of immature germ cells associated with an increase of lipids stored in Sertoli cells and the formation of giant multinucleated spermatids. These abnormalities are identical, in their morphological appearance, to those observed upon inactivating either Ncoa1 or Ncoa2 in the whole organism, thereby demonstrating that all the functions that Ncoa1 exert in reproduction are carried out in Sertoli cells.
Limitations, reasons for caution: These results were obtained in mice and therefore the relevance on human spermatogenesis remains to be demonstrated.
Wider implications of the findings: Increase in Sertoli cell lipid stores, loss of immature germ cells, and formation of giant multinucleated spermatids are commonly detected in testes of elderly men, suggesting that deficiencies in molecular pathways involving NCOA1 and NCOA2 in human Sertoli cells could participate in testicular senescence.
Trial registration number: NA.

P-072 Severe testicular microlithiasis in Ultrasonographic (US) images indicates the micro-obstruction in seminiferous tubule and may predict high sperm retrieval rate in non-obstructive azoospermia (NOA) patient

T. Sho[1], S. Nariyoshi[1], K. Nakano[2], G. Sukegawa[2], Y. Tsuji[1]
[1]*Tenjin Tsuji Clinic, Urology, Fukuoka, Japan*
[2]*Ebisu Tsuji Clinic, Urology, Shibuya, Japan*

Study question: Can US finding of severe testicular microlithiasis predictive successful sperm retrieval?
Summary answer: Severe testicular microlithiasis in US images may predict high sperm retrieval rate in NOA patient.
What is known already: Testicular microlithiasis has been reported to be infrequent condition associated with testicular tumors or testicular deficiencies. However the mechanisms of testicular microlithiasis or sperm retrieval rate of micro-TESE in patients with NOA with testicular microlithiasis are not well known.
Study design, size, duration: Echo patterns of the testis were observed by 10~14MHz linear probe, of the 596 patients who visited our clinic for male infertility from July 2003 to August 2015. Endocrinological measurements and US images of the testis were obtained before surgery, and compared with the results of micro-TESE.
Participants/materials, setting, methods: We evaluated 596 patients who underwent microTESE. US findings were compared with testis volumes, microscopic findings (HE stain), FSH, and sperm recovery rate. US analysis was performed using a 10- or 14-MHz linear array transducer. To optimize US images for visualization of the seminiferous tubules, gain and contrast were appropriately adjusted with graphic software.
Main results and the role of chance: Severe testicular microlithiasis (high echoic lesion with acoustic shadowing at surfaces of testis) were observed in 6 (1.0%) out of 596 NOA patients. Median age was 39 years old (range: 32–62 years old), and on physical examination, testis volume was 2–11 ml (average 4.21ml), serum follicle stimulating hormone value was high (13.0–36.3mIU/ml; average 26.3mIU/ml). All of 6 patients with severe testicular microlithiasis underwent microTESE for treatment of azoospermia, and sperm retrieval was successful in all patients with severe testicular microlithiasis. Many calcifications with layered structure were observed in every seminiferous

tubule tissue in microscopic findings, and Johnsen's score count was 1.55–6.50 (average 4.21).

Limitations, reasons for caution: Severe testicular microlithiasis was observed in only 6 patients out of 596 NOA patients in our clinic. However, to discuss about sperm retrieval rate in patients with severe microlithiasis, more number of patients should be included for the future study.

Wider implications of the findings: Severe testicular microlithiasis indicates the micro-obstruction in seminiferous tubule in NOA patient. When severe testicular microlithiasis was observed in NOA patients in US analysis, its finding may be the predictive factor of successful sperm retrieval in NOA patient.

Trial registration number: Not required.

P-073 Association of varicocele and classical sperm characteristics with antioxidant enzymatic activity – superoxide dismutase and glutathione peroxidase, selenium, sperm DNA fragmentation and membrane mitochondrial potential

B. Zorn[1], M. Prezelj[2], M. Kolbezen[1], A. Kopitar[3], E. Vrtacnik-Bokal[4]
[1]*University Medical Centre Ljubljana, Department of Ob/Gyn - Andrology Centre, Ljubljana, Slovenia*
[2]*University Medical Centre Ljubljana, Institute of Clinical Chemistry and Biochemistry, Ljubljana, Slovenia*
[3]*University of Ljubljana, Institute of Microbiology and Immunology, Faculty of Medicine, Ljubljana, Slovenia*
[4]*University Medical Centre Ljubljana, Department of Ob/Gyn, Ljubljana, Slovenia*

Study question: Oxidative stress (OS) has been mentioned as being a cause of male infertility. Are the OS markers, actually used, useful in diagnosing sperm pathology ?

Summary answer: Beside lower SOD and GPx in men with varicocele, no association was retrieved between DNA fragmentation and MMP and other markers of seminal oxidative stress.

What is known already: Seventy years have passed after the discovery of detrimental effect of reactive oxygen species (ROS) on sperm and its possible repair after addition of antioxidant enzymes.

Low ROS levels are normal whereas seminal oxidative stress (OS) with ROS produced in excess, can impair sperm.

High antioxidant enzymatic scavengers (SOD, GPx), total antioxidant activity and selenium are characteristic of normal sperm.

Technology fails to propose reliable tests to detect accurately oxidants and antioxidants and their negative effects on sperm.

Beside sperm standard characteristics, DNA fragmentation and MMP distinguish normal sperm from abnormal and predict natural conception.

Study design, size, duration: Eighty eight males from infertile couples were consecutively enrolled at the outpatient clinic at the University Medical Center Ljubljana over a period of two years. Aoospermics were excluded.

Participants/materials, setting, methods: Men underwent clinical examination: medical history of testicular mal descent, testicular volume and palpable varicocele. Sperm analysis was performed according to WHO 1999 guidelines. The percentage of sperm with DNA fragmentation was determined by TUNEL method, MMP was determined by means of $DiOC_6(3)$. TAC, **s**uperoxide dismutase (SOD), glutathione peroxidase (GPx) and selenium were determined by spectrophotometric assays.

Main results and the role of chance: The classical sperm characteristics (concentration, motility, morphology) were related to DNA fragmentation negatively and to MMP positively (all $p < 0.001$). GPx and SOD were negatively related to the presence of a clinical varicocele ($p < 0.001$ and $p = 0.031$, respectively). Selenium was associated with sperm concentration and morphology ($r = 0.236$, $p = 0.038$ and $r = 0.257$, $r = 0.024$, respectively). Selenium was also related to GPx ($r = 0.231$, $p = 0.043$) and SOD ($r = 0.534$, $p < 0.001$).

This study does not retrieve clear relationships between OS markers, standard sperm characteristics, DNA fragmentation and MMP.

Limitations, reasons for caution: Limited number of participants; may be not the adequate OS tests selected.

Wider implications of the findings: Necessity to develop basic research on oxidative stress and to develop screening tests.

Trial registration number:/

P-074 The common DEFB126 NM_030931.3:c.314_315delCC genetic variant: an indicator for treatment and donor selection in subfertile couples?

G. Filippini[2], M. Bellavia[1], E. Al Zaman[1], F. De Angelis[1], E. Crugnola[2], S. Cuomo[1], T. Suter[1], M. Jemec[1]
[1]*ProCrea, Fertility Center, Lugano, Switzerland*
[2]*ProCreaLab, Human Genetic Laboratory, Lugano, Switzerland*

Study question: Does the common β-defensin 126 (*DEFB 126*) genetic variant c.314_315del affect the success rate of donor intra-uterine insemination (D-IUI)?

Summary answer: The results show no difference in the pregnancy rate between the three different variants of *DEFB126* (ins/ins; del/del; del/ins).

What is known already: The *DEFB126* variant NM_030931.3:c.314_315delCC has been suggested to modify immunoprotection and efficient movement of sperm in the female reproductive tract. In a study of 509 Chinese couples, odds of pregnancy were significantly reduced (to 60%) when the male had the del/del genotype. *In vitro,* there was 84% reduction in the rate of penetration of a hyaluronic acid (HA) gel by sperm from del/del males. The authors suggested two mechanisms: impaired penetration of cervical mucus and reduced sperm-oocyte adhesion.

Study design, size, duration: Retrospective cohort study of 126 women with 205 D-IUI cycles from 37 semen donors, who underwent D-IUI between 2013 and 2015. D-IUI was selected both to remove the barrier of cervical mucus, and to determine whether this test could improve donor selection.

Participants/materials, setting, methods: Participants included all women who commenced D-IUI treatment in our fertility center. Exclusion criteria included the presence of female factors and women older than 36. Pregnancy was defined as β-HCG > 15 IU/ml; pregnancy rate was estimated for each genotype group of *DEFB126* (ins/ins; del/del; del/ins). The *DEFB126* variant was tested by PCR and capillary electrophoresis on the donors' DNA stocked in the genetic laboratory.

Main results and the role of chance: In all there were 58 pregnancies in the 205 D-IUI cycles (28.3%). There were 14 pregnancies in the group ins/ins (30.4%); 21 in the group del/del (30.8%) and 23 in the group del/ins (25%). The pregnancy rate of the three groups was not statistically different.

Limitations, reasons for caution: This pilot study was performed retrospectively, and only on sperm donors. All participants were Caucasian, in contrast to the original study.

Wider implications of the findings: As we studied IUI cycles, our results suggest that any effect of the del/del genotype is related to cervical mucus. Therefore IUI would be the treatment of choice in couples with del/del males. Furthermore, *DEFB126* analysis is useful in the workup of infertile couples but not in sperm donors selection.

Trial registration number: None.

P-075 Reconsidering of human round spermatid injection into the oocyte (ROSI)

A. Tanaka[1], M. Nagayoshi[1], Y. Takemoto[1], I. Tanaka[1], T. Miki[1], T. Yamaguchi[1], H. Kusunoki[2], S. Watanabe[3]
[1]*Saint Mother Hospital, Department of Obstetrics and Gynecology, Kitakyushu, Japan*
[2]*Hirosaki University Graduate School of Medicine, Faunal Diversity Sciences, Kobe, Japan*
[3]*Hirosaki University Graduate School of Medicine, Department of Anatomical Science, Hirosaki, Japan*

Study question: Can an improved ROSI be considered a worthy clinical treatment despite the fact that conventional ROSI has been recognized as being ineffective for non-obstructive azoospermia?

Summary answer: In this study ROSI fully proved to be effective clinically when there is proper identification of round spermatid and oocyte activation.

What is known already: To date, the application of ROSI in clinical IVF has had disappointing results due to difficulties in accurate identification of round spermatids among other round spermatogenic cells and insufficient oocyte activation. Incomplete male-specific DNA methylation imprinting in round spermatids might be the cause of the insufficiency of ROSI. It is believed that existence of round spermatid is associated with testicular spermatozoon. That is no testicular spermatozoa means no round spermatid.

Patients who may be candidates for ROSI should receive careful and thorough pretreatment counseling to ensure they are clearly informed of the limitations and potential risks of the procedure.
Study design, size, duration: A total of 90 non-obstructive azoospermic men whose first Micro-TESE conducted by andrologists showed no testicular spermatozoa or late staged spermatids but had round spermatids found at our hospital and received ROSI from September 2011 to December 2014 participated in this study. After approval of the Institutional Review Boards of the Saint Mother Obstetrics and Gynecology Clinic. This study was registered and adhered to International Committee of Medical Journal Editors criteria.
Participants/materials, setting, methods: Round spermatids, cytologically selected after thawing, were injected into ooplasm which was activated 10 minutes before the injection by electrical stimulation with an alternating current pulse of 2V/cm for 8s + direct current pulse of a single 1.2kV/cm for 99μs. We examined pattern of Ca^{2+} oscillation in oocytes after electrical stimulation and ROSI plus electrical stimulation to know the efficacy of the oocyte activation.
Main results and the role of chance: The percentages of occurrence of 1PN, 2PN and 3PN after electrical stimulation were 80% (8/10), 20% (2/10) and 0 respectively. Fertilization and rate to develop over 4 cell stage were 58.8% (590/1004), 50.6% (508/1004) respectively. The pregnancy rate per transferred cycle, miscarriage rate and birth rate in fresh embryo transfer cycles and freezing-thawed transfer cycles were [16.7%(26/156), 65.3%(17/26), 5.8%(9/156)], [23.9%(16/67), 50.0%(8/16), 11.9%(8/67)] respectively. No abnormal karyotype and genomic imprinting abnormalities (IGF2, H19, SNRPN) were identified in any of the newborn babies. All of 6 female and 13 male babies are healthy and no serious physical or cognitive disorders have been reported so far. Although round spermatid injection alone could induce small Ca^{2+} oscillations, ROSI with prior electrical stimulation showed effective in inducing repetitive, large Ca^{2+} oscillations.
Limitations, reasons for caution: The limitation of this clinical study concerns the small size of the study group and electrical stimulation for oocyte activation could not be the optimal one judging from the high percentage of miscarriages and immatured centrosome. The inefficient demethylation and remethylation of DNA after ROSI might be a prime concern.
Wider implications of the findings: This study presents evidence that ROSI has a high potential to help many non-obstructive azoospermic men whose most advanced spermatogenic cells are round spermatids. After confirmation of the safety of ROSI, it could be chosen as a first line treatment instead of ICSI using dead or anomalous spermatozoa.
Trial registration number: UMIN Clinical Trials Registry UMIN000006117.

P-076 Y chromosome microdeletion and spermatogenesis in Japanese men due to spermatogenic dysfunction

Y. Shimomura[1], K. Suzuki[1], T. Iwahata[1], T. Kobayashi[1], T. Shin[1], Y. Kobori[1], H. Okada[1], A. Miyata[2]
[1]Dokkyo Medical University Koshigaya Hospital, Urology, Koshigaya, Japan
[2]Dokkyo Medical University Koshigaya Hospital, Reproduction Center, Koshigaya, Japan

Study question: What is the frequencies of microdeletions of AZFa, AZFb, AZFc and the sperm retrieval rate by TESE in azoospermia due to spermatogenic dysfunction from Japanese population?
Summary answer: The frequency of Y chromosome microdeletions in infertile men from Japan was comparable to the frequency reported in other countries and regions.
What is known already: Genetic factors cause about 15% of male infertility. Azoospermia factors: AZFa, AZFb (P5/proximal P1), and AZFc (b2/b4) present on Yq are most important for spermatogenesis.
Study design, size, duration: This study is Retrospective analysis for azospermic patients who conducted TESE from April 2007 to December 2014.
Participants/materials, setting, methods: We included 980 azoospermia due to spermatogenic dysfunction (ASD) men in present study, belonging to the age group of 20–51 years. For each patient genomic DNA was extracted from peripheral blood using, the QIAamp DNA mini extraction kit. Y Chromosome Deletion Detection System, Version 2.0 was used for Y chromosome deletion detection system. A single surgeon performed microdissection testicular sperm extraction (TESE) for all enrolled ASD patients. The pathological diagnosis of resected testicular specimen was examined.
Main results and the role of chance: The overall prevalence of Y chromosome microdeletions in infertile men was 8.1% (79/980). Prevalence of Y chromosome microdeletions in AZFa, AZFb, AZFabc, AZFbc (P5/distal P1 or P4/distal P1) and AZFc are 0.1%, 0.8%, 0.7%, 2.0% and 4.4%, respectively. Microdissection TESE failed in all patients with AZFa, AZFb, AZFabc, and AZFbc. Sperm were retrieved in 28/43 AZFc deleted patients (62.2%). The presence of an AZFc deletion was associated with significantly increased of sperm retrieval when compared with the 33.0% retrieval rate in idiopathic nondeleted azoospermic men who consecutively underwent microdissection TESE at our institution during the study period.
Limitations, reasons for caution: Study data were obtained retrospectively, which might have affected the quality of the data. Furthermore, the sample size was too small to draw definite conclusions from the results. We need to accumulate additional data from similar cases.
Wider implications of the findings: None.
Trial registration number: None.

P-077 Relationship between serum oxidative stress/antioxidant power in infertile men and age, parameter of sperms or ART result

M. Kobayashi[1], A. Yoshida[1], M. Kobayashi[1], N. Fujisawa[1], Y. Yamada[1], K. Seida[1]
[1]Kiba Park Clinic, Tokyo, Japan

Study question: How serum oxidative stress (OS) and antioxidant power (AOP) in infertile men influence parameters of sperms and outcome of ART?
Summary answer: There were no correlations between OS/AOP and parameters of sperms. The normal fertilization rates in the elevated OS and lower AOP groups were significantly lower.
What is known already: OS is a consequence of an imbalance between the production of reactive oxygen species and the body's antioxidant defense mechanisms. OS has also been implicated in the pathogenesis of many human diseases such as cancer, diabetes and motor neuron disease. OS can lead to gamete damage, deformity and eventually infertility.
Study design, size, duration: The value of serum OS and AOP in 225 infertile men were measured between March and October of 2015. Among the 225 men, sperm parameters of the 48 men were measured on the day of oocyte retrieval and the ART results of the 83 males were assessed.
Participants/materials, setting, methods: D-ROMs (reactive oxygen metabolites) and BAP (biological anti-oxidant potential) in the serum were measured. Correlation between serum d-ROMs or BAP and sperm DNA fragmentation index, sperm concentration or sperm motility rate were observed. The ART results were compared in terms of the value of men's serum d-ROMs and BAP.
Main results and the role of chance: There was no correlation between the men's age and the levels of d-ROMs while the level of BAP decreased with advancing age. There were no correlations between serum d-ROMs or BAP and sperm DNA fragmentation index, sperm concentration or sperm motility rate. The normal fertilization rate in the men's d-ROMs elevated group was significantly lower than that in the d-ROMs normal group. There were no significant differences in the good-quality embryo rate on day 3 and the blastocyst formation rate between the two groups. The normal fertilization rate in the men's BAP lower group was significantly lower than that in the normal group. There were no significant differences in the good-quality embryo rate on day 3 and the blastocyst formation rate between the two groups.
Limitations, reasons for caution: Sample of this study was small. At this study, the levels of OS and AOP in the seminal plasma weren't measured.
Wider implications of the findings: The value of serum OS and AOP did not influence sperm DNA fragmentation index, sperm concentration or sperm motility rate. The normal fertilization rate in the men's serum OS elevated group was significantly lower and the normal fertilization rate in the men's serum AOP lower group was significantly lower.
Trial registration number: N/A.

P-078 Influence of monotherapy with darunavir-ritonavir on semen quality and on the presence of HIV in the semen of HIV+ patients

A. Clavero[1], P. Navas[1], M. Gonzalvo[1], M. López Regalado[1], I. Sánchez[1], A. Guzman[1], L. Martínez-Granados[1], H. Gutierrez[1], M. Navarrete[1], B. Romero[1], I. Rodriguez[1], J. Pasquau[2], R. Javier-Martínez[2], M.A. Rus[2], J.A. Castilla[1]

[1]Unidad de Reproduccion- UGC Laboratorio y UGC Obstetricia y Ginecologia- CHU Granada., Unidad de Reproducción, Granada, Spain
[2]Servicio de Medicina Interna- Unidad de Enfermedades Infecciosas-CHU Granada, Enfermedades Infecciosas, Granada, Spain

Study question: Is monotherapy with darunavir-ritonavir as safe as triple therapy in relation to the presence of HIV in semen, and is semen quality maintained?
Summary answer: Changing triple therapy to monotherapy does not alter semen quality and is as safe as triple-therapy in relation to the presence of HIV in semen.
What is known already: Opinions differ regarding the effect of HIV infection and of the various treatments used on the semen parameters of these patients. Moreover, studies have confirmed that patients with undetectable viral load and no sexually transmitted disease do not transmit the virus sexually. However, little research has been conducted into the viral load in semen among patients receiving monotherapy with protease inhibitors, and the effect of new therapies, facilitating medication adherence, on the semen quality of HIV patients remains unknown.
Study design, size, duration: Observational study in HIV patients with undetectable viral load (<20 copies) in blood plasma under triple therapy, including 2 nucleos(t)ide analogues, and who are candidates for monotherapy with a boosted protease inhibitor (darunavir-ritonavir). The variables analysed were age, CD4/mL, nadir CD4, type of triple therapy, semen viscosity, appearance, liquefaction, volume, pH, sperm concentration, progressive and total motility, vitality, andrological history and reproductive history.
Participants/materials, setting, methods: For each patient, two separate semen samples were analysed, at 15-day intervals, before discontinuing triple therapy, and another two samples were analysed after 48 weeks of monotherapy with darunavir-ritonavir. All semen samples were processed and evaluated in accordance with WHO (2010) recommendations. The technique used to quantify HIV-1 RNA in the final sample processed was real-time PCR, an adaptation of the HIV-1 COBAS Ampliprep/Taqman assay quality of HIV patients remains unknown.
Main results and the role of chance: A total of 28 patients, with a mean age of 41 ± 9.13 years (22–55), were included. The percentages of patients with values above the WHO 2010 lower reference limit for all semen parameter values were similar before and after the change to monotherapy: normozoospermia (57.1% vs. 61.9%), oligoteratozoospermia (7.1% vs. 9 6%), oligoasthenozoospermia (7.1% vs. 4.8%), oligoteratoasthenozoospermia (10.7% vs. 4.8%), teratozoospermia (14.3% vs. 4.8%), asthenozoospermia (0% vs. 9 6%), oligozoospermia (3.6% vs. 4.8%). The positive viral load in seminal fluid in patients with triple therapy, in the first semen sample, was 14.81%, ranging from 35 to 1210 copies/mL. The positive viral load in seminal fluid in patients with triple therapy in the second sample was 4.55% with 399 copies/mL. The corresponding values in monotherapy with darunavir-ritonavir were 3.13% (positive viral load: 139 copies/mL) in the first sample and 0% in patients with positive viral load in the second sample. No relationship was observed between the presence of HIV in semen and the type of therapy.
Limitations, reasons for caution: These findings need to be verified in studies with larger numbers of patients. ence of HIV in semen.
Wider implications of the findings: The results obtained could facilitate the response to the reproductive wishes of seronegative partners of HIV-positive patients.
Trial registration number: No trial registration number.

P-079 Recipient nationality and marital status in relation to choice of ART and donor type

E. Johansen[1], P. Reeslev[1], O. Schou[1], P. Larsen[1], L. Madsen[1]
[1]Cryos International ApS, Denmark, Aarhus C, Denmark

Study question: Does recipient nationality and marital status affect the preference for anonymous/non-anonymous donors and does recipient nationality relate to choice of ART?
Summary answer: The preference for non-anonymous vs. anonymous donors is influenced by marital status and nationality of the recipient. The latter also influences the choice of ART.
What is known already: Many countries regulate use of anonymous/non-anonymous gamete donors, but often in conflict with the recipient's preferences. Views concerning the recipient's right to autonomy and interest of the child vary greatly both between individuals and national laws, e.g., certain countries only allow treatment for heterosexual couples and with anonymous donor sperm. In contrast, other countries allow for both anonymous and non-anonymous donors and treatment regardless of marital status. These differences induce some recipients to seek alternative solutions either abroad, i.e., CBRC, home insemination or unauthorized suppliers.
Study design, size, duration: A multiple-choice questionnaire was e-mailed to recipients with the purpose of investigating preferences and experiences of these recipients. The current analysis emphasizes the recipient's opinion with respect to donor anonymity status and recipients choice of ART as a function of marital status and nationality. 1463 replies were received.
Participants/materials, setting, methods: Recipients of donor sperm from the sperm bank Cryos International - Denmark received a multiple-choice questionnaire by e-mail and responded from September 2014 until October 2015. Results were tested for statistical significance using the Chi-square test, and, hence, comparisons were accomplished employing nationalities harboring most of the responders, i.e., Germany, United Kingdom, France, Italy, Netherlands, Sweden, and Denmark.
Main results and the role of chance: The frequency of people living in a homosexual relationship using donor sperm was significantly higher in Germany, United Kingdom, France, and Italy compared to Denmark, Netherlands, and Sweden, where the marital status of the largest group of recipients were single. Furthermore, recipients who were single or in a homosexual relationship, did find it more important that there was a wide selection of non-anonymous donors than those living in a heterosexual relationship, who found it more important that there was a wide selection of anonymous donors, than the other groups. Furthermore, the survey revealed that the majority of the recipients from all seven nationalities found it important that there was a wide selection of non-anonymous donors where recipients from the Netherlands found it even more important than recipients from the remaining countries.

Recipients from the various countries were also asked for their choice of treatment, including home insemination, IUI, IVF and ICSI. Interestingly, the survey revealed that recipients from Germany, United Kingdom, France, and Italy presented the highest frequency with respect to home inseminations whereas recipients from Denmark revealed the lowest. The Netherlands and Sweden were located between those two groups with respect to home insemination frequency.
Limitations, reasons for caution: Only a minority responded to the questionnaire. It is unknown if all groups are equally likely to respond. Recipients where clinics purchased the donor sperm are not represented, this number varies between countries. These facts might both represent a bias. Therefore, the results should be regarded as tendencies.
Wider implications of the findings: This study contributes to the debate of the importance of providing both anonymous and non-anonymous gamete donors and also for the importance of providing everyone an equal opportunity to establish a family regardless of marital status.
Trial registration number: N/A.

P-080 Sperm chromatin integrity (SCSA analysis) in specific ejaculate fractions can improve semen evaluation under clinical settings

M. Álvarez-Rodríguez[1], S. Liffner[1], A. Vicente-Carrillo[1], M. Hammar[1], H. Rodriguez-Martinez[1]
[1]Obstetrics and Gynecology, Clinical and Experimental Medicine IKE, Linköping, Sweden

Study question: Is the standard semen analysis according to World Health Organization (WHO) criteria enough for clinical evaluations prior to fertility interventions?
Summary answer: Fertile semen donors and patients (partners in an infertile couple) with similar WHO-values under evaluation prior to ART-intervention differed in DNA fragmentation index (DFI).
What is known already: Standard semen evaluation is considered insufficient to disclose differences in patients where semen quality is within WHO-acceptable limits, despite proof of subfertility. The SCSA uses flow-cytometry to measure the stability of double-stranded sperm chromatin upon acid exposure. Results are given as%-sperm with denatured DNA, in relation with the total fluorescence measured, which is termed the DNA fragmentation index (DFI). Correlations to fertility after ART are reported (Oleszczuk et al., 2016, Andrology. 10.1011/andr.12153) but yet not widely accepted. Human has a

fractionated ejaculate, with differences in sperm quality, yet samples are still collected/handled in a single tube (bulk ejaculate).
Study design, size, duration: Retrospective. Sperm samples from fertile semen donors ($n = 9$) and patients (partners in an infertile couple with unknown etiology, $n = 8$) under evaluation prior to ART-intervention attending the Reproductive Medicine Centre (RMC), Linköping were frozen for SCSA analysis. Ejaculates were collected as two fractions (F1 = prostate-dominated jets, F2: rest of the ejaculate, seminal vesicle dominated), semen had similar standard (WHO criteria) semen outcome values.
Participants/materials, setting, methods: Consentual fertile semen donors ($n = 9$, 2 ejaculates/person) and patients ($n = 8$, 1 ejaculate/patient) attending clinical setting (RMC, Linköping, Sweden). Ejaculates (donors 2 and patients 1 ejaculate/person) were collected by masturbation in two fractions (F1 & F2). Samples were standard evaluated for volume, sperm concentration (manual counting) and motility (subjective) following WHO-criteria and also for SCSA using flow-cytometry, with outcomes for sperm immaturity (HDS) and DNA fragmentation (DFI). Statistical analysis was performed in R environment (ISBN3-900051-07-0).
Main results and the role of chance: The SCSA showed large variation among individuals and fractions (Table 2), being DNA-fragmentation-index (DFI) per ejaculate (F1+F2) significantly lower in donors than in patients ($P < 0.05$, Kruskal-Wallis rank sum test).

Table 1: Semen characteristics in ejaculate fraction 1 (F1) for the fertile vs patient population (WHO standards 2010, Mean ± SD).

Category	*n*	*n* ejaculates	Volume (mL)	Total sperm number (10^6)	Sperm motility (%)	Round cells	
Total motile	Progressive motile						
Fertile donors	9	18	3.8 ± 1.6	40.8 ± 18.3	67 ± 6.9	60 ± 6.7	No (0–18)
Infertile patients	8	8	1.6 ± 0.3	68 ± 14	71 ± 10	50 ± 3.3	Yes (2/10)

Table 2: DNA fragmentation index (single stranded DNA, DFI, %) and sperm immaturity (HDS, %), Mean ± SEM and ranges in spermatozoa present in the fractions (F1 & F2) of ejaculates from fertile vs patient population; SCSA analysis.

Category	*n*	*n* ejac	Fraction	DFI (%)	DFI range (min–max)	HDS (%)	HDS range (min–max)
			F1	7.1±0.9	3.1–16.1	12.6±2.1	5.5–39.8
Fertile donors	9	18	F2	8.1±1.1	2.7–20.9	12.0±1.9	3.1–36.0
			F1+F2	7.6±1.3[a]	2.7–20.9	12.3±1.4	3.1–39.8
			F1	10.1±2.0	4.3–20.9	11.8±1.5	5.0–17.2
Infertile patients	8	8	F2	13.4±4.0	5.1–39.9	11.6±1.4	6.2–18.2
			F1+F2	11.8±2.2[b]	4.3–39.9	11.7±1.0	5.0–18.2

[a,b]Different superscripts ($p < 0.05$).

Limitations, reasons for caution: Low number of individuals. Sample processing and storage are crucial steps for the accuracy of the SCSA, requiring that $1–2 \times 10^6$ spermatozoa/mL to be extended in TNE buffer and frozen (−20–80C) as soon as possible after sample collection.
Wider implications of the findings: SCSA offers an accurate way to differentiate the status of the sperm DNA. Note that spermatozoa with unstable chromatin remain capable of fertilization. Use of the sperm-rich fraction (F1) eases handling of the ejaculate for diagnostics and, particularly, ART.
Trial registration number: N.A.

P-081 Effects of temperature and concentration on human sperm quality during *in vitro* handling

R. Gualtieri[1], S. Braun[1], A. Merolla[1], V. Barbato[1], S. Sudhakaran[1], R. Talevi[1]
[1]*Università degli studi di Napoli Federico II, Department Biology, Napoli, Italy*

Study question: Do the temperature and concentration affect the motility, viability and DNA fragmentation of human sperm during *in vitro* handling?
Summary answer: Viability and DNA integrity of semen or swim-up samples were better preserved at RT versus 37°C. Washed sperm were better preserved at low concentration.
What is known already: Human semen may have a variable degree of sperm DNA fragmentation. Moreover, sperm handling during ART can increase the basal sperm DNA fragmentation and this has been correlated to oxidative stress (OS). As sperm DNA fragmentation and OS may result in poor fertilization, embryo development and even exert long term effects on newborns, it is fundamental to understand the factors that can add a iatrogenic damage to sperm during ART.
Study design, size, duration: Sperm macroscopic and microscopic features were analyzed in 20 patients. Experiment I: semen samples incubated 1h at RT or 37°C. Experiment II: swim up samples incubated 3h at RT or 37°C. Experiment III: washed samples incubated 3h at 37°C at different sperm concentrations (RANGE: 1, 100–75; 2, 50–35; 3, 25–15; 4, $10–5 \times 10^6$).
Samples were analyzed for motility, viability and DNA fragmentation.
Participants/materials, setting, methods: Seventeen normospermic, two oligospermic and one asthenospermic patients were included in the study. Samples were analysed according to WHO (2010) for concentration, motility and kinetics through Sperm Class Analyzer. Viability was evaluated through Live/Dead far red and eosin test; DNA fragmentation was analyzed through the TUNEL assay.
Main results and the role of chance: Experiment I: whole semens samples had a higher viability (time 0, 75.7%; 1h RT, 72.7%; 1h 37°C, 58.6; $P < 0.001$) and lower DNA fragmentation after 1hr incubation at RT than at 37°C (Time 0, 9.4%; 1h RT, 11.7%; 1h 37°C, 21.3%; $P < 0.001$). Experiment II: swim-up samples had a lower DNA fragmentation after 3h at RT than at 37°C (time 0, 9.4%; 3h RT, 13.3%; 3h 37°C, 18.3%; $P < 0.001$). Experiment III: washed sperm samples had a lower DNA fragmentation at low compared to high sperm concentration after 3h of incubation at 37°C (Time 0, 8.3%; Range 1, 17%; Range 2, 13%; Range 3, 10.5%; Range 4, 8%; $P < 0.001$). No significant differences of motility and kinetics were detected in all experiments.
Limitations, reasons for caution: As this is a preliminary study, findings should be confirmed on a higher number of patients.
Wider implications of the findings: As temperature and cell concentration affect the viability and DNA integrity of spermatozoa during *in vitro* handling, it should be avoided to incubate whole semen or swip-up samples for long times at 37°C and at high sperm concentration during routine ART procedures.
Trial registration number: None.

P-082 Abdominal obesity and unbalanced metabolism in men consulting for unexplained subfertility

C. Dupont[1], C. Faure[2], B. Gautier[3], I. Aknin[4], S. Cens[5], C. Uthurriague[5], I. Cedrin[6], C. Julia[3], S. Hercberg[3], R. Levy[7]

[6]*APHP- Hôpital Jean Verdier, Service de médecine de la reproduction, Bondy, France*
[7]*APHP - Tenon, Reproductive Biology Unit- CECOS, Paris, France*

Study question: Are male abdominal obesity and metabolic status involved in unexplained subfertility?
Summary answer: BMI and abdominal obesity were increased in subfertile patients, with lower HDL cholesterol levels and higher glycaemia.
What is known already: Overweight and obesity are known to impact male fertility and sperm parameters (Sermondade, 2013). More recently, an impact of metabolic syndrome and abdominal obesity on male reproductive functions has been highlighted (Michalakis, 2013, Metabolism). BMI and abdominal obesity are strongly associated with systemic oxidative stress and low grade inflammation, which could affect the testicular microenvironment and negatively impact sperm production. It could also impact sperm DNA integrity and explain subfertility even if conventional semen parameters are in normal ranges.

Study design, size, duration: Data from subfertile ($n = 97$) and fertile ($n = 98$) men under 45 years recruited in the ALIFERT study were recorded between September 2009 and December 2013. Inclusion criteria excluded patients with current or previous metabolic disease. Subfertile men were partner of subfertile couples. They presented with a primary idiopathic infertility >12 months and had normal sperm characteristics.

Fertile men were included if they had, one child under 2 years spontaneously conceived with a time to pregnancy <12 months.

Participants/materials, setting, methods: Height and waist circumference were measured by the same trained investigator. Weight and body composition were evaluated using the Tanita BC-420MA analyzer. Plasma total cholesterol, high-density lipoprotein (HDL-cholesterol), low-density lipoprotein (LDL-cholestérol), triglycerides and glucose concentrations were measured after a 12-hour fasting period.

Main results and the role of chance: Fertile and subfertile males were similar in term of age (33.2 vs 34.5, $p = 0.061$). BMI (25.9 vs 24.0, $p < 0.001$), waist circumference (91.5 vs 86.3, $p < 0.001$) and abdominal obesity assessed by impedancemetry (6.7 vs 4.1, $p < 0.001$) were increased in subfertile patients. No significant differences of total cholesterol (2.01 vs 2.02, $p = 0.97$), LDL cholesterol (1.28 vs 1.27, $p = 0.89$) and triglycerides (1.26 vs 1.07, $p = 0.077$) levels were observed between fertile and subfertile men. Nevertheless, subfertile patients had lower HDL cholesterol levels (0.49 vs 0.53, $p = 0.011$) and higher glycaemia (4.9 vs 4.3, $p < 0.001$) compared to fertile men.

Limitations, reasons for caution: The definition of unexplained subfertility may be subject to controversy.

Wider implications of the findings: Although subfertile patients presented no alteration of conventional semen parameters, they show higher BMI, higher adiposity and metabolic unbalanced that could explain the difficulty to conceive. Measure of abdominal obesity and assessment of metabolic status should be part of infertility investigations, and treatment should be undertaken before starting ART procedures.

Trial registration number: P071224.

P-083 Land of Fires vs National Park of Cilento (South of Italy): two different enviromental impacts on Sperm DNA Fragmentation

T. Notari[1], L. Montano[2], S. Raimondo[3], P. Bergamo[4], S. Lorenzetti[5], L. Iannuzzi[6]

[1]Assisted Reproductive Unit - Hospital S. Luca - Vallo Della Lucania, Salerno, Italy

[2]Andrology Unit - Hospital S. Francesco d'Assisi- Ecofoodfertility Project Coordination Unit, Oliveto Citra, Salerno, Italy

[3]Research Centre "Gentile S.A.S.", Seminolgy Unit, Gragnano, Napoli, Italy

[4]National Research Council CNR, ISA, Institute of Food Sciences, Avellino, Italy

[5]ISS – National Health Institute, Food Safety and veterinary Public Health, Roma, Italy

[6]CNR-ISPAAM, Research Council Institute for System of Animal Production in the Mediterranean Environment, Napoli, Italy

Study question: The purpose of this study was to evaluate the relationship between areas of residence with different environmental characteristics and the damage extent in spermatic DNA.

Summary answer: Sperm DNA Fragmentation (SDF) differs significantly between (HIP) high environmental impact province and LIP (Low Impact Province).

What is known already: Reproductive health in men is affected by genetic, environmental and lifestyle factors and the adverse effects played by environmental pollution has been evidenced by epidemiological studies. DNA fragmentation levels are a valuable biomarker for male infertility, in particular, the sperm chromatin dispersion test (SCD), giving a SDF value, is considered a reproducible test.

Study design, size, duration: Retrospective study of 175 men underwent to SCD test for infertility, since 2013 to 2015. 500 spermatozoa per DNA test (87,500 total) were analyzed for evaluation of DNA fragmentation by Sperm Chromatin Dispersion method (Halosperm®, Halotech DNA SL).

Participants/materials, setting, methods: 175 healthy non-smoking, non-drinker males, without exposure to environmental factors, selected according to their residence in High (Naples-Caserta province – HIP, $n = 70$), or in Low environmental Impact (Salerno province - LIP, $n = 105$) areas of the Campania region (Southern Italy). The obtained value of SDF were expressed as the percentage of fragmented DNA sperms. The calculation of significance was means of the GraphPad Prism 6.0 software and a value of $P < 0.05$ was considered significant.

Main results and the role of chance: Sperm DNA fragmentation rate significantly increased in High Impact Provinces, well known as "Land of Fires", while is lower in Low Impact Province, the area of National Park of Cilento, (Southern Italy), famous for the origin of Mediterranean diet. A total of 70 samples were analyzed in HIP group (HIP $n = 70$) and 105 samples in LIP group (LIP $n = 105$).

Mean value observed in HIP group was 34 ± 12.3 vs LIP group 27.2 ± 10.9, $P = 0.0003$. The results support the effectiveness of the considered markers in the quantification of DNA damages as well as the relationship between sperm DNA damage extent and the environmental characteristics of the area of residence.

Limitations, reasons for caution: This is an observational study on the relationship between SDF and environmental impact. We don't know the reason of these difference, maybe due to the presence of specific factors. The results support the idea that the relationship between sperm DNA damage and the area of residence can affect male fertility.

Wider implications of the findings: This study confirm that particularly anthropyzed and industrialyzed areas play a key rule in infertility. This study represents a starting point for future analyses to be carried out under the project EcoFoodFertility, which will investigate the role of seminal fluid as a "sensor" of environmental quality in different European areas.

Trial registration number: Not requested. Basic observational retrospective study.

P-084 Sperm DNA fragmentation and mitochondrial membrane potential are better for predicting natural pregnancy than semen analysis

S. Malic[1], B. Golob[1], A.N. Kopitar[2], A. Ihan[2], M. Kolbezen[1], B. Zorn[1]

[1]Andrology Centre, Reproductive Unit, Department of Obstetrics and Gynecology, University Medical Centre Ljubljana, Slovenia, Ljubljana, Slovenia

[2]Institute of Microbiology and Immunology, Faculty of Medicine, University of Ljubljana, Slovenia, Ljubljana, Slovenia

Study question: Standard semen analysis is not sufficient for natural pregnancy prediction, i.e., in identifying those who are likely to conceive without medical assistance, and those who are not.

Summary answer: Sperm DNA fragmentation and mitochondrial membrane potential - MMP alone or combined may be superior to standard semen parameters in the prediction of natural pregnancy.

What is known already: Semen analysis is more useful in the diagnosis of extreme male factor infertility. An association between sperm DNA fragmentation, MMP and normal fertility potential has been reported previously. Sperm DNA damage has been associated with unsuccessful attempts to conceive. Data on a relationship between DNA sperm fragmentation, measured by TUNEL, and natural conception are scarce and inconsistent. MMP has been shown to be connected wit unsuccessful attempts to achieve assisted conception. An impact of MMP values has never been confirmed on the population of fertile men.

Study design, size, duration: A three-year prospective, cross-sectional was conducted on 51 fertile and 85 infertile couples with no female pathology present. After two year observational period infertile couples were divided regarding the occurrence of conception into subgroup of men who did not conceived - Group IA, and subgroup of men who conceived - Group IB.

Participants/materials, setting, methods: The infertile men were males from infertile couples coming for fertility evaluation with 12–18-month history of unsuccessful attempts to conceive, were observed for additional 6–12 months in terms of achieving a natural pregnancy. Control group were 51 men of currently pregnant women. Sperm DNA and MMP were measured by TUNEL and DiOC&(3) coupled with flow cytometry. The study was carried out at the outpatient infertility clinic, Andrology Unit of the University Medical Centre Ljubljana.

Main results and the role of chance: Twenty-eight of 85 (33%) men from infertile couples conceived naturally after two year observational period. All 28 women delivered after 37 week of pregnancy. The median values of DNA fragmentation and MMP in infertile men were different to those in the fertile controls.

Optimal threshold values of DNA fragmentation and MMP were 22.4% as determined by ROC analysis (AUC 0.69 [95% CI: 0.57–0.81]) and 62.5% (AUC

0.67 [95% CI: (0.55–0.79)]), respectively. The men in the infertile group with values of DNA fragmentation ≤22.4% and with MMP values [3] 62.5% had significantly higher odds for conception (OR 4.92 [95% CI: 1.86–13.02] and OR 4.61 [95% CI: 1.76–12.11], respectively). On contrary all three measures of antioxidative status of seminal plasma did not reach the clinically important discriminative value. Both sperm function tests combined had significant odds for natural conception (OR 6.96 [95% CI: 2.48–19.58]) with probability of 0.64 (64%) for both normal values, and 0.19 (19%) for both abnormal values. Normal combined parameter also influenced time to natural pregnancy achievement.

Limitations, reasons for caution: While this finding is compelling it is not yet conclusive, and should be validated on larger independent sample. Our results demonstrated also some uncertainties as well as false detection rates, which were expected considering the small sample size and still unknown sources of variability connected to unique sperm cell biology.

Wider implications of the findings: Irrespective of the results of standard semen analysis these clearly defined infertile groups of men such as ours will benefit from combined sperm function tests in clinical decision making and hence might avoid unsuccessful attempts to conceive. Such decision making is time and cost effective and has positive effects.

Trial registration number: This study was not a RCT.

P-085 The impact of paternal age on Intra Cytoplasmic Sperm Injection (ICSI) cycle outcome in ART: a retrospective study

L. Karakoc Sokmensuer[1], S. Mumusoglu[1], G. Bozdag[1], H. Yegenoglu[1], N. Coskun[1], A. Sever[1], S. Gunalp[1]
[1]*Hacettepe University, Obstetrics and Gynecology, Ankara, Turkey*

Study question: Does paternal age effect clinical pregnancy, miscarriage and live birth rate in ICSI-cycles?

Summary answer: Miscarriage rates were observed significantly higher in male >40 years old. Live birth rates were significantly lower in >40 years old.

What is known already: There is a tendency for delayed parenthood both for women and men in last decades. It was shown that the miscarriages and chromosomal abnormalities were increasing naturally concieved couples with men over 40 years old. However only seven studies have been focused on paternal age effect on ICSI-cycle outcomes. These studies show discordant findings in terms of effects on embryo quality, pregnancy rate and live birth rate.

Study design, size, duration: We enrolled 1252 couples who have undergone consecutive ICSI with ejeculated spermatozoa between 2010 and 2014. To minimize female age and overian reserve effect women with female age >35 and antral follicle count <5 were excluded. Totally 998 couples were retrospectively analyzed.

Participants/materials, setting, methods: Paternal age were grouped as Group 1 (20–30y, $n = 276$); Group 2 (31–40y, $n = 659$) and Group 3 (41–50y, $n = 63$). Male sperm concentrations, percentage of sperm motility, female body mass index (BMI), antral follicle count were similar between groups. Blastocyst transfer rate were similar in three groups (Group 1, 40.4%; Group 2, 37.1%; and Group 3, 35.2% respectively).

Main results and the role of chance: Clinical pregnancy rate per transfer were comparable in all groups. (Group 1, 31.7%; Group 2, 36.5%; and Group 3, 24.1% respectively). However, miscarriage rates were observed significantly higher in male age group >40 years old compared to others (Group1, 13.2%; Group 2 12.9% and Group 3, 30.7%; $p < 0.001$). Live birth rates per transfer were significantly lower in male age group > 40 years old (Group 1, 20.1%; Group 2, 22.9%; and Group 3, 11.1%, respectively $p < 0.001$). Mean female age in groups were 27.0 ± 3.1, 30.2 ± 3.5 and 32.7 ± 2.6, respectively ($p < 0.001$). Although there was significant difference between groups in terms of female age, we did not clinically take into account due to young female ages in all groups.

Limitations, reasons for caution: Retrospective design of the study and not taking into account of the men's lifestyle factors like smoking could be limitations.

Wider implications of the findings: Analyses of retrospective data demonstrated that miscarriage rate were increased with the paternal age in ICSI-cycles in ART. Live birth rate per transfer were also reduced with the increased paternal age in these patients. Physicians should inform the ART patients about this potential risk.

Trial registration number: NA.

P-086 The effects of smoking, harmful environmental exposure and physical exercise on semen quality

R. Pinto Leite[1], J. Matos[1,2], Z. Gomes[1], M. Brito[1], O. Moutinho[1]
[1]*Hospital Center of Trás-os-Montes and Alto Douro, Department of Obstetrics and Gynaecology, Vila Real, Portugal*
[2]*University of Minho, Center of Molecular and Environmental Biology, Braga, Portugal*

Study question: The aim of this work is evaluate the influence of life style in semen parameters using a questionnaire that was developed for use in routine infertility consultation.

Summary answer: Men that practice moderate exercise have better semen parameters. For smokers, no differences were found in sperm parameters either they practice exercise or not.

What is known already: Men life style has influence on their fertility. Smoking has impact on sperm motility, sperm count and volume and increases DNA damage, leading to a reduce fertilization capacity. Harmful environment exposure such as heat sources, pesticides and radiation have effect in spermatogenesis. Also, physical exercise appears to be beneficial but only to a certain extent. The moderate practice of exercise can increase the rates of total sperm count, concentration, vitality and motility, and this happens because exercise prevents over and underweight and regulates hormone levels. In men that practice regular and rigorous exercise this parameters have lower rates.

Study design, size, duration: Sperm quality was evaluated in order to see the influence of exercise, smoking and exposure to different environmental conditions in 373 men whom have consulted for couple's infertility during the past 3 years. Subjects are aged between 27 and 46 years old. Semen analysis was performed as part of routine diagnostic testing according to WHO 2010.

Participants/materials, setting, methods: All participants answered an anonymous questionnaire about smoking habits, environmental exposure and quantity of exercise per week. Data obtained was used to classify subjects in 4 groups relating quantity of exercise per week (absent, 1 or 2 times per week and more than 2 times per week), smoking or non smoking and exposure or not to harmful environment factors (such as heat sources). Men with different ages are equally distributed for the 4 groups.

Main results and the role of chance: The percentage of men with normal semen parameter rates, is higher when they practice exercise (mostly moderate exercise) and aren't exposed to harmful environment and don't smoke. Also, non-smokers that practice exercise (moderate or rigorous) and are exposed to harmful environment conditions have better sperm parameters than those that don't practice any exercise.

For smokers, either having exposure to harmful environmental conditions or not, the percentage that presents normal rates of sperm parameters is identical and independent of the physical exercise.

Limitations, reasons for caution: Major limitations are the reduced number of individuals in this study, some questions present in the questionnaire lead sometimes to misunderstandings and other variables like weight, days of abstinence and infections that were not taken into account and may influence the sperm parameters.

Wider implications of the findings: The influence of smoking habits, harmful environment exposure and physical activity is well documented, but information lacks relating the three of them.

This study's results suggest that physical exercise is important in having better sperm parameters, although in smokers, exercise appears to have no influence in sperm parameters.

Trial registration number: NA.

P-087 An investigation of the potential effect of sperm nuclear vacuoles in human sperm on DNA fragmentation using a neutral Comet assay

E. Pastuszek[1,2], K. Lukaszuk[1,2], J. Kiewisz[1], P. Skowronska[1,2], J. Liss[1], M. Lukaszuk[1], A. Bruszczynska[1]
[1]*Invicta, Reproduction and Fertility Centre, Gdansk, Poland*
[2]*Medical University of Gdansk, Department of Obstetrics and Gynecological Nursing, Gdansk, Poland*

Study question: Is there a link between presence of sperm vacuoles and DNA fragmentation?

Summary answer: Lower Motile Sperm Organelle Morphology Examination (MSOME) grading correlates consistently with lower sperm DNA fragmentation.

What is known already: Sperm with fragmented DNA may be morphologically normal and therefore still be selected for fertilization following standard sperm analysis. Assessment of spermatozoa under high magnification provides details about the presence and size of the human sperm vacuoles. Their presence has been already shown to correlate with abnormal chromatin condensation. Studies evaluating the association of sperm morphology and DNA fragmentation have found contradictory results. Currently there is no non-invasive test allowing for determination of spermatozoa DNA damage.

Study design, size, duration: Semen samples were collected from ten partners (mean age 33.6 ± 4.20) of women undergoing IVF treatment at INVICTA Fertility Clinic in August 2015. Standard semen parameters were obtained according to the guidelines of the WHO 2010. The semen samples were prepared using the swim-up method. Men had a normal karyotype, no AZF microdeletions, no CFTR gene mutations. Exclusion criteria were history of varicocele, cryptorchidism, presence of sperm infections, anti-sperm antibodies, smoking and obesity.

Participants/materials, setting, methods: MSOME analysis was performed and spermatozoa were graded into four groups (I-IV) according to Vanderzwalmen's criteria, assigning the best quality spermatozoa, without vacuoles to Grade I. A total of 1869 motile spermatozoa were analyzed by the Neutral Comet assay. Comets were categorized into five classes (0–4) assigning the spermatozoa without DNA fragmentation to Class 0.

Main results and the role of chance: Spermatozoa from MSOME Grade I presented the highest number of spermatozoa without nuclear DNA damage, than Grade II, III, IV groups ($p < 0.05$) as determined with the neutral Comet assay (dsDNA damage).

Grade I spermatozoa presented significantly lower DNA decondensation than Grade II, III, IV ($p < 0.05$).

Our results suggest that even MSOME Grade I spermatozoa shows some DNA fragmentation. In that group about 10% of the spermatozoa presented DNA decondensation, but hardly any (<0.2%) had high degree of DNA fragmentation. Additionally, our results suggest that even MSOME Grade IV spermatozoa normozoospermic patients consist of approximately 32% spermatozoa that have non fragmented nuclear DNA.

Limitations, reasons for caution: The study was limited by relatively small number of normozoospermic patients.

Wider implications of the findings: Our study confirmed the association between nuclear vacuoles and chromatin damage. However, the observation of nuclear vacuoles in the sperm without precise DNA fragmentation investigation is not sufficient for optimal sperm selection for ICSI. New sperm selection methods allowing for low/noninvasive determination of DNA fragmentation are still needed.

Trial registration number: Not applicable.

P-088 Conventional sperm analysis: is it telling us the whole story?

I. Vilella Amorós[1], M. Guijarro[2], L. García[2], J. Sarasa[1], M. Enciso[1], M. Fernández[2], J. Aizpurua[2]
[1]*iGLS, Genetic Department, Alicante, Spain*
[2]*IVF Spain, Reproductive Medicine, Alicante, Spain*

Study question: Can a comprehensive assessment of sperm quality including gene expression evaluation of protamines reveal male factor functional defects affecting embryo development and ART outcomes?

Summary answer: Altered gene expression ratio of protamine 1 and 2 in human sperm samples is associated to defective embryo development and reduced blastocyst rate.

What is known already: Male infertility impacts 50% of infertile couples. Conventional semen analyses, while helpful, may fail to identify subtle sperm defects, which could influence ART outcomes. A considerable number of studies have reported the utility of evaluating additional sperm parameters to identify these subtle functionality deficiencies. Recent studies have associated aberrant sperm gene expression protamine ratios (mRNA-P1/P2 ratio) and male infertility. Protamines are sperm-specific nuclear proteins essential for packaging the paternal genome in the sperm nucleus. The normal mRNA P1/P2 ratio has been described as 1:1. Variations in this proportion may have implications in sperm function, fertilization and embryo development.

Study design, size, duration: A total of 30 human sperm samples from couples with suspected male factor and at least one previous failed IVF-cycle seeking ART at our center between December 2014 and December 2015 were included in this retrospective study. Comprehensive semen quality analyses including concentration, motility, morphology, apoptosis, sperm DNA fragmentation (SDF) and mRNA-P1/P2 ratio were performed in all samples after 2 days of abstinence. The impact of semen quality parameters on embryo development was explored.

Participants/materials, setting, methods: Conventional semen parameters (concentration, motility and morphology) were analyzed based on WHO criteria (2010). Apoptotic cell levels were evaluated by flow citometry using annexin V-fluorescein isothiocyanate (FITC)/propidium iodide (PI) assay. SDF was assessed using SCSA methodology and mRNA P1/P2 ratio was evaluated by qRT-PCR (Ferticert® test). The impact of semen parameters on embryo development (fertilization rate, blastocyst rate and good morphological quality blastocyst rate) was explored.

Main results and the role of chance: A significant correlation was found between mRNA-P1/P2 ratio and blastocyst rate (Rho Spearman test, $R = 0.680$, $p < 0.05$). Low mRNA-P1/P2 ratio was associated with reduced blastocyst rate and high mRNA-P1/P2 levels were linked to high blastocyst yield. No other sperm parameter was found to significantly correlate with either fertilization or embryo development rates. Normal P1/P2 ratio is established between 0.92–1.08 values; levels below and above this range are considered to be altered.

Samples with low mRNA-P1/P2 ratio showed a blastocyst rate significantly lower when compared to normal mRNA-P1/P2 ratio samples (46.89 ± 8.15 vs 61.69 ± 2.28, $p = 0.034$). High mRNA-P1/P2 samples showed a blastocyst rate significantly higher than controls (93.94 ± 6.06 versus 61.69 ± 2.28 $p = 0.034$).

mRNA-P1/P2 ratio correlated with the percentage of early apoptotic cells (Rho Spearman test, $R = 0.576$, $p < 0.05$). Samples with low mRNA-P1/P2 levels showed lower apoptotic live sperm levels compared to samples with normal mRNA-P1/P2 ratios (15.35 ± 1.11 vs 28.88 ± 11.69, $p = 0.001$). No differences in any of the other semen quality parameters studied were found between the groups.

These results are highlighting the importance of evaluating mRNA-P1/P2 ratio in male factor suspected cases in order to identify functional deficiencies undetected in a conventional spermiogram.

Limitations, reasons for caution: A higher number of samples would be necessary in order to improve the statistical power. Further data regarding clinical outcomes must be included to confirm the predictive value of the analyzed parameters. Female factor controlled cases (ovodonation cycles) would help confirm the conclusions drawn in the present study.

Wider implications of the findings: Gene expression protamine ratio assessment is a reliable and valuable biomarker that offers extra information about sperm functionality. The implementation of this technique as part of the routine spermiogram performed in IVF-centers could be very useful to identify male factor infertility cases and improve diagnosis and ART-treatment of infertile couples.

Trial registration number: None.

P-089 Men born small for gestational age may be at risk of developing male-factor subfertility

S. Liffner[1], M. Hammar[1], M. Bladh[1], E. Nedstrand[1], H. Rodriguez-Martinez[1], G. Sydsjö[1]
[1]*Linköping University, Ob/gyn, Linköping, Sweden*

Study question: In males accepted for infertility intervention, are non-optimal birth characteristics associated with a higher risk of male-factor infertility in adulthood?

Summary answer: Men needing infertility treatment are often born with non-optimal birth characteristics suggesting that being born SGA may be a risk factor for infertility in males.

What is known already: Being born with low birth weight, prematurely or SGA increases the risk of developing diseases in adulthood, such as those associated with metabolic syndrome. An association between non-optimal birth characteristics and the reproductive ability in adulthood has been demonstrated in some previous studies, whereas other studies have not been able to find an increased risk of infertility. Men conceiving by ICSI are more often born SGA than men becoming fathers by conventional IVF, suggesting that intrauterine growth restriction may be a risk factor of male factor infertility in adulthood.

Study design, size, duration: Retrospective cohort study of a clinical sample of 1,152 men born in Sweden between 1973 and 1986, partners in couples who following clinical evaluation and diagnosis were accepted for infertility

treatment at Centre of Reproductive Medicine, Linköping University Hospital, 2005–2010. Thirty-three men were excluded due to incomplete investigations. Of the remaining men, 1,067 gave their permission to retrieve information from their medical charts and from the Medical Birth Register (MBR).

Participants/materials, setting, methods: Men were categorized according to infertility type diagnosed by the physician conducting the evaluation of the couple (male, female, combined or unexplained infertility). All information regarding birth characteristics – birth weight, gestational age at birth, prematurity and also perinatal diagnoses – was retrieved from MBR and not self-reported. Men were thus allotted to a reference group (optimal birth characteristics) or an exposed group (non-optimal birth characteristics).

Main results and the role of chance: The cause of infertility was female factor in 27.2%, male factor or combined in 42.5% and unexplained in 30.3%. In the male factor group, 4.5% were born SGA compared with 6.8% in the combined group, 4.1% in the female group and 3.3% in the unexplained group. Despite this tendency, no difference was found when calculating relative risk. When combining the groups of male and combined factor, 11.3% of these men were born with any non-optimal birth characteristic, compared with 10.1% of all men. The prevalence of all of the non-optimal birth characteristics was higher in the male factor and combined infertility groups than in the total material but did not reach statistical significance, partially due to low statistical power.

Limitations, reasons for caution: The major limitation of this study is the relatively small sample size leading to a low absolute number of men in each category of infertility type born with non-optimal birth characteristics. The unexplained infertility group may include individuals where the cause is a male-factor but is yet to be determined.

Wider implications of the findings: Men with male or combined factor infertility are more often born with non-optimal birth characteristics. Male factor is diagnosed entirely by semen analysis using WHO criteria but other parameters could differ between men born with and without optimal birth characteristics. Further studies with larger cohorts will be needed.

Trial registration number: Not applicable.

P-090 Sperm source and early embryonic development

J. Kopeika[1], Y.H. Youssef[2], P. Howells[1], M.M. Hosni[1], G. Osma Castellanos[1], J. Grace[1], M. Shabbir[1], V. Bolton[1], Y. Khalaf[1]
[1]*Guy's and St Thomas NHS Trust, Assisted Conception Unit, London, United Kingdom*
[2]*El Galaa teaching hospital, Obstetrics and Gynaecology, Cairo, Egypt*

Study question: Does the source of sperm affect early embryo quality and live birth rate?

Summary answer: Embryo morphology and live birth rate show no differences with respect to sperm source, provided the injected sperm are motile, whether with or without pentoxifylline (PF).

What is known already: There are conflicting data in the literature concerning whether or not the source of sperm (fresh or frozen, ejaculated or surgically retrieved) used in ICSI has an impact on embryo quality and cycle outcome.

Study design, size, duration: This is an observational cohort study of 320 couples undergoing ICSI for severe male factor infertility between 2009 and 2015, of whom 194 had surgical sperm retrieval (SSR) for obstructive and non-obstructive azoospermia, and 126 used ejaculated sperm.

Participants/materials, setting, methods: The following groups of sperm quality were compared: 1) ejaculated motile sperm ($n = 126$); 2) surgically retrieved motile sperm ($n = 83$); 3) surgically retrieved sperm showing motility only after exposure to PF ($n = 76$); 4) surgically retrieved sperm that showed no motility after exposure to PF exposure ($n = 10$). For categorical data, chi-square statistic and for quantitative data, the Student's t tests for unequal variances were used.

Main results and the role of chance: Female age, ovarian reserve, BMI and ovarian response were not significantly different between the groups. There was no significant difference in ICSI fertilisation rate between groups 1 (69%), 2 (61%) and 3 (59%), all of which were significantly higher than group 4 (36%), ($P < 0.01$). Similarly, of the embryos that developed, a higher proportion formed good quality blastocysts when sperm from group 1 (15%), 2 (8%) and 3 (9%) were used, compared to group 4 (0%), ($P < 0.0016$). The live birth rate was 35%, 31%, 29% and 12% for groups 1 to 4th respectively ($P < 0.03$).

Limitations, reasons for caution: This is a cohort study and it is not possible to rule out that more than one variable such as environmental and other female factors could affect the outcome and influence the quality of embryos and live birth rate.

Wider implications of the findings: Contrary to some reports, it appears that the source of sperm has no impact on embryo quality and live birth. Rather it is extremely poor quality sperm that show no motility after PF has a significant impact on embryo quality and live birth rate.

Trial registration number: Not applicable.

P-091 Strict sperm morphology predicts outcome of intrauterine insemination: a prospective observational study

H. Asakura[1], Y. Nakahara[1], M. Nagaike[1], E. Yamazaki[1], K. Nishio[1]
[1]*Ohgimachi ART Ladeis' Clinic, Reproductive Medicine, Osaka, Japan*

Study question: This study was intended to evaluated whether value of Kruger strict sperm morphology (SSM) could predict pregnancy after intrauterine insemination (IUI).

Summary answer: The values of Kruger SSM% independently affected IUI pregnancy rates, and cut-off value of 4.0% was selected as a criterion by ROC analysis.

What is known already: SSM values less than 4% were shown to be the best predictor of decreased fertilization and pregnancy rates after IVF. WHO included SSM of greater than 4% as the lower reference value for normal sperm morphology. The association between SSM and IUI outcome has been investigated previously, but study results are conflicting. There is an ongoing debate regarding relevance of SSM for decision making in undergoing IUI.

Study design, size, duration: The study was conducted in prospective observational manner from 2010 to 2015 with 325 non-donor IUI cycles. IRB consent was obtained from each participant.

Participants/materials, setting, methods: The couples attending non-donor IUI were recruited for the study at a single fertility clinic. IUI was performed after spontaneous LH surge or hCG induced ovulation in natural or clomiphene cycle. IUI was prepared using commercial sperm density gradients. Kruger SSM value was calculated from 200 sperms according to 2010 WHO manual and criteria. MedCalc® version 16 was used for statistical analysis.

Main results and the role of chance: The average ages for husband and wife, IUI orders, pre-wash semen volume, total sperm concentration, motility were (mean ± S.D.): 37.8 ± 5.4 & 36.1 ± 4.1 y.o., 2.2 ± 1.7, 2.8 ± 1.4 ml, 196 ± 246 x million/mL, 48.1 ± 17.2%, respectively. The average Kruger SSM value and injected total motile sperm count were: 4.8 ± 3.0%, 23.1 ± 25.0 x million.

There were 29/319(9.1%) positive urine hCG and 26/307(8.4%) positive clinical pregnancy were observed among known outcomes.

The relationship between SSM values and IUI outcomes is summarized as below:

Kruger SSM value	£2.0%	2.0–4.0%	4.0–6.0%	6.0–8.0%	³8.0%
Cycle numbers	55	86	89	42	53
Clinical pregnancies	1	6	7	5	8
Clinical pregnancy rate	1.8%†	7.0%	7.9%	11.9%	15.1%

†: $p = 0.034$ against SSM ≥8.0%.

ROC curve analysis revealed SSM value with 4.0% was selected significance ($p < 0.05$) as a cut-off both for positive urine hCG (sensitivity 62.1%, specificity 62.1%), and for clinical pregnancy (sensitivity 65.4%, specificity 61.2%).

Using wife and husband ages, injected total motile sperms, and Kruger SSM% as independent variables against presence of clinical pregnancy, stepwise logistic regression analysis selected SSM% as the only significant variable ($p = 0.01$) to predict the IUI outcome.

Limitations, reasons for caution: Non-randomized, non-controlled nature of the study. Heterogenous population with various infertility factors, method of ovulation induction, and treatment order.

Wider implications of the findings: There was a declining trend of IUI pregnancy rates with lower Kruger SSM%. Sperm with SSM% lower than 4.0% had significantly lower chance of pregnancy with IUI, and the criteria can be used to counsel infertility couples to accelerate to ART including intracytoplasmic sperm injection to circumvent fertilization failure.

Trial registration number: Not applicable.

P-092 Pregnancy after vas deferens sterilization: surgical repermeabilization or assisted reproduction?

V. Uvin[1], M. De Brucker[1], V. Veerle[1], H. Tournaye[1]
[1]*UZ Brussel, CRG, Jette, Brussels, Belgium*

Study question: Should we opt for surgical repermeabilization or intracytoplasmic sperm injection (ICSI) after a vasectomy?
Summary answer: Repermeabilisation procedure is a good alternative for patients who opt for a more spontaneous solution. Time to pregnancy is longer than in an immediate ICSI traject.
What is known already: About 7.4% of men regret their vasectomy and express a renewed child wish. The choice between surgical vasectomy reversal or ICSI remains difficult for the patient and it's fertility specialist. It remains important for both to be well informed about reversal results and influencing factors of success. Following factors increase probability of conception: surgeons' experience, vasovasostomy instead of epidymovasostomy and female age under 40 years. Peroperative presence of sperm in the vasal fluid and shorter obstructive interval remains unclear in literature. ICSI: intracytoplasmic sperm injection; IVF: in vitro fertilization.
Study design, size, duration: We included 99 male patients from 2006 until 2011 who did a reanastomosis procedure and 64 female patients who did immediately an ICSI treatment where the partner had a vasectomy in the past, this from 2006 until 2011 aswell.
Participants/materials, setting, methods: During a 5 years' period we selected 163 patients. One group of patients (n=99) underwent a reanastomosis procedure after vasectomy. The other group of included patients had a medical history of vasectomy and started immediately with IVF/ICSI (n=64).
Main results and the role of chance: 163 patients, who had a vasectomy in their medical history and have a renewed child wish, from 2006 until 2011 were included. 99 patients underwent a reversal procedure, 64 patients chose immediately for ART. In the overall reversal group the crude cumulative delivery rate (crude CDR) was 49.5%. In this group 45 tried to get pregnant spontaneously, this is the "primary reanastomosis" pathway where the crude CDR was 40.0%. The other 52 patients, which is called the "switchers" pathway, did a reversal procedure and switched to IVF/ICSI, here the crude CDR was 57.4%. Only a few patients opted for insemination (4 cases), where 2 switched again to IVF/ICSI.

The 64 patients who underwent immediately IVF/ICSI had a crude CDR of 43.8% and an expected CDR of 51.6%. This pathway was called the "primary IVF/ICSI" pathway.

The difference in delivery rate of the primary reanastomosis group (40.0%) versus the primary IVF/ICSI group (43.8%) is not significant.

The repermeabilization is a good alternative for patients who don't want to switch to insemination and IVF/ICSI, but they have to wait longer for delivery of a liveborn. If the patient chooses immediately for ART, data shows a good pregnancy rate and faster pregnancy.

The male mean age at vasectomy was 35.5 years, at reanastomosis 44.4 years. The mean obstructive interval was 9.5 years, with maximum 27 years and minimum 1 year. 90% had already children, an average of 2 children, the majority of a previous relation.
Limitations, reasons for caution: The study population is rather small (n= 163).
Study funding/competing interest(s): No conflict of interest are declared. No funding was used for this study.
Wider implications of the findings: Better counseling possibilities for couples with a vasectomy in history. It can help physicians and patients to make an optimal decision in case of a renewed childwish in these patients. If time to pregnancy is important, we suggest to chose immediately for IVF/ICSI treatment.
Trial registration number: Not necessary for this type of study.

P-093 Human papilloma virus sperm infection and its correlation with *in vitro* fertilization

N. Grieco[1], A. Maffei[2], M.A. Di Filippo[2], G. D'aniello[2], S. Ronsini[2]
[1]*Hospital S. Luca, Department of Obstetrics, Gynecology and Physiopathology of Human Reproduction, Vallo della Lucania SA, Italy*

Study question: To evaluate the reproductive outcome of infertile couple undergoing assisted reproduction technique with or without HPV (Human Papilloma Virus) semen infection.
Summary answer: We found a correlation between the presence of HPV at sperm level and the reduction in assisted pregnancy rate.
What is known already: HPV infection is one of the most common sexually transmitted disease. It has been detected in multiple anatomic sites, including the cervix, anus, penis, and some areas of unprotected genital skin, such as vulva and scrotum.

In males, HPV DNA has been found in external genitalia, in urethra, in the deferent ducts, epididymis and testis, and seminal fluid too.

Some authors report a reduction of pregnancy in *in vitro* fertilization in presence of HPV cervical infection compared with no infection, as reported by some authors, but very few works associates human HPV sperm infection to *in vitro* fertilization results.
Study design, size, duration: A total of 156 men were enrolled between January and December 2015. Their semen were tested for the presence of HPV in semen.

82 of them underwent to *in vitro* fertilization and they were included in our retrospective study. Couples were divided into two groups based on the presence or absence of HPV semen infection. The presence of HPV was related to clinical pregnancy rate.
Participants/materials, setting, methods: Study was conducted in the Department of Obstetrics, Gynecology and Physiopathology of Human Reproduction, Hospital S. Luca, Vallo della Lucania, SA, Italy. No patient enrolled resulted positive for HIV, HCV, HBV and treponema pallidum. No patient showed azoospermia, leukospermia, anti sperm antibodies and varicocele.

Women showed normal BMI and idiopathic infertility.

Sperm parameters were evaluated according to the World Health Organization manual, and the presence of HPV DNA researched by the use of HPV assay and a highly sensitive nested polymerase chain reaction assay.
Main results and the role of chance: 23 of the total semen samples were HPV positive.

Median value of sperm concentration was 40.55 millions/ml and 49.44 millions/ml in HPV negative and HPV positive group, respectively ($P > 0.05$).

HPV non infected and HPV infected semen samples had similar morphology (medians 6.39% vs 5.69%; $P > 0.05$), but different progressive motility (median 17.54% vs 7.69%; $P < 0.05$).

We evaluated the amount of DNA fragmented sperm and found an a similar dfi (DNA fragmented index) in the two groups (30.75% vs 27.99%; $P > 0.05$).

15 out of 64 couples without HPV semen infection had successful I C S I (23.4%), and 2 out of 18 couple (11.1%) in the infected group had successful ICSI ($P < 0.05$)
Limitations, reasons for caution: Differences between data were determined by two-tail to student's test after acceptance of normal distribution with the Kolmogorov-Smivov test.

P value (two sided) of less than 0.05 were considered to statistically significant. Our results are supported by a concise study design but with a small sample size.
Wider implications of the findings: In literature there are few studies that demonstrates a correlation between HPV sperm infection and reduction of pregnancy rate. If our results are confirmed they could change the clinical approach to HPV infected couples.
Trial registration number: None.

P-094 Association of serum vitamin D with sex hormones and semen quality

A. Kouhkan[1], S. Abbasihormozi[1], A. Alizadeh[1], A. Shahverdi[1], A. Matinibehzad[1], M. Saddighigilani[2], R. Salmanyazdi[2], Z. Zolfaghari[1]
[1]*Department of Embryology, Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR - Tehran - Iran, Embryology, Tehran, Iran*
[2]*Department of Andrology, Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR - Tehran - Iran, Andrology, Tehran, Iran*

Study question: The objective of this study was to investigate the association between serum 25(OH) vitamin D with semen quality and hormones in Iranian subfertile men.
Summary answer: High incidence of 25(OH) D deficiency and insufficiency were observed in our participants. It looks that it is correlated to sperm motility in AOT men.

What is known already: Vitamin D deficiency is one of the most common health problem in worldwide and Iran. Previous studies have shown that vitamin D is involved various adverse events including hypertension, cardiovascular disease, stroke, diabetes and cancer.

The issue of whether vitamin D levels are effective factor for male reproductive biology is suspected and conflict data exists on the potential association between serum vitamin D and semen quality and sex hormones.

Study design, size, duration: This cross - sectional study, during March-September 2014, was conducted on 278 men (ranged 20–50 yr. old) referring to Royan infertility clinic (Tehran, Iran), consisted of 186 normospermic and 92 AOT (Astheno-, Oligo- and Terato spermic) groups according to WHO criteria. Blood and semen samples were obtained for assessment of sex hormones, 25-hydroxyvitamin D, parathyroid hormone, calcium and semen parameters. Vitamin D levels were classified as deficiency (≤20ng/ml), insufficiency (21–29ng/ml) and normal (≥30ng/ml).

Participants/materials, setting, methods: Semen analysis was examined after 2–5 days of sexual abstinence based on WHO-recommended methods by CASA system (computer-assisted sperm analysis) measurement of serum 25-hydroxyvitamin D, Parathyroid hormone (PTH) and Calcium and sex hormones were done by ELIZA.

Main results and the role of chance: Vitamin D deficiency, insufficiency and normal levels were observed in 58.6%, 29.5% and 11.9% of participants respectively. Serum 25 (OH) vitamin D was inversely correlated with PTH ($P < 0.045$). In normospermic men, serum 25 (OH) D levels and categorized were not correlated with semen parameters and reproductive hormones. But sperm motility showed a positive correlation with 25 (OH) D categorized in AOT men ($r = 0.131$, $p = 0.028$).

Limitations, reasons for caution: No limitation.

Wider implications of the findings: Last cross-sectional studies have found the association of serum 25(OH) D levels and semen parameters in young healthy men, but the results were quite discordant.

Trial registration number: No.

P-095 Next generation sequencing reveals a novel mutation in the XY-linker region of phospholipase C zeta (PLCζ), resulting in truncated protein and oocyte activation deficiency

S.N. Amdani[1], C. Jones[1], K. Späth[1], D. Babariya[1], T. Malinauskas[2], L. Gemmell[3], M. Ferrer-Buitrago[4], B. Heindryckx[4], D. Wells[1], P. De Sutter[4], K. Coward[1]

[1]Oxford University, Nuffield Department of Obstetrics and Gynaecology, Oxford, United Kingdom

[2]Oxford University, Division of Structural Biology, Wellcome Trust Centre for Human Genetics, Oxford, United Kingdom

[3]Case Western Reserve University, School of Medicine, Cleveland, OH, USA

[4]University Hospital Ghent, Department for Reproductive Medicine, Ghent, Belgium

Study question: Is the novel mutation located in the XY-linker region of PLCζ the possible cause of repeated low fertilization rates or total fertilization failure (TFF) in a patient?

Summary answer: The novel mutation in PLCζ at position 322 of the amino acid sequence results in a significantly truncated and non-functional form of PLCζ.

What is known already: PLCζ is a sperm-specific protein responsible for oocyte activation, and abnormalities in the expression, structure and localization of PLCζ have been causally linked to oocyte activation deficiency (OAD) and male factor infertility. While the precise etiology of OAD remains inconclusive, three rare genetic anomalies have already been described for PLCζ in patients experiencing OAD (His398Pro, His233Leu and Ile489Phe).

Study design, size, duration: A case study of a male patient who experienced repeated low fertilization outcome or TFF throughout a series of four failed intracytoplasmic sperm injection (ICSI) cycles, and to evaluate the potential role played by PLCζ deficiency.

Participants/materials, setting, methods: The patient's sperm sample was first subjected to the mouse oocyte activation test (MOAT) and then analyzed by exome sequencing. A predicted three-dimensional model of the mutant PLCζ was designed using Modeller and PyMOL. The ability of the mutation to induce calcium oscillations was evaluated by injecting mutant PLCζ cRNA into mouse oocytes, and comparing the resultant calcium release profile to that induced by control wild type PLCζ cRNA.

Main results and the role of chance: Five out of 26 mouse oocytes (19%) were activated following MOAT, thus categorizing our patient as a low MOAT subject in which a sperm-related deficiency was the most likely cause of infertility. Exome sequencing revealed a change of amino acid from a Lysine (K) to a stop codon at position 322 (K322STOP). The location of mutation is at the region of the PLCζ gene which encodes the XY-linker. Next generation sequencing (NGS) subsequently confirmed the presence of the mutation in both buccal and sperm samples from the patient. NGS also identified the presence of a mixed population of normal (53%) and mutant (47%) sperm in the patient's semen. A predicted three-dimensional model of PLCζ K322STOP revealed a severely compromised protein, in which 286 amino acids (47%) were missing in contrast to wild type PLCζ. The absence of amino acids resulted in the lacking of several critical catalytic residues and the entire Y and C2 functional domains. Four out of six mouse oocytes injected with wild type PLCζ cRNA successfully induced calcium oscillations in a form which were characteristic of normal fertilization, whereas injections of PLCζ K322STOP cRNA failed to cause calcium release (0/7 mouse oocytes).

Limitations, reasons for caution: Since the three-dimensional structure of wild type PLCζ has not yet been determined, our present model of PLCζ structure was created by reference to the structures of other PLCs. Consequently, it is only possible to speculate upon the potential effect of PLCζ K322STOP on PLCζ structure and function.

Wider implications of the findings: Our data describes the most deleterious PLCζ mutation discovered thus far, which results in a translated protein that is truncated by 47% of the wild type protein and therefore is incapable of causing calcium release when injected into mouse oocytes.

Trial registration number: NA.

POSTER VIEWING SESSION

EARLY PREGNANCY

P-096 Genotyping analysis of protein S-Tokushima and the involvement of protein S antigen and activity in patients with recurrent pregnancy loss

Y. Matsukawa[1], E. Asano[2], T. Tsuda[3], H. Kuma[4], T. Kitaori[1], K. Katano[1], Y. Ozaki[1], M. Sugiura-Ogasawara[1]

[1]Nagoya City University, Obstetrics and Gynecology, Nagoya, Japan

[2]Ichinomiya Municipal Hospital, Obstetrics and Gynecology, Ichinomiya, Japan

[3]Shino-Test Corporation, Research and Development, Kanagawa, Japan

[4]Nagasaki International University, Pharmaceutical, Nagasaki, Japan

Study question: To determine whether a protein S (PS) deficiency and PS-Tokushima can influence a subsequent pregnancy outcome in patients with recurrent pregnancy loss (RPL).

Summary answer: There was no association between PS-Tokushima and RPL, and a PS deficiency or low PS activity was not a reliable clinical predictor of subsequent miscarriage.

What is known already: A meta-analysis revealed that PS deficiency is associated with recurrent fetal loss and late non-recurrent fetal loss but not with recurrent early miscarriage.

The PS-Tokushima missense mutation was reported to serve as a genetic risk factor for DVT in the Japanese population. A previous cross-sectional study showed no increase in the prevalence of PS-Tokushima in patients with recurrent early pregnancy loss or in patients with IUFD and/or fetal growth restriction. There has been limited number of prospective studies examining the pregnancy outcome in patients with both a PS deficiency and recurrent RPL.

Study design, size, duration: The frequencies of PS-Tokushima were compared between 355 patients and 101 controls. The total PS antigen, activity, and specific activity were compared between the 210 patients and 101 controls since only 210 patients were available to provide plasma samples.

All patients were seen between September 2008 and July 2014, and subsequent pregnancies of all patients were followed up until December 14, 2014.

Participants/materials, setting, methods: The study group consisted of 355 Japanese women with two or more consecutive pregnancy losses. Control subjects consisted of 101 women with at least one child and no history of infertility or miscarriage.

To confirm the genotype, purified templates were sequenced with a BigDye Terminator v3.1 Cycle Sequencing kit. The PS antigen, activity, and specific activity (total PS activity/total PS antigen) were determined with a total PS-assay system.

Main results and the role of chance: Nine of 355 (2.5%) patients and one of the 101 (1.0%) controls were positive for PS-Tokushima. There was no significant difference in the prevalence of the mutation.

There were no differences in levels of PS antigen, PS activity and PS-specific activity between patients and controls.

All 8 patients with PS Tokushima gave live birth without heparin and two patients had live births with aspirin alone. One patient with PS Tokushima and a history of IUFD miscarried again in spite of heparin use. There was no significant difference in subsequent live birth rates between patients with low or normal PS-specific activity/PS activity without heparin prophylaxis after excluding miscarriages caused by an abnormal embryonic karyotype using multivariate logistic regression analysis (OR, 1.84; 95% CI, 0.59-5.75/OR, 3.40; 95% CI, 0.96–12.07).

Limitations, reasons for caution: We were able to measure total PS antigen and activity in only 210 patients because of the lack of plasma samples. Another limitation was that we examined only 20 patients with IUFD.

Wider implications of the findings: The PS Tokushima mutation and low PS activity were not risk factors for early RPL. Therefore, we propose that testing for PS antigen and/or activity is not needed, as it is without clinical benefit and constitutes an unnecessary expense.

Trial registration number: N/A.

P-097 Efficacy of intrauterine injection of granulocyte colony stimulating factor (G-CSF) on treatment of unexplained recurrent miscarriage

S. Zafardoust[1], M.M. Akhondi[2], M.R. Sadeghi[2], A. Mohammadzadeh[2], A. Karimi[2], S. Jouhari[2], S. Ansaripour[2]
[1]*Avicenna Infertility, Tehran, Iran*
[2]*Avicenna Infertility, Avicenna research institute, Tehran, Iran*

Study question: Does G-CSF improve pregnancy outcomes in patients with recurrent miscarriage?

Summary answer: we couldn't suggest intrauterine injection of G-CSF for improvement of clinical pregnancy rate and reduce of abortion among patients with unexplained RM.

What is known already: GCS-F (Granulocyte Colony-stimulating Factor) is an important cytokine with critical role in embryo implantation and pregnancy. The previous studies showed that that transvaginal endometrial perfusion with G-CSF might be helpful for improvement of implantation rate among patients with thin endometrium and repeated implantation failure (RIF).

Study design, size, duration: In present randomized clinical trial, during a 12-month period, a total of 68 patients were randomly allocated into two study groups including intrauterine G-CSF (300µg, Filgrastim, Switzerland) injection and control group (no G-CSF injection). All patients were in I/O (Ovulation Induction) cycle. In G-CSF group, intrauterine injection of G-CSF was done twice in cycle. All enrolled patients were under 40 years old and had at least two times unexplained pregnancy loss.

Participants/materials, setting, methods: Pregnancy was evaluated by titer of βhCG, presence of gestational sac (implantation) was assessed by vaginal ultrasonography and finally clinical pregnancy was confirmed by detection of fetal heart rate (FHR).

Main results and the role of chance: Eighteen out of 68 patients were excluded from the final analysis due to different reasons. No significant difference were observed between two study groups when we compared the rate of chemical pregnancy (26.1% vs. 29.6%, $P = 1.000$), implantation (26.1% vs. 22.2%, Fisher's exact test $P = 0.673$), clinical pregnancy (17.4% vs. 11.1%, Fisher's exact test P: 0.657) and abortion (8.7% vs. 18.5% Fisher's exact test $P = 0.921$).

Limitations, reasons for caution: In previous studies, intrauterine injection of G-CSF was not evaluated in recurrent miscarriage patients. So we can not compare our results with them.

Wider implications of the findings: In previous studies, intrauterine injection of G-CSF was not evaluated in recurrent miscarriage patients. So we can not compare our results with them.

Trial registration number: IRCT2013012211430N3.

P-098 TSHR as a new susceptibility locus: The first genome-wide association study for obstetric antiphospholipid syndrome

M. Sugiura-Ogasawara[1], Y. Omae[2], M. Kawashima[2], L. Toyo-oka[2], H. Sawai[2], T. Horita[3], T. Atsumi[3], D. Fujita[4], A. Murashima[5], S. Morimoto[6], T. Kitaori[1], K. Katano[1], Y. Ozaki[1], K. Tokunaga[2]
[1]*Nagoya City University, Department of OB/GYN, Nagoya, Japan*
[2]*Graduate School of Medicine- The University of Tokyo, Human Genetics, Tokyo, Japan*
[3]*Hokkaido University Graduate School of Medicine, Rheumatology-Endocrinology and Nephrology, Sapporo, Japan*
[4]*Osaka Medical College, Obstetrics and Gynecology, Takatsuki, Japan*
[5]*National Center for Child Health and Development, Maternal-Fetal-Neonatal and Reproductive Medicine, Tokyo, Japan*
[6]*Juntendo University Urayasu Hospital, Internal Medicine and Rheumatology, Urayasu, Japan*

Study question: Is genetic susceptibility associated with obstetric antiphospholipid syndrome (APS)?

Summary answer: Our findings demonstrate that a *TSHR* risk allele-homozygous genotype and an *HLA-DQB1*05:01* allele-negative genotype can indicate a susceptiblity for obstetric APS in the Japanese population.

What is known already: APS is the most important treatable cause of recurrent pregnancy loss (RPL). However, the live birth rate is only about 70–80% with the current treatment. Recent genome-wide association studies (GWAS) of systemic lupus erythematosus (SLE) have shown that a number of molecules may be involved in the pathophysiology of B cell/T cell responses and the NF-kB signaling pathway. Since APS is a lupus-related disease, genetic susceptibility has been speculated to be associated with obstetric APS. This is the first GWAS for obstetric APS focusing on RPL.

Study design, size, duration: A GWAS was performed to compare 115 Japanese patients with obstetric APS diagnosed according to criteria of the International Congress on APS and 419 healthy individuals. Samples were collected between November 2009 and March 2014.

Participants/materials, setting, methods: Among the 155 patients recruited in this study, we decided to include 115 patients with strongly positive for lupus anticoagulant. 600,307 SNPs were genotyped and allele or genotype frequencies were compared. Imputation analyses were also performed for the candidate regions detected by the GWAS.

Main results and the role of chance: One SNP (rs2288493) located on the 3'-UTR of *TSHR* showed a significant APS association ($P = 7.85E-08$, OR = 6.18) under a recessive model even after applying a Bonferroni correction by the number of analyzed SNPs. A total of 56 SNPs from 11 distinct genomic regions, *TSHR*, *NGF*, *C1D*, *CDH18*, *SYCP2L*, *HLA-DRA*, *HCRTR2*, *GATA3*, *FRMD4A*, *PTPRO* and *MRPS23,* showed evidence suggestive of an association ($P < 5E-06$). In addition, analysis of *HLA* alleles revealed that the *HLA-DQB1*05:01* allele was protective with a significant association ($P = 0.0037$, OR = 0.28).

Limitations, reasons for caution: Sample size is relatively small. Further study will help to confirm the biological significance of the genes implicated in APS, and will ultimately result in specific treatment to improve the pregnancy outcome of the affected patients.

Wider implications of the findings: In the present study, not only *TSHR* but also other genes suggestive of APS have supplied us with clues to account for the unexplained mechanisms in early miscarriage, fetal loss, preeclampsia and many features of this disease.

Trial registration number: N/A.

P-099 Local injection of diluent vasopressin followed by suction curettage as initial treatment of cervical ectopic pregnancy

H. Ishikawa[1], R. Shinno[2], A. Omoto[1], Y. Unno[2], H. Usui[1], M. Shozu[1]
[1]*Chiba University- Graduate School Medicine, Reproductive Medicine, Chiba-city- Chiba, Japan*
[2]*Matsudo City Hospital, Obstetrics and Gynecology, Matsudo, Japan*

Study question: Is injection of diluent vasopressin to the uterine cervix and myometrium followed by suction curettage safe and effective as treatment of cervical ectopic pregnancy?
Summary answer: The procedure is a safe and effective because it is easy to perform, is not associated with any critical complications, and possibly minimizes blood loss.
What is known already: Conservative treatment options for cervical pregnancy are local and general administrations of methotrexate, dilatation and curettage with or without local injection of potassium chloride or methotrexate, uterine artery embolization, and their combination. However, uncontrolled massive bleeding during the procedures requires hysterectomy. Local injection of diluent vasopressin to the myometrium surrounding the uterine fibroids is a well-established technique for reducing blood loss during myomectomy and hysterectomy. Vasopressin has not only a vasoconstrictive effect but also a smooth muscle contractive activity.
Study design, size, duration: This is a retrospective review of 13 consecutive first-trimester cervical pregnancies from 2007 to 2015. We conducted a chart review of data on total blood loss, side effects during the procedure, and duration until conversion of serum human chorionic gonadotropin (hCG) assay results to negative.
Participants/materials, setting, methods: We injected diluent vasopressin 10 to 100 times to the cervix surrounding a gestational sac and/or myometrium of the lower segment under transvaginal ultrasonographic guidance in women who were affected with cervical pregnancy. For cases where the fetal heart beat remained active after the injection, we injected additional vasopressin into the gestational sac. After confirming that the fetal heartbeat had stopped, we aspirated the chorionic villi, including the gestational sac, at 60 mm Hg.
Main results and the role of chance: The mean age and serum hCG level of the patients before the procedure were 31.4 ± 7.2 years and 16,929 ± 20,869 mIU/mL, respectively. The mean duration between the procedure and the conversion of serum hCG assay results to negative was 57.4 ± 22.2 days. We observed spontaneous evacuation of the villi containing a gestational sac to the external os after the vasopressin injection in 4 of the 13 patients. The procedural duration was shorter than 15 minutes, and the whole blood loss volume during the procedure was less than 100 mL in all the cases. The vasopressin injection and subsequent suction curettage had no adverse effects during the procedure. Additional methotrexate administration was needed in one patient because of persistent trophoblastic disease after the curettage. None of the patients required blood transfusion and additional uterine artery embolization or hysterectomy.
Limitations, reasons for caution: This observational study conducted a retrospective chart review and included a relatively small sample size.
Wider implications of the findings: Local injection of diluent vasopressin followed by suction curettage is a dominant treatment option for cervical pregnancy in patients who wish to preserve future fecundity. Spontaneous evacuation of the gestational sac is also expected, with minimal blood loss.
Trial registration number: Not applicable.

P-100 The association between first trimester uterine artery Doppler velocimetry indices and adverse perinatal outcomes in IVF cycles

H. Timur[1], N. Yilmaz[2], M. Cinar[2], H.A. Inal[3], N. Hancerliogullari[2], M. Alkan[4], M. Kaba[5], D. Uygur[6]
[1]Zekai Tahir Burak Women's Health and Education Hospital, Perinatology, Ankara, Turkey
[2]Zekai Tahir Burak Women's Health and Education Hospital, Reproductive Endocrinology, Ankara, Turkey
[3]Konya Education and Research Hospital, Reproductive Endocrinology, Konya, Turkey
[4]Zekai Tahir Burak Women's Health and Education Hospital, Radiology, Ankara, Turkey
[5]Akdeniz University, Perinatology Unit, Antalya, Turkey
[6]Zekai Tahir Burak Women's Health and Education Hospital, Perinatology Unit, Ankara, Turkey

Study question: This study aimed at evaluating if first trimester uterine artery doppler velocimetry values may predict adverse perinatal outcomes in patients with IVF
Summary answer: The first trimester uterine artery doppler velocimetry indices including RI and S/D values are good parameters to predict adverse perinatal outcomes in IVF pregnancies
What is known already: Pregnancies following assisted reproductive techniques (ART) are at increased risk of maternal and perinatal complications. The fetal well being is generally evaluated by the biophysical profile (BPP) and the non-stress test (NST) and doppler velocimetry evaluation. Doppler velocimetry studies may evaluate the status of the pregnant women by indirectly examining uteroplacental perfusion adequacy with uterine artery doppler velocimetry indices. Previous studies reported that doppler studies in the first trimester of pregnancy may predict the adverse perinatal outcomes in spontaneous pregnancies.
Study design, size, duration: This prospective cross sectional study was designed at Department of Reproductive Endocrinology from May 2013 to June 2014. A total of sixty two infertile women who underwent IVF procedure and became singleton pregnancy (group 1 = study) and a fifty three healthy women were selected randomly among the pregnant women who attended to routine antenatal follow-up program (group 2 = control) were included to the study.
Participants/materials, setting, methods: After a routine fetal scan the cases had transvaginal doppler velocimetry from bilateral uterine arteries. The doppler velocimetry measured were; right and left side uterine artery (RUA/LUA) systole-diastole ratio (SD), pulsatility index (PI) and resistance index (RI). Adverse perinatal outcomes (delivery type, preterm birth (delivery occurred at gestational ages between 22 and 36 weeks), low birth weight, low APGAR score and neonatal intensive care unit (NICU) requirement recorded and compared with the doppler velocimetry.
Main results and the role of chance: There were no statically significantly difference between groups in terms of; BMI, week of doppler measurement, LUAPI and RUAPI levels ($p > 0.05$). Gestational age at birth, first minute APGAR scores, NICU requirement ratios, birth weight, preterm birth ratios, abortion ratios, delivery type, LUASD, LUARI, RUASD, RUARI levels were statically significant difference between groups ($p < 0.05$). According to the ROC curve analysis LUASD, RUASD and RUARI were predictive for preterm birth and low birth weight and LUARI for NICU. Correlation analysis showed that there was a positive correlation between LUASD, LUARI, RUASD, RUARI levels and preterm birth ratios, NICU requirement ratios in the study group. And also, birth weight showed a negative correlation in terms of LUASD, LUARI, RUASD and RUARI levels in the study group. Caesarean deliveries were higher in the study group. The incidence of preterm birth was significantly higher in IVF pregnancies ($p < 0.05$).
Limitations, reasons for caution: The limitation of this study is small sample size. However, this sample size was sufficient to show statistically significant differences in uterine artery doppler velocimetry parameters between the groups. No other sonographic factors such as uterine artery doppler velocimetry, biophysic profile, etc. was performed to evaluate fetal well being before delivery.
Wider implications of the findings: The first trimester uterine artery doppler velocimetry indices including RI, S/D and PI values are good parameters to predict adverse perinatal outcomes. For this, IVF pregnancies with bad uterine artery doppler result in the first trimester should be examined closely to predict adverse perinatal outcomes.
Trial registration number: None.

P-101 Area under the curve of estradiol monitorisation: a novel approach to evaluate detrimental effect of estrogen exposure on implantation along the COH

T. Kutlu[1], E. Ozkaya[2], H. Ayvaci[3], B. Devranoglu[1], I. Sanverdi[1], Y. Sahin[1], T. Senol[1], A. Karateke[1]
[1]Zeynep Kamil Kadin ve Çocuk Hastaliklari Hastanesi, Uskudar, Istanbul, Turkey
[2]Zeynep Kamil Kadin ve Çocuk Hastaliklari Hastanesi, Obstetrics and Gynecology, Uskudar, Istanbul, Turkey
[3]Turkey

Study question: To assess the utility of area under the curve of estradiol monitorisation during ART cycles to predict failure of implantation and clinical pregnancy.

Summary answer: Calculation of the area under the estradiol monitorisation curve during ART cycles may be used to predict failure of implantation and clinical pregnancy.
What is known already: Low levels of exogenous estradiol maintained the responsive endometrium for a long period of time, however high doses of estradiol lead to development of refractory endometrium. Estradiol in a narrow range is a key factor for the duration of the window of implantation in uterine receptivity in mice. There is a possibility of receptivity window manipulation by different doses of estradiol.
Study design, size, duration: Prospective data analyses to assess the Area under the curve of estradiol monitorisation (AUCEM) during ART cycles and compare between the age and BMI matched groups of infertile women with (n = 109) and without (n = 173) successful embryo implantation.
Participants/materials, setting, methods: After approval of the Hospital Ethics Committee and consents from all participants, study was conducted from January 2014 to December 2014 in the IVF/ICSI unit of Zeynep Kamil Women and Children's health Training and Research hospital. A total of 282 women who underwent ART were prospectively screened and AUCEM was calculated for each participant. Patients were divided into two groups with (n = 109) and without (n = 173) successful implantation.
Main results and the role of chance: Comparison of groups with and without positive clinical implantation showed a significant difference between the groups in terms of area under the curve of estradiol monitorisation, estradiol per day and the endometrial thickness at trigger day (P = 0.05). Additionally, comparison of groups with and without positive clinical pregnancy showed a significant difference between the groups in terms of area under the curve of estradiol monitorisation, estradiol per day and the endometrial thickness at trigger day (P = 0.05).
Limitations, reasons for caution: A larger sample size is required to generalize the results. Our study lack the comparison between the previously reported tools like endometrial receptivity array and the AUCEM and we have no data with regard to predictive value of AUCEM for live births.
Wider implications of the findings: According to our results it may be considered to postpone embryo transfer in cases with high AUCEM and prefer freezing all embryos.
Trial registration number: Trial registration was not needed.

P-102 Optimism in live birth rates of unicornuate uterus patients

K. Ozgur[1], H. Bulut[1], M. Berkkanoglu[1], K. Coetzee[1]
[1]*Antalya IVF, Antalya, Turkey*

Study question: To analyse the effect of a unicornuate uterus anomaly on the reproductive outcomes of IVF treatment.
Summary answer: Pregnancies in patients with unicornuate uteruses are high-risk pregnancies with poor perinatal and obstetric outcomes that require intensive obstetric observation and care, and mandatory SET.
What is known already: Unicornuate uterus is a relatively uncommon congenital uterine anomaly, classified as a type II anomaly, with a predicted incidence of 1:4000 in the general population. This anomaly has been reported to have poor reproductive outcomes from spontaneous pregnancies, i.e., increased extra-uterine implantation, placental complications, first and second trimester miscarriage, fetal mal-presentation, intrauterine growth retardation, intrauterine fetal demise, and preterm birth.
Study design, size, duration: In this retrospective observational study, the files of patients who presented for first consultations at one single ART center, during the period from January 2012 to December 2015, were screened for the diagnosis of unicornuate uterus. The identified files were analysed in respect of medical/fertility history, diagnostics, and the reproductive outcomes of ART treatments received.
Participants/materials, setting, methods: During the study period, 5704 first consultations were performed and 48 diagnoses (0.84%) of unicornuate uterus were confirmed.
Main results and the role of chance: The mean age of the diagnosed patients was 31.0 years, with a mean antral follicle count of 20.3. Of the 48 patients diagnosed, 37 underwent ART treatment, including fresh (n = 21) and frozen ET (n = 39). The overall pregnancy and clinical pregnancy rates were, 62.0% and 50.0% respectively. The clinical pregnancies included one (3.2%) ectopic pregnancy. Twenty pregnancies have progressed beyond week 14 of gestation, and of these 15 have delivered. The 15 live births were delivered at a mean gestational age of 36.5 weeks and birthweight of 271.7 g, with 66.7% premature and 26.7% low birth weight (LBW).
Limitations, reasons for caution: Although the study includes a large number of ART treatments for a low incidence intrauterine anomaly such as unicornuate uterus, the study is retrospective and has inherent limitations and biases.
Wider implications of the findings: The study highlights the high pregnancy loss and premature delivery rate associated with unicornuate uteruses and, therefore, the mandatory need for SET, but also that more than 60% of clinical pregnancies result in a live delivery.
Trial registration number: N/A.

P-103 HLA-E was involved in the effect of progesterone on the ADAM19 expression in JEG-3 cells

H. Zhongying[1], Q. Ma[1], W. Fan[1], S. Li[1]
[1]*West China Second University Hospital Sichuan University, Department of Obstetrics and Gynecology, Chengdu, China*

Study question: To investigate if HLA-E, one of the MHC-Ib molecules expressed in trophoblast cells plays a role in the regulation of ADAM19 by progesterone.
Summary answer: The silence of HLA-E expression decreased the expression level of ADAM19 and diminished the up-regulatory effect of progesterone on ADAM19 in trophoblast cell line JEG-3.
What is known already: ADAM19 is highly expressed in human placentas and suggested to be involved in the key processes of trophoblast invasion and degradation of extracellular matrix during early pregnancy, but the regulation of ADAM19 in trophoblasts has been poorly understood. HLA-E, one of the MHC-Ib molecules, contributed to the establishment of an immune tolerance at maternal-fetal interface during pregnancy. In our previous study, both ADAM19 and HLA-E were up-regulated following progesterone treatment in trophoblast cell line JEG3. We performed this study to determine if HLA-E plays a role in the regulation of invasive-related gene ADAM19 in trophoblast cells.
Study design, size, duration: This control study was carried out over a one year period. The JEG-3 cells were divided into 5 groups: the blank control (group 1), progesterone treatment (group 2), transfection of lentivirus carrying siRNA targeting HLA-E before progesterone treatment (group 3), transfection of lentivirus carrying siRNA targeting HLA-E (group 4) and transfection of the negative control siRNA (group 5). Independent experiments were repeated three times with triplicates for each treatment.
Participants/materials, setting, methods: The JEG-3 cells were obtained from The JEG-3 cells (Cell Resource Center, IBMS, CAMS/PUMC). The expression silence of HLA-E in JEG-3 cells was induced through transfection with the lentivirus carrying siRNA targeting HLA-E to examine its effect on the expression of ADAM19. In 5 groups cells were collected 48 h after different treatments. The mRNA and protein levels of ADAM19 in JEG-3 cells were detected by real-time quantitative PCR and Western blot assay, respectively.
Main results and the role of chance: In this study, the expression level of ADAM19 mRNA in JEG-3 was up-regulated following treatment of progesterone (group 2) while down-regulated after transfected with lentivirus carrying siRNA targeting HLA-E (group 4), both with significant difference compared to the control groups. In group 3, the HLA-E in JEG-3 was silenced by transfection of siRNA targeting HLA-E before progesterone treatment. Data showed that there was no significant difference in ADAM 19 mRNA expression level compared with the controls, indicating that the up-regulatory effect of progesterone on ADAM19 mRNA expression in JEG-3 was abolished by HLA-E silence. The protein levels detected in group 2, 3 and 4 showed similar changing tendency as observed in mRNA levels, when compared with the controls.
Limitations, reasons for caution: JEG-3 cell line, a common extravillous trophoblast cell (EVT) model, was used in this study to investigate the regulation of ADAM19. Further studies are necessary to determine if HLA-E has the same effect on ADAM19 expression in trophoblast cells from early gestational placenta.

Wider implications of the findings: HLA-E, although not fully understood, contributes to the maintenance of pregnancy. We found in this study that HLA-E was involved in the regulation of ADAM19 in EVT model JEG-3, which may provide a new clue to investigate the regulation of invasive ability of trophoblasts at maternal-fetal interface.
Trial registration number: None.

P-104 Expression of hypoxia inducible factor and vascularization status was altered in peri-implantation endometrium of women with recurrent miscarriage

Y. Liu[1], X. Chen[1], L. Jiang[2], C.C. Wang[1], J. Huang[1], T.C. Li[1]
[1]*The Chinese University of Hong Kong, Department of Obstetrics and Gynaecology, Shatin, New Territories, Hong Kong*
[2]*Shenzhen People's Hospital, The Second Affiliated Hospital of Jinan University, Department of Obstetrics and Gynaecology, Shenzhen, China*

Study question: To compare the expression of hypoxia inducible factor 1α (HIF1α) and micro blood vessels in peri-implantation endometrium of women with recurrent miscarriage and fertile controls.
Summary answer: The aberrant expressions of HIF1α and blood vessels in peri-implantation endometrium suggested altered hypoxia and vascularization status may account for endometrial contribution to recurrent miscarriage.
What is known already: In the unexplained recurrent miscarriage cases, embryo aneuploidy occurred in just less than 50% cases, indicating that subtle endometrial factors may account for the remaining cases. The vascularization and oxygen status of endometrium plays an important role in the success of pregnancy and it is now well accepted that HIF1α is the main mediator of the regulation of oxygen homeostasis and many other cellular processes in normal cells.
Study design, size, duration: 24 women diagnosed as recurrent miscarriage and 36 women of proven fertility were recruited from two university hospitals from November 2014 to October 2015. Endometrial biopsy samples were obtained precisely 7 days after luteinization hormone surge in a natural cycle.
Participants/materials, setting, methods: Immunohistochemistry was used to determine expression of HIF1α and micro blood vessels identified by von Willebrand factor (vWF) in endometrium. A semi-quantitative analysis was performed by using *H*-score analysis of staining intensity for HIF1α in the luminal epithelium, glandular epithelium and stroma, separately. The number, diameter and volume of vWF-positive endometrial micro vessels were counted by ImageJ software.
Main results and the role of chance: A significantly higher endometrial expression of HIF1α was observed in luminal epithelium ($P = 0.007$) and stroma ($P = 0.039$) in women with recurrent miscarriage compared to fertile controls. There was no significant difference in HIF1α expression in glandular epithelium between both groups. An increased number of micro blood vessels ($P = 0.008$) as well as volume of blood vessels ($P = 0.008$) was found in women with recurrent miscarriage. The mean diameter of blood vessels did not differ significantly between two groups.
Limitations, reasons for caution: Immunohistochemistry and *H*-score analysis for staining intensity are semi-quantitative methods to determine the amount of protein expression. The study could potentially be strengthened by the micro dissection of endometrium into different compartments and protein levels may be measured by quantitative ELISA kit.
Wider implications of the findings: The significantly altered expression of HIF1α as well as increased number and volume of micro blood vessels in the peri-implantation endometrium provides a molecular explanation for the endometrial factors contributing to recurrent miscarriage.
Trial registration number: NA.

P-105 Flow cytometric evaluation of epithelial b3-Integrin expression in endometrium of recurrent miscarriage patients and correlation with endometrial receptivity array

K. Marron[1], C. Harrity[2], D. Walsh[2]
[1]*Sims International Fertility Clinic, Zentra Laboratory, Dublin, Ireland*
[2]*Sims International Fertility Clinic, Medical Department, Dublin, Ireland*

Study question: Can a simple cost effective flow cytometric technique be used to screen candidates into those who are receptive and those requiring the more expensive endometrial receptivity array (ERA) for assessment.
Summary answer: Percentage epithelial β3 integrin expression correlates reasonably well to the gold standard 238 gene profile array of the Igenomics ERA test.
What is known already: Many techniques now exist to assess the receptivity status of female endometrial tissue and range from fully validated molecular techniques such as the ERA (or endometrial receptivity array) which is a genetic test to immunohistochemical techniques on fixed and stained tissue slides assessing various markers such as Cyclin E, p27 and β3 integrin. All are characterised by relatively high cost and considerable time to results. Flow cytometry is generally not employed for this type of evaluation but correctly set up allows for an almost instantaneous low-cost assessment of the material.
Study design, size, duration: The receptivity status of 23 IVF patients was assessed using both the ERA and FCM epithelial β3 integrin evaluation designed and applied in our Clinic. We set an initial cut off value of 60% of epithelial cells expressing β3 as being the level required for receptive status. FCM findings were recorded in advance of ERA findings. Data collection and validation of the technique is ongoing but we wish to present our preliminary findings here.
Participants/materials, setting, methods: A standard stimulation regimen was employed across all participants with 5 days exogenous progesterone prior to pipelle biopsy on the sixth day (corresponding to approximately day 21–24 of the patient cycle). 4 patients were reassessed following 7 days progesterone and an original pre-receptive finding on ERA. Biopsies were split into ERA preservative solution and RPMI for FCM. The FCM tissue was mechanically dissociated and evaluated immediately using specific antibodies to epithelial cells and β3 integrin.
Main results and the role of chance: Using the ERA test, 14 patient samples were called pre-receptive, 12 were fully receptive and 1 was post-receptive. The almost 50:50 split between receptive and pre-receptive data sets is far higher than expected based on published ERA findings in a general population (~75% receptive vs. 25% non-receptive), indicating the origin of difficulties with IVF RM/IF patients may be multifactorial. Simultaneous assessment using the epithelial β3 integrin FCM technique showed good correlation between the tests. The greatest predictive value was in the 12 fully receptive patients where the two tests concurred 83% (10 out of 12) of the time. Of the 14 pre-receptive patients on ERA, 6 were actually interpreted as receptive using β3 expression alone. This latter decrease in the predictive value to approximately 57% concurrence may indicate the greater difficulty in assessing borderline cases using this technique. Subsequent cases will be assessed with a new benchmark of 65% epi b3 expression required to attain receptive status. 4 ERA assessed non-receptive cases were re-assessed following an additional 1–2 days of progesterone and were found to move into receptive status using both techniques indicating that the window of implantation can be relatively easily manipulated.
Limitations, reasons for caution: The study is ongoing and the data set is small. Set up and interpretation of FCM results is variable and may not yield the same results in another institution. The cut off value of 60% epithelial β3 expression was assigned based on initial ERA findings in 5 patients.
Wider implications of the findings: As well as its accepted role in assessing immune populations such as natural killer cells, T regulatory cells etc., in endometrial tissue the flow cytometer can give strong cost effective indications of receptivity status with application of the correct markers, acting as an entry level test employed prior to ERA.
Trial registration number: This is an observational study and not a clinical trial. Full patient consent obtained.

P-106 A one year retrospective analysis comparing live birth outcomes from embryos grown and transferred from an undisturbed time-lapse culture system with a conventional culture system

K. McEvoy[1], D. Brison[2], S. Roberts[3], C. Turner[1], T. Adeniyi[1], L. Wood[1], Y. Wilson[1], A. Lloyd[1], D. Critchlow[1], H. Hunter[1], G. Horne[1]
[1]*St Mary's IVF Unit, Reproductive Medicine, Manchester, United Kingdom*

[2]The University of Manchester, Reproductive Medicine, Manchester, United Kingdom
[3]The University of Manchester, Statistics, Manchester, United Kingdom

Study question: Will an undisturbed time-lapse culture system influence an embryo's ability to grow, implant and yield a live birth?

Summary answer: An undisturbed environment yields embryos that are more advanced in development and an increase clinical pregnancy and live birth rate.

What is known already: With the introduction of novel time-lapse incubator technology (e.g., EmbryoScope™), embryos can be cultured in an undisturbed environment without being removed daily for observation. Meseguer (2011) initially showed an improved live birth rate using this system, however a review by Swain (2014) suggested that there is no one incubator type, undisturbed or otherwise, that yields better clinical pregnancy or live birth rates. Other studies (Kirkegaard, 2012; Park, 2015) have shown no improvement in embryo quality using undisturbed compared to conventional culture. Therefore the question of whether and how undisturbed culture is beneficial is not yet fully answered.

Study design, size, duration: A one year retrospective analysis of embryo growth (stage and grade) and live birth outcomes. The treatment group were the cycles cultured in undisturbed conditions (EmbryoScope™) (n = 317 cycles, 2468 embryos) compared to control cycles with removal for daily observation in a (Hunter G-185 Flatbed) incubator (n = 341 cycles, 2282 embryos). All cycles used Vitrolife sequential (G1+/G2+) media under 5% O_2. 98% of cycles used own gametes and embryos.

Participants/materials, setting, methods: Cycles with 3–12 zygotes on day 1 were allocated to EmbryoScope or Hunter incubators in a non-systematic manner depending on the number of cycles and availability of space on the day in each incubator. Embryos were transferred on day 3 or 5, with additional grading on day 2 (by removal from the Hunter incubators). Selection for transfer was by conventional grading, not using morpho kinetic time-lapse parameters in the EmbryoScope cycles.

Main results and the role of chance: Using Mann-Whitney and Fisher's statistical tests, it was found that cycles using the EmbryoScope/undisturbed culture had a significantly increased chance of a live birth (42% vs. 31%) (P = 0.006), as well as a significantly reduced chance of biochemical/early loss (4.4% vs. 11.1%) (P = 0.001) than those cycles cultured in the Hunter/Conventional culture system. Embryos also grew at a faster rate as there were more 4 cell embryos on day 2 and 8 cell embryos on day 3 in the EmbryoScope, compared to the Hunter group (P = 0.002). This suggests embryo development is more advanced in an undisturbed culture system. Differences in full embryo morphological grade (including cell evenness and fragmentation) requires further analysis.

The patient/cycle groups were similar between the two systems in terms of clinical parameters: treatment type (IVF/ICSI); Age; Day of transfer (3 or 5); and attempt number. The average number of zygotes was slightly higher in the treatment group (on average 1 embryo more, $p < 0.001$), however, when comparing cycles that yielded the same numbers of embryos, EmbryoScope resulted in improved live birth rates up to cycles that obtained 9 embryos. Above this, results are too low to compare.

Limitations, reasons for caution: The cycle allocation was not formally randomised. Patients who had fewer than 3 or more than 12 embryos were excluded from the study. Patients had slightly more fertilised embryos in treatment group. EmbryoScope cycles selected for blastocyst culture needed a G2+ media refresh on morning of day 3.

Wider implications of the findings: Our study suggests that undisturbed culture in EmbryoScope may improve treatment success, irrespective of the use of time-lapse selection algorithms. Conventional culture methods which cause disruption of the culture environment (atmospheric oxygen, pH, temperature, osmolality) to grade embryos during growth may negatively affect embryo growth and implantation potential.

Trial registration number: N/A.

P-107 Spontaneous abortion rates are decreased by using sperms following annexin V magnetic activated cell sorting (MACS) in ART for recurrent miscarriage patients

H.C. Kwon[1], G. Yi[1], J. Park[1], S. Lee[1]
[1]miraewaheemang hospital, department of OB/GYN, Seoul, South Korea

Study question: Are sperms collected by annexin V MACS detrimental for spontaneous abortion in recurrent pregnancy loss couples during *in vitro* fertilization (IVF)?

Summary answer: when sperms collected by annexin-V-MACS are used for recurrent miscarriage couples during ART, spontaneous abortion rates are decreased and so, live birth rates are increased.

What is known already: About 12–15% of clinical pregnancies end in spontaneous abortion. Most pregnancy losses results from chromosomal or genetic, abnormalities, and random events. The abnormality may come from the egg and/or sperm.

Study design, size, duration: A total of 107 recurrent miscarriage patients were investigated in this study between September 2011 and December 2014. In this study, the recurrent miscarriage was defined as the occurrence of two or more consecutive pregnancy loss. The recurrent miscarriage couples were divided into two groups according to sperm preparation method. (Swim-up group: sperms were prepared with swim-up protocol; annexin-V-group: sperms were collected by annexin-V-MACS). Swim-up group included 37 cycles and annexin-V-group included 70 cycles.

Participants/materials, setting, methods: Once the sperm and anti-annexin-V antibody conjugated microbead are mixed for 15 min, the damaged sperm and microbead bind together. This complex cannot pass through the magnetized column, so we can prepare healthy sperms in the pass-through fraction. Finally the healthy sperms can be used for ICSI. We carried out tunnel-assay and halo-assay to examine DNA damage and apoptosis. We performed immunefluorescence staining using Annexin-V antibody on sperms to check the sorting-ability of Annexin-V column.

Main results and the role of chance: The results of halo test showed that the percentage of DNA damaged sperm were dramatically low in Annexin V group than swim-up group (4.3% versus 1.6%). In tunnel assay, we found that the number of apoptotic sperms is also lower in Annexin V group than swim-up group. In swim-up group, 6 cases out of 16 ongoing pregnancies were found to be miscarriage, and in Annexin V group, only 3 cases out of 29 ongoing pregnancies were found to be miscarriage (spontaneous abortion rates; swim-up versus annexin V group: 37.5 vs. 10.3 p = 0.031). In conclusion, Live birth rate in ART treatment for recurrent miscarriage patients were significantly higher in Annexin V group than swim-up group (Annexin group vs. swim-up group: 27.0 vs. 37.1).

Limitations, reasons for caution: A major limitation of this study is the small sample size, and our study was restricted to patients treated by GnRH antagonist protocol and so requires confirmation in a GnRH agonist protocol.

Wider implications of the findings: In recurrent pregnancy loss patients, using sperm collected by annexin V MACS can be an alternative solution to overcome miscarriage.

Trial registration number: None.

P-108 The correlations between chromosomal distribution of early pregnancy loss and the existence of an embryo as well as the postmortem embryonic pole length after IVF-ET

Y. Ouyang[1], Y. Tan[2], Y. Yi[1], F. Gong[3], G. Lin[4], X. Li[1], G. Lu[3]
[1]Reproductive & Genetic Hospital of CITIC-Xiangya, Imaging Department, Changsha, Hunan, China
[2]Institute of Reproductive and Stem Cell Engineering, Central South University, Genetic Center, Changsha, Hunan, China
[3]Institute of Reproductive and Stem Cell Engineering, Central South University-Reproductive & Genetic Hospital of CITIC-Xiangya, Reproductive Center, Changsha, Hunan, China
[4]Institute of Reproductive and Stem Cell Engineering, Central South University-Reproductive & Genetic Hospital of CITIC-Xiangya, Stem Cell Engineering Center, Changsha, Hunan, China

Study question: To compare the chromosomal distribution in embryos from early pregnancy loss (EPL) with or without embryo after IVF-ET.

Summary answer: The chromosomal distribution differs in EPLs with or without embryo after IVF-ET.

What is known already: About 15% of clinical pregnancies will suffer EPL in natural conception and chromosomal abnormalities are the main causes. The miscarriage rate in IVF population is up to 24–30%. Three previous studies

have compared the chromosomal distribution in association with presence or absence of embryo, and the results were inconsistent. Furthermore, few researches have been conducted on the correlations between postmortem fetal pole length and chromosomal karyotypes.
Study design, size, duration: The data of 2172 women who underwent dilation and curettage (D&C) from January 2008 to December 2013 for missed abortion were retrospectively analyzed. The existence of an embryonic pole as well as the length of postmortem embryonic pole of embryos from EPLs were checked by transvaginal sonography (TVS). And ultrasound findings were compared with the karyotype results.
Participants/materials, setting, methods: This analysis included 2172 infertility patients who got singleton pregnancy and experienced EPL after IVF-ET. EPLs were divided into embryonic (1227) and anembryonic group (945) based on TVS diagnosis. The crown-rump length (CRL) of fetal pole (once observed) was measured twice for each fetus after confirmation of fetal death, subject to the final measurement before D&C. And the karyotype analysis was performed using comparative genomic hybridization (CGH) plus fluorescence in situ hybridization (FISH) technology.
Main results and the role of chance: In the 2172 cases, 1227 (56.49%) were found to be embryonic, and 945 (43.51%) were anembryonic miscarriages. The chromosomal abnormality rate was significantly higher in miscarriages with embryo than that of without embryo (52.24% vs. 35.35%, $p < 0.01$). Monosomies were found more frequent in embryonic than those in anembryonic group (6.76% vs. 3.81%, $p < 0.01$). The abnormal karyotype rate was significantly higher in the yolk sac only than that of in the empty sac group (43.39% vs. 28.11%, $p < 0.01$). There were statistically significant differences in the length of post-mortem embryonic pole among groups with different karyotypes. In addition, trisomy 21, monosomy X and triploidy were found with the longest length of postmortem embryonic pole. And longer than 20mm appears to be a prediction for trisomy 21 or monosomy X.
Limitations, reasons for caution: We used nonparametric test to compare the embryonic pole lengths due to non-normal distribution and non-homogeneous variances which may result from the limited cases of some rare chromosomal abnormalities. Another limitation was there was no mosaicismy contained in the cytogenetic results because CGH was unable to detect mosaicismy.
Wider implications of the findings: Chromosomal distribution in EPLs with embryo was different from that without embryo, and the postmortem fetal pole lengths were correlative with different karyotypes after IVF-ET. These findings may help clinicians to analyze possible causes when encountering these two kinds of miscarriages. CGH+FISH technology is reliable technology for screening the chromosomal anomaly quickly.
Trial registration number: None.

P-109 The effect of Fresh-ET and FET on maternal and neonatal outcomes

L. Sun[1], M. Xiaojuan[2], H. Jijun[2], Q. Ruofan[2], G. Yichun[2], W. Xingling[2]
[1]*The Third Affiliated Hospital of Zhengzhou University, Zhengzhou, China*
[2]*The Third Affiliated Hospital of Zhengzhou University, Reproductive Center, Zhengzhou, China*

Study question: To investigate whether the maternal high-E 2 environment and embryo cryopreservation increases the risks of maternal pregnancy complication and LBW and SGA birth.
Summary answer: The high estrogen level increases the incidence of SGA and LBW in fresh ET cycle and embryo freezing technology does not affect the birth weight.
What is known already: During a fresh IVF-ET cycle, exogenous gonadotropins are administered to promote the development of multiple follicles resulting in estradiol levels that can be 10–20 times greater than physiologic level. There have been increasing concerns that a disrupted endocrine environment may deteriorate the responses of gamete/embryo and impede embryonic development. It is shown that even singletons after ART are at increased risk for low birth weight (LBW), and singletons conceived through fresh ET have lower birth weight and more LBW than those through frozen ET.
Study design, size, duration: The clinical data were retrospective analyzed from patients treated with IVF/ICSI in the reproductive center of the third Affiliated Hospital of Zhengzhou University between January 2008 to September 2012. This study included 1336 patients who performed Fresh-ET (high-$E_{2\ group\ 587\ cases}$ and low-E_2 group 749 cases), 640 patients canceled transplant in fresh IVF cycle performed FET (FET group), all delivered singleton term infants. Naturally conceived singletons during the same period served as a control group ($n = 668$).
Participants/materials, setting, methods: The clinical data were retrospective analyzed from patients treated with IVF/ICSI in the reproductive center of the third Affiliated Hospital of Zhengzhou University between January 2008 to September 2012. This study included 1336 patients who performed Fresh-ET (high-$E_{2\ group\ 587\ cases}$ and low-E_2 group 749 cases),640 patients canceled transplant in fresh IVF cycle performed FET (FET group), all delivered singleton term infants. Naturally conceived singletons during the same period served as a control group ($n = 668$).
Main results and the role of chance: The live birth rate of FET group is higher than Fresh-ET group, difference was statistically significant ($P < 0.05$). The incidence of ectopic pregnancy rate, abortion rate, premature birth rate, pregnancy complications incidence in Fresh-ET group is higher than FET group, difference was statistically significant ($P < 0.05$). The pregnancy rate is similar between the two groups and has no statistically significance. The incidence of LBW and SAG was statistically significant between High-E_2 group and Low-E_2 group ($P < 0.05$), and the incidence of LBW and SGA in High-E_2 group was higher than that in Low-E2 group.
Limitations, reasons for caution: The clinical data were retrospective analyzed from patients treated with IVF/ICSI in the reproductive center of the third Affiliated Hospital of Zhengzhou University between January 2008 and September 2012, which is a cohort study, not randomized controlled.
Wider implications of the findings: Compared with the fresh ET cycle, FET increases the birth weight of the newborn, and pregnancy complications are reduced. The ectopic pregnancy rate, abortion rate, premature delivery rate, pregnancy complication rate of Fresh-ET group was higher than that of the FET group, and the live birth rate in FET group is higher than Fresh-ET group.
Trial registration number: 123456789.

P-110 Urinary human chorionic gonadotrophin (hCG) levels in early pregnancies correlate with serum hCG and may be used for the monitoring of early pregnancy well-being

S. Johnson[1], S. Jayne[2], S. Nigel[2], W. James[2]
[1]*SPD Development Company Ltd, Bedford, United Kingdom*
[2]*University of Leeds Teaching Hospital, Department of obstetrics, Leeds, United Kingdom*

Study question: Do urinary hCG levels in early viable, ectopic and miscarried pregnancies correlate with serum hCG and represent a reliable marker of early pregnancy well-being?
Summary answer: Urinary hCG profiles in early pregnancy were representative of serum hCG for all studied outcomes and differed substantially between viable and ectopic/miscarried pregnancies.
What is known already: Quantitative assessment of serum (hCG) levels represents the gold standard for the monitoring of early pregnancy. However, this analysis is currently performed in diagnostic laboratories and cannot be carried out at the point of care. In addition, repeated blood tests can be inconvenient for patients requiring regular monitoring of serum hCG for suspected ectopic pregnancy, miscarriage or pregnancy of unknown location. Although qualitative urinary hCG tests represent a common and convenient tool for the diagnosis of pregnancy, it remains unclear whether quantitative assessment of urinary hCG could be used for the monitoring of early pregnancy well-being.
Study design, size, duration: An observational cohort study to monitor urinary and serum hCG levels was carried out in 82 female volunteers attending an early pregnancy unit (EPU). The monitoring was started on the day of referral and continued until 12 weeks pregnancy (since last menstrual period) for viable pregnancy or until resolution of an ectopic pregnancy/miscarriage diagnosis.
Participants/materials, setting, methods: The study recruited two groups of volunteers: women with a previous history of miscarriage or ectopic pregnancy (Group A, $n = 55$) and women with suspected ectopic pregnancy (Group B, $n = 27$). Urinary hCG levels were measured in the first morning urine samples using AutoDELFIA. Serum hCG levels were measured using an automated

immunoassay system. Urine creatinine was measured to examine effect of urine concentration correction.
Main results and the role of chance: Pregnancy outcome was classified as "viable" for 49 (59.8%) volunteers, "miscarriage" for 17 (20.7%), "ectopic pregnancy" for 11 (13.4%), "inconclusive" for four, and "missing" for one volunteer. Time profiles of log urinary hCG concentrations differed considerably for the three main pregnancy outcomes ("viable", "ectopic", "miscarriage"). Specifically, urinary hCG had a very similar time profile in volunteers with viable pregnancies, but differed substantially in those with ectopic pregnancies and miscarriages depending on the type and timing of the pregnancy outcome. For all three outcomes, urinary hCG concentrations rose steeply in the first days of pregnancy and reached a peak between 50 and 70 days before dropping off to varying degrees. Viable pregnancy profiles were best modelled by the critical exponential model. Miscarriage and ectopic pregnancy urinary hCG profiles were not modelled well, mainly due to inadequacies in the data, but appeared different to viable pregnancies. The study demonstrated a clear linear relationship between log urinary and log serum hCG levels that was common for all pregnancy outcomes and was judged to be valid. The slope between the two was estimated to be 1.006 with a correlation of 0.923.
Limitations, reasons for caution: The study did not include a sufficient number of volunteers with miscarriage and ectopic pregnancy, and there were indications of inadequate timing and frequency of data collection in these participants. Collectively, this was likely to affect performance of the models used to characterize urinary hCG profiles in these clinical scenarios.
Wider implications of the findings: The possibility to model urinary hCG profiles in viable pregnancies and consistency of the modelled profiles between participants opens new possibilities for the use of quantitative urinary hCG testing to differentiate between normal and compromised pregnancy development as an alternative to serum hCG testing.
Trial registration number: Not Applicable.

P-111 Miscarriage risk in women with twice, once and never poor response in two consecutive IVF treatment cycles.

T. Honorato[1], A. Hoek[1], H. Groen[2], F. Broekmans[3], C. Lambalk[4], T. Mooij[5], F. Van Leeuwen[5], M. Haadsma[6]
[1]University Medical Center Groningen/University of Groningen, Department of Obstetrics & Gynaecology, Groningen, The Netherlands
[2]University Medical Center Groningen/University of Groningen, Department of Epidemiology, Groningen, The Netherlands
[3]University Medical Center Utrecht, Department of Reproductive Medicine and Gynaecology, Utrecht, The Netherlands
[4]VU University Medical Center, Department of Obstetrics & Gynaecology, Division of Reproductive Medicine, Amsterdam, The Netherlands
[5]Netherlands Cancer Institute, Department of Epidemiology, Amsterdam, The Netherlands
[6]University Medical Center Groningen/University of Groningen, Department of Genetics, Groningen, The Netherlands

Study question: Does poor response in two consecutive IVF cycles increase the risk of miscarriage compared to once or never poor response?
Summary answer: Women with twice poor response more often experienced miscarriage compared to women with once and never poor response, independent of age.
What is known already: Poor response to ovarian hyperstimulation in IVF treatment is associated with an increased risk of miscarriage. Poor response may represent diminished ovarian reserve or may be accidental. Despite changes in hyperstimulation dosage or protocol, women with a diminished ovarian reserve easily experience a poor response in subsequent cycles as well. These women are hypothesized to have lower quality oocytes as compared to accidental poor responders. We hypothesize that women with twice poor response are therefore at an increased risk for miscarriage compared to women with once (accidental) or never poor response in two consecutive cycles.
Study design, size, duration: This study is part of the OMEGA-project, a Dutch nationwide retrospective cohort ($N = 19840$) including IVF-treated women between 1983 and 1995. All patients included completed two consecutive IVF-cycles within one year. Women treated with gamete or zygote intrafallopian transfer, ICSI, oocyte orembryo-donating were excluded, as were women with missing cycle information, extra-uterine or artificially terminated pregnancies.
Participants/materials, setting, methods: Patient's characteristics were obtained via questionnaires and medical records. Women achieving an ongoing pregnancy (viable intra-uterine pregnancy ≥16 weeks) after their second cycle were compared with those experiencing miscarriage (loss between 4 and 16 weeks). Poor response was defined as ≤3 oocytes and normal response as ≥4 oocytes. The frequency of poor response was divided into twice, once or never poor response. Odds ratios (OR) were calculated with logistic regression and categories were compared with trend analysis.
Main results and the role of chance: Complete data was available for 8457women, of which 5427 had 2 cycles, resulting in 1065 pregnancies. Of these, 773 ongoing pregnancies and 196 miscarriages we applicable for analysis. Women were on average 32.9 (±3.9) years and main causes of infertility included tubalfactor (37.3%), male factor (24.9%) and unexplained origin (22.3%). Twice poor response occurred in 4.4% (43/969) of the women, once in 17.4% (169/969) and never poor response in 78.1% (757/969). Women with twice poor response more often experienced miscarriage (37.2%) compared to women with once poor response (22.5%) (crude OR, 95% CI 2.0, 1.0–4.2; $P = 0.05$) and compared to never poor response (18.8%) (crude OR, 95%CI 2.6, 1.3–4.9; $P = 0.004$). Female age was identified as the only confounder to affect odds ratio materially (adjusted OR, 95%CI 2.3, 1.2–4.4; $P = 0.01$). There was no interaction between confounders including female age, response category, BMI and smoking. For the once poor responders, miscarriage rates were comparable between women experiencing poor response in their first or in their second IVF cycle (resp. 22.3% and 23.1%; $P = 0.92$). Our trend analysis showed a statistically significant decreasing risk among women with twice, once and never poor response ($P = 0.01$).
Limitations, reasons for caution: We analyzed an early dataset (1983–1995) and stimulation protocols were usually "short flare up" and "downregulation" protocols, therefore generalization should be cautious. Additionally, there was no information on ovarian reserve tests.
Wider implications of the findings: Women with twice poor response more often experienced miscarriage compared to women with once and never poor response, independent of age. This suggests that diminished ovarian reserve is related to lower oocyte quality. Our results are a valuable "prove of concept" of the relationship between poor response and oocyte quality.
Trial registration number: Not applicable.

P-112 Embryo transfer performed under ultrasound guidance can reduce the risk of caesarean scar pregnancy in women with isthmocele?

D. Baldini[1], C. Lavopa[1], A. Malvasi[2], G.M. Vizziello[1], I. Cobuzzi[1]
[1]Momò Fertilife, Centre for Reproductive Medicine, Bisceglie, Italy
[2]Ospedale Santa Maria, Obstetrics and Gynecology, Bari, Italy

Study question: Embryo transfer (ET) performed under 2D trans-abdominal sonography (2D-TAS) guidance can reduce the risk of caesarean scar pregnancy (CSP) during assisted reproductive treatments (ART)?
Summary answer: The location of the air bubbles assessed with 2D-TAS during ET didn't predict the site of implantation because other factors such as contractility were involved.
What is known already: The presence of an isthmocele, a triangular defect in the myometrium at the site of a previous caesarean delivery scar represent a risk factor for CSP and the incidence has risen with the increasing number of caesarian section deliveries performed. During ART, the possibility to identify with ultrasound the position of the catheter tip and/or the position of the air bubbles following embryo transfer could help the clinician to overcame the risk of CSP. However, it is possible that the embryo undergoes significant migration and the embryo position may change following transfer into the uterine cavity.
Study design, size, duration: A retrospective cohort study including 33 women with a previous caesarean section who underwent a 2D TAS guided ET at the Momò; Fertilife' Private Centre for Reproductive Medicine, Bisceglie, Italy, between August 2011 and October 2015.
Participants/materials, setting, methods: None of the patients had a ratio scar myometrial thickness/normal myometrial thickness ≤50%. At least one embryo of good quality (≥7 blastmomeres of equal size, with <10% fragmentation) was loaded into an atraumatic catheter and transferred into the middle of the uterine cavity under TAS guidance, aiming for an inner catheter tip placement of 15 mm from the fundus. In women achieving a pregnancy, the position of the gestational sac was subsequently assessed.

Main results and the role of chance: Over a period of four years, of 33 patients with secondary infertility and one previous cesarean section, 8 singleton and 2 double gestational sac were visualised after ART. Of these, 2 CSP were detected by transvaginal sonography (TVS) in the first trimester observing, respectively, one and two gestational sac with the "double ring sign" and the cardiac activity located anteriorly at the level of the internal os. The incidence of CSP was 1:540 (2/1080), which was much higher than spontaneous condition, suggesting ART could be a contributor to the occurrence of CSP. The twin pregnancy was treated with a dilatation and curettage under TVS guidance while the singleton pregnancy experienced a large amount of vaginal bleeding and a healthy boy weighing 2600 gr was delivered by an emergency caesarean section at 35 weeks' gestation.
Limitations, reasons for caution: Although the air bubbles seen at the time of ET are thought to demonstrate the position of the embryo, they are in fact a surrogate marker of the embryo itself, as this cannot be directly visualized by ultrasound scan.
Wider implications of the findings: The exact position of the embryo flash immediately following embryo transfer is not related to a good clinical outcome because the majority migrated towards the fundus or the cervix denoting an increased risk of embryo expulsion from the uterine cavity and its localization in an ectopic site such as isthmocele.
Trial registration number: None.

P-113 Embryonic aneuploidy: Is it responsible for the increased risk of early pregnancy loss in patients with PCOS?

L. Luo[1], Q. Wang[1], Q. Lei[2], M. Lin[3], X. Huang[1], M. Chen[1], C. Zhou[1]
[1]*1st Affiliated Hospital of Sun Yat-Sen University, Center of Reproductive Medicine, Guangzhou, China*
[2]*Guangdong Women and Children Hospital, Department of Obstetrics, Guangzhou, China*
[3]*Peking University Third Hospital, Department of Obstetrics and Gynecology, Beijing, China*

Study question: Is chromosome aneuploidy responsible for the increased risk of clinical miscarriage for women with polycystic ovary syndrome (PCOS)?
Summary answer: Abortuses of PCOS women are significantly less likely to have chromosome aneuploidy, independently of maternal age.
What is known already: It is widely known that the embryonic chromosomal anomalies are responsible for over 50% of early pregnancy loss after assisted reproductive technique. However, there is still a lack of knowledge about the cytogenetic information of embryos from abortuses of PCOS and no evidences were found to determine whether the increased risk of clinical miscarriage for PCOS women is due to embryonic aneuploidy or other endocrinologic factors.
Study design, size, duration: This prospective observational cohort study, between January 2010 and February 2014, followed up 1461 patients who conceived with *in vitro* fertilization and embryo transfer (IVF-ET). 100 patients diagnosed as clinical pregnancy loss were finally recruited including 32 with PCOS and 68 without PCOS.
Participants/materials, setting, methods: Cytogenetic analyses were performed by using cultured chromosome karyotyping and multiplex ligation-dependent probe amplification (MLPA) subtelomere assay combined with fluorescence in situ hybridization (FISH) before the year of 2013. Since 2013, diagnoses were made by using array-based comparative genomic hybridization (array-CGH) combined with cultured chromosome karyotyping. Incidence of chromosome aneuploidy in PCOS miscarriages was compared to non-PCOS miscarriages subjected to the Chi Square test. Predictive parameters for aneuploidy were tested in a logistic regression analysis.
Main results and the role of chance: There were 119 singleton clinical pregnancies in the PCOS group, of which 35 (29.4%) with follow-up miscarried; which compares to 11.3% (75/664) in the non-PCOS group, $P = 0.001$. No significant differences were found in the baseline characteristics between patients with and without PCOS, including maternal age, BMI, pregnancy history, gestational age, total dosages of gonadotropin for ovarian stimulation as well as methods of diagnosis. In PCOS group, 9 out of 32 (28.1%) abortuses demonstrated aneuploidy, which was significantly lower than Non-PCOS group (49 out of 68, 72.1%), $P < 0.01$. Maternal age was found to be an important predictor of aneuploidy; controlling for maternal age, abortuses of women with PCOS were significantly less likely to have chromosome aneuploidy (OR 0.14, 95% CI 0.05 to 0.39, $P = 0.001$).
Limitations, reasons for caution: Submicroscopic aberrations could be underestimated before the year of 2013 due to the unavailability of diagnoses made by using the array technique. To make firm conclusions on the incidence of embryonic chromosomal anomalies for PCOS miscarriages, a larger sample size diagnosed by using advanced sequencing technique is needed.
Wider implications of the findings: The present findings suggested hat the increased risk of clinical miscarriage for PCOS women is likely to be due to maternal factors other than aneuploidy, such as high testosterone level, anomalies in progesterone production and insulin resistant resulting in endometrial disorders.
Trial registration number: Empty.

P-114 Hydroxychloroquine treatment for recurrent pregnancy loss – a pilot study

H.S. Nielsen[1], E.C. Larsen[1], L. Lunoee[1], K. Kirchheiner[1], M. Krog[1], O.B. Christiansen[1]
[1]*Copenhagen University Hospital Rigshospitalet, Fertility Clinic and Recurrent Pregnancy Loss Unit, Copenhagen, Denmark*

Study question: Can treatment with hydroxychloroquine (HCQ) 200 mg/day initiated prior to pregnancy increase the chance of a live birth in women with ≥4 unexplained pregnancy losses?
Summary answer: Among 15 HCQ treated women 12 (80%) have either ongoing second trimester pregnancies (8) or given birth (4). This is higher than expected 50%, $p = 0.035$
What is known already: Recurrent pregnancy loss (RPL) affects up to 3% of couples aiming for parenthood. RPL is associated with both physical and psychological short and long-term consequences. Half of the cases are unexplained with no proven treatments available. Fetal chromosomal abnormalities decrease with increasing number of losses and there is accumulating evidence that immunology plays a causal role in unexplained RPL. HCQ is a well-known anti-malaria drug with expanding indications in cancer and auto-immune diseases due to its anti-inflammatory, immune modulating and anti-thrombotic effects. HCQ is considered safe in pregnancy but its potential impact in unexplained RPL is unexplored.
Study design, size, duration: A pilot study in a prospective cohort of unexplained RPL with ≥4 losses. The cohort consists of 41 eligible women. Recruitment has taken place between October 1st 2014 and December 31th 2015.
Participants/materials, setting, methods: We included 41 eligible women from a Danish National Tertiary Referral Center for RPL. Tablet HCQ treatment of 200 mg/daily was administered orally after informed consent. Treatment was started preconceptionally and treatment was recommended 2 months before pregnancy and throughout pregnancy until gestational week 28. Women were informed about the HCQ treatment, contraindications, potential benefits and harm and follow-up procedures (Eyes cheked by ophthalmologist yearly, hemoglobin, platelets and leucocytes every third month during treatment).
Main results and the role of chance: Of the 41 women who initiated HCQ, four have given birth, eight are ongoing second trimester pregnant; four are first trimester pregnant, three lost their pregnancy and 22 are not pregnant yet. Among the 15 with ongoing second trimester pregnancy/live birth/pregnancy loss the median age is 37 (26–43), the median number of losses is 4 (4–10) and the median time of HCQ treatment prior to pregnancy is 2 months (0–5). The success rate for live birth/ongoing second trimester pregnancy is 12/15 (80%) which is significantly higher than the expected 50%, $p = 0.035$ (success rate in placebo group in a large randomized controlled trial of women with RPL and ≥4 losses). Treatment was initiated less than one month prior to pregnancy in all three pregnancies that failed. HCQ was well tolerated among the women. One complained about tinnitus but decided to continue treatment as the pregnancy sustained longer than ever before. Blood tests were unaffected by HCQ.

Although this is the largest cohort of HCQ treatment in unexplained RPL the low number of participants and the non-randomized design increases the risk that the results are due to chance. We expect the outcome numbers to increase at least 100% before ESHRE 2016.
Limitations, reasons for caution: The significant increase in live birth/ongoing second trimester pregnancies found in this prospective pilot study of HCQ treatment of unexplained RPL should be interpreted with caution due to the low number of participants and the non-randomized design.
Wider implications of the findings: There are no proven treatments to increase live birth rate in unexplained RPL. If the findings of this pilot study of HCQ

treatment in unexplained RPL patients can be confirmed in future randomized controlled trials, HCQ can be a well-tolerated, cheap and effective treatment of unexplained RPL.
Trial registration number: Pilot studies do not require registration according to Danish Legislation.

P-115 Maternal Killer-cell Immunoglobulin-like Receptor (KIR) and fetal HLA-C compatibility in ART-oocyte donor influences live birth rate

D. Alecsandru[1], A. Barrio[1], P. Aparicio[1], M. Aparicio[2], J.A. Garcia-Velasco[1]
[1]Instituto Valenciano de Infertilidad IVI-Madrid, Department of Immunology and Department of Reproductive Endocrinology and Infertility, Madrid, Spain
[2]Instituto Valenciano de Infertilidad IVI-Madrid, Department of Reproductive Gynecology and Infertility, Madrid, Spain

Study question: Has the maternal KIR an impact in pregnancy, miscarriage and live birth rates (LBR)/cycle in donor oocytes –ART by paternal and oocyte donor HLA-C?
Summary answer: The combination of maternal KIR-parental, donors HLA-C, could predict which couple can benefit for donor selection by HLA-C, in order to increase the LBR.
What is known already: Pregnancies have an increased risk of recurrent miscarriage (RM), preeclampsia or fetal growth restriction (FGR) in mothers KIR AA when the fetus has more HLA-C2 genes than the mother. In human populations, pregnancy disorders are predicted to reduce the frequency of KIR A haplotype, HLA-C2, or both and this selection is thought to have originated during human evolution. In ART oocyte donor cycles, the oocyte HLA-C behaves as paternal HLA-C and the KIR-HLA-C combination is not taken into consideration nowadays during donors' selection. KIRAA women have lower live birth rate after doble embryo transfer (DET) in egg-donation ART cycles.
Study design, size, duration: Between January 2015 and December 2015, we performed a prospective study that included 30 women, with unknown etiology of their recurrent reproductive failure: recurrent implantation failure (RIF) ($N = 21$) and RM ($N = 9$) which had a total of 112 oocyte donor-assisted reproductive cycles (ART).
Participants/materials, setting, methods: Thirty patients undergoing to ART –oocyte donor, selected from our IVI Clinics, with normal karyotype (both members), trombophilic, and immunological results were studied prospectively. All women had KIR AA genotype and their partners HLA-C2 genes. They had 54 embryo transfer cycles with unknown HLA-C-oocyte donors and 28 cycles with HLA-C1C1 donors. Pregnancy, miscarriage and LBR/cycle after embryo transfer (ET) with unknown oocyte donor HLA-C and after transfers with HLA-C1C1 oocyte donor were studied.
Main results and the role of chance: The median age of our patients was 40 years and their body mass index ranged from 20.2 to 28.23 kg/m2. The median age of the patients' partners was 41 years. These couples had a mean of 3 previous failed egg donation ETs, and had been trying to conceive for a mean of 7+3 years. The median age of the oocyte donors was 25 years. From a total of 112 ART-oocyte donor cycles, 82 were included in the study; 30 cycles were not considered because the ETs were cancelled or not performed at the data collection time.

Higher pregnancy rate per cycle after HLA-C1C1 oocyte donor transfer (85.71%) compared with unknown HLA-C oocyte donor cycles (31.48%) were observed in the same patients KIR AA with HLA-C2 partners ($p < 0.0001$). Higher miscarriage rate per cycle after unknown HLA-C oocyte donor transfer (94.44%) compared with HLA-C1C1 oocyte donor transfer (8.33%) were observed ($p < 0.0001$).

Significantly increase LBR per cycle were observed after ET with HLA-C1C1 oocyte donor (82.14%) compared with the LBR in the same KIR AA patients-HLA-C2 partners after cycles with unknown HLA-C oocyte donor (0%) ($p < 0.0001$).
Limitations, reasons for caution: We must assume that is a small sample and that is the first report observing differences in LBR by oocyte donor HLA-C in mothers KIRAA with HLA C2 partners. However, apart from the statistical significance, the association strength is noticeably high, allowing greater confidence in the findings.
Wider implications of the findings: We speculate that completing a normal pregnancy is possible only for mothers KIR AA who carry a baby with a least one non–self HLA-C1. Therefore, selecting HLA-C1 amongst oocyte and/or sperm donors for patients undergoing to egg donation ART and KIR AA, could be more efficient and safer.
Trial registration number: Not applicable since no intervention has made.

P-116 Aneuploidy Screening and Genome Profiling in Couples with Spontaneous Recurrent Pregnancy Loss

S. Cheung[1], T. Cozzubbo[1], N. Pereira[1], Q.V. Neri[1], Z. Rosenwaks[1], G.D. Palermo[1]
[1]Weill Cornell Medicine, Reproductive Medicine, New York, NY, USA

Study question: To investigate whether all genome sequencing by the involvement of specific genes can supplement sperm aneuploidy studies in patients with spontaneous recurrent pregnancy loss (RPL).
Summary answer: Gene sequencing confirmed a higher sperm aneuploidy and also evidenced mutations in a set of spermatogenesis-related genes in men that presented with RPL.
What is known already: At least 15% of infertility cases are related to genetic disorders, such as chromosomal and single-gene alterations. As a result, genetic tests are currently more frequently used as a diagnostic procedure in couples experiencing infertility or unexplained pregnancy loss. For this purpose, it is important to screen the male partner which is presently assessed by semen analysis, chromatin fragmentation, and fluorescent in situ hybridization (FISH) on spermatozoa. FISH is only capable of assessing a limited number of chromosomes, whereas all chromosomes assessment carried out by Next Generation Sequencing (NGS) may contribute to more proper profiling of the male genome.
Study design, size, duration: In a 14 month period, we assessed spermatozoa aneuploidy in 11 men with recurrent pregnancy losses. FISH analysis for chromosomes X, Y, 13, 15, 16, 17, 18, 21 and 22 was carried out. All chromosomes analysis was carried out by Next Generation Sequencing (NGS) and copy number variants (CNVs) were recorded to validate the chromosomal disomies involved. Genes with the highest CNVs were then noted for all chromosomes in each sample.
Participants/materials, setting, methods: FISH was performed on at least 1000 spermatozoa of 11 consenting men, with a threshold of >1.6% (euploid), maintaining a 2–3% error. Extracted DNA was amplified from at least 500 spermatozoa per sample using PCR-based random hexamer amplification yielding a DNA concentration of 447.8 ± 198ng/ul and quality of 1.7 ± 0.1nm. CNVs were recorded using CASAVA and VarScan2 software. The genes found to have the highest CNVs in each sample were selected and grouped by function.
Main results and the role of chance: A total of 11 men with an average age of 44.9 ± 7yrs had a semen specimen concentration of 27.0 ± 34 × 10^6/ml, motility of 23.0 ± 26%, and normal morphology of 1.5 ± 2%. The overall average aneuploidy by 9 chromosome FISH for those patients was 0.39%. When sperm aneuploidy assessment was carried out by CNV count, the aneuploidy rate rose to 4.07% ($P = 0.0001$). By NGS, we were able to detect a total of 14 putative gene mutations that were present in our study group. A few of these genes, ADAM3A, NXF2, RBMY1F, and DPY19L2, appear to be related to the development of a normal male gamete. When we assess the ability of these couples to reproduce with the help of assisted reproductive technology, only the couples treated with IVF and/or ICSI, but not IUI, were able to establish a pregnancy that resulted in a delivery of a healthy child.
Limitations, reasons for caution: Although this approach of assessing aneuploidy and gene mutations by NGS may certainly help in clarifying covert male genetic contributions involved in recurrent pregnancy loss, more cases need to be studied to further validate our findings.
Wider implications of the findings: The utilization of NGS for analysis of spermatozoa is beneficial to the assessment of aneuploidy, and detection of CNVs allow to screen for gene mutations. NGS may help identify specific genes to provide insight to underlying genetic causes of recurrent pregnancy loss, therefore clarifying the etiology of idiopathic male infertility.
Trial registration number: N/A.

P-117 Effects of previous ectopic pregnancies and the pertaining treatments on *in vitro* fertilization/intracytoplasmic sperm injection and frozen-thawed embryo transfer outcomes

T. Du[1], H. Chen[1], Q. Chen[1], Q. Lyu[1], Y. Kuang[1]
[1]Shanghai 9th People's Hospital, Department of Assisted Reproduction, Shanghai, China

Study question: What are the influences of previous ectopic pregnancies and the pertaining treatments on *in vitro* fertilization/intracytoplasmic sperm injection (IVF/ICSI) and frozen-thawed embryo transfer outcomes?
Summary answer: Previous ectopic pregnancies (EPs) affect intrauterine implantation and EP rate.
What is known already: EP is an important cause of morbidity and mortality worldwide with unelucidated pathogenesis. In women who seek for the help of assisted reproductive technology, those with a history of EP can reach a proportion about 14%. A recent study reported that in fresh embryo transfer cycles of IVF/ICSI, previous EP and different treatments of it had no effect on the main IVF/ICSI outcomes, except an increased risk of recurrent EP. However, numerous studies suggested that frozen-thawed embryo transfer (FET) cycles were associated with a different endometrial environment and lower risk of EP compared with fresh embryo transfer cycles.
Study design, size, duration: This was a retrospective cohort study involving women undergoing 12,266 IVF/ICSI-FET cycles in the period between May 2013 and June 2015.
Participants/materials, setting, methods: Women with previous EP(s) and women got fallopian diseases without EP were strictly matched by age, number of cycles, type of infertility, presence of polycystic ovary syndrome, endometriosis and/or male factor infertility, and divided into four groups according to the times of previous EPs: one EP group (n = 959 cycles), recurrent EPs group (n = 375 cycles) and their control groups. Subgroups were made according to the stage of embryos transferred, endometrial preparation or treatment (surgical vs. non-surgical, rematched) of EP.
Main results and the role of chance: Main baseline characteristics and main ovarian stimulation outcomes had no statistically significant differences between experimental groups and their control groups, or between subgroups and their control groups, nor did the main pregnancy outcomes. However, the intrauterine implantation rate of recurrent EPs group (REG) (29.7% vs.36.6%, relative risk reduction [RRR]: 18.9%, 95% confidence interval [CI]: 5.5%–32.2%), cleavage stage embryo transfer subgroup (28.1% vs.34.7%, RRR: 19.0%, 95% CI: 4.6%–33.4%) and mild stimulation subgroup of REG (29.8% vs.45.1%, RRR: 33.9%, 95% CI: 13.7%–54.2%) were significant lower than their control groups. Meanwhile, the blastocyst forming rate in the blastocyst stage embryo transfer subgroup of REG was significant higher than its control group (27.0% vs.21.8%, relative risk increase [RRI]: 23.9%, 95% CI: 9.8%–37.9%). And a significant higher EP rate was observed in one EP group (6.4% vs.2.5%, RRI: 156.0%, 95% CI: 52.6%–259.4%), REG (5.3% vs.1.0%, RRI: 430.0%, 95% CI: 65.0%–795.0%) and the cleavage stage embryo transfer subgroup of REG (6.0% vs.1.2%, RRI: 400.0%, 95% CI: 54.2%–745.8%) than their control groups.
Limitations, reasons for caution: This was a retrospective study with thus inevitable selection bias. Moreover, the date was not derived from multiple centers. The sample size was quite limited, especially for the recurrent EPs group. And treatments of EP were performed in various hospitals. For surgical treatment, we didn't differentiate between salpingectomy and salpingostomy.
Wider implications of the findings: Women with a history of recurrent ectopic pregnancies have a compromised intrauterine implantation outcome after IVF/ICSI-FET, which to some extent indicates an altered endometrium that may play an important role in the pathogenesis of ectopic pregnancy. And for those women, blastocyst stage embryo transfer is suggested.
Trial registration number: Does not apply.

P-118 Primary recurrent miscarriage is linked to elevated peripheral natural killer cells

R.J. Kuon[1], K. Vomstein[1], C. Seitz[2], M. Weber[3], U. Markert[3], T. Strowitzki[1], V. Daniel[4], B. Toth[1]
[1]*University Hospital, Department of Gynecological Endocrinology and Fertility Disorders, Heidelberg, Germany*
[2]*University Hospital, Department of Neonatology, Heidelberg, Germany*
[3]*University Hospital, Placenta-Lab, Department of Obstetrics, Jena, Germany*
[4]*University Hospital, Department of Transplantation-Immunology, Heidelberg, Germany*

Study question: Are altered levels of peripheral und uterine natural killer cells (pNK, uNK) present in patients with recurrent miscarriage (RM) and controls?
Summary answer: Compared to controls, higher pNK percentages were present in primary, but not in secondary RM and no correlation between pNK and uNK was detected.
What is known already: NK cells play an important role during early pregnancy and are part of immune diagnostics in RM. PNK and uNK can be distinguished according to their receptor expression and interaction with other players of the immune system. Recent studies indicate that elevated pNK and uNK might be associated with RM. However, controversial debates are ongoing as the comparison of the studies is difficult due to small cases included and inconsistent inclusion criteria.
Study design, size, duration: Between 10/2011 and 12/2015, in total n = 590 RM patients and 51 healthy female controls (regular menstrual cycle, no oral contraceptives) were included. Patients were screened according to a standard diagnostic protocol for anatomical, endocrine, autoimmune, hemostatic, genetic and immune disorders. Finally, n = 268 couples with ≥3 consecutive RM were identified. Subgroups consisted of n = 151 primary RM, n = 85 secondary RM, n = 147 idiopathic RM and n = 121 non-idiopathic RM patients.
Participants/materials, setting, methods: Diagnostic was performed in non-pregnant patients and controls in the mid-luteal phase. Peripheral blood levels of CD45+CD3−CD56+CD16+ NK cells were determined using four-color fluorescence flow cytometry and analyzed as a percentage of lymphocytes (%) and total NK concentration. In addition in n = 129 RM patients an uterine biopsy was taken during luteal phase to evaluate CD56+ NK cells by immunohistochemistry.
Main results and the role of chance: Patients with primary RM showed higher absolute pNK than patients with secondary RM (mean ± SD/µl 247.7 ± 123.8 vs. 205.7 ± 117.4, p = 0.01; 12.5% ± 5.7 vs. 11.1% ± 4.7, p = 0.04). In comparison to controls, there were higher NK percentages in idiopathic RM (controls: 10.5% vs. 12.1%, p = 0.02), non-idiopathic RM (12.1%, p = 0.04), primary RM (p = 0.007) but not in secondary RM patients (p = 0.40). With regard to uNK, there was no difference in uNK levels between the subgroups of RM and no correlation to pNK levels within the study population. However, seven idiopathic RM patients but none of the non-idiopathic RM patients showed strongly elevated uNK levels of >600/mm^2 (p = 0.06).
Limitations, reasons for caution: Whereas peripheral NK cells were studied in patients and controls, uterine biopsies for uNK cell analysis were only performed in patients but not in controls, limiting the conclusion.
Wider implications of the findings: A different immune etiology in primary compared to secondary RM might be responsible for altered pNK levels in these subgroups of RM patients. It seems that pNK and uNK are two distinct populations of immune cells and that both parameters need to be considered independently in RM patients.
Trial registration number: NA.

P-119 Multiple pregnancy after double embryo transfer is associated with a lower chance of miscarriage

E. Kolman[1], A.W. van den Belt-Dusebout[2], M. Spaan[2], I.M. Krul[2], E. Groeneveld[1], M. Hauptmann[2], F.E. van Leeuwen[2], C.B. Lambalk[1]
[1]*VU University Medical Centre, Gynaecology and fertility medicine, Amsterdam, The Netherlands*
[2]*Netherlands Cancer Institute, Epidemiology, Amsterdam, The Netherlands*

Study question: Are implantation rates (multiple pregnancy after double embryo transfer (DET)) associated with recurrent pregnancy loss (RPL) (two or more miscarriages)?
Summary answer: Women with RPL more often have lower implantation rates after DET.
What is known already: Angiogenesis is important in embryo implantation and recently it has been shown that RPL might be associated with increased instead of decreased angiogenesis. Women with RPL may be superfertile with as a result they may fail to discriminate between good and poor quality embryos, allowing implantation of all embryos including those with poor quality and consequently more often a clinical miscarriage as result. Therefore, we hypothesize that multiple pregnancy after DET resulting from optimal implantation might also associate with recurrent miscarriage both as implication of superfertility.
Study design, size, duration: We used the Dutch OMEGA cohort comprising 12,812 women who received at least one in-vitro fertilization (IVF) cycle

between 1983 and 2001. They were sent a questionnaire from 1997 till 2000 or from 2010 till 2013. Medical record data, including embryos transferred per woman per IVF cycle and the outcome, was linked to the questionnaire data. Number of miscarriages per woman was obtained from the women's questionnaires.

Participants/materials, setting, methods: Women were ordered according to their number of miscarriages in the following groups; zero miscarriages, one miscarriage and two or more miscarriages. Mean implantation rates were calculated from all IVF-cycles per woman. The association between mean implantation rate and total amount of miscarriages was estimated with an ordinal logistic regression. Sensitivity analyses were performed with implantation rate of each first IVF cycle per women and the maximum of all IVF cycles per woman.

Main results and the role of chance: There were 10,058 women (78.5%) without miscarriages, 1,922 women (15.0%) with one miscarriage and 832 women (6.5%) with two or more miscarriages. In the ordinal logistic regression we choose every step to be an increase of ten per cent. The odds ratio (OR) for mean implantation rate of all IVF cycles per woman was 0.86 (95% confidence interval (CI) 0.84 – 0.87). This means that for every ten per cent increase in implantation rate (for example from fifty per cent to sixty per cent) the OR of having RPL compared to having one miscarriage is 0.86 and this is the same for having one miscarriage compared to having zero miscarriages. ORs for first IVF cycle (0.92, 95% CI 0.90 – 0.93), for maximum implantation rate (0.91, 95% CI 0.90 – 0.93), for all women with a multiple embryo transfer (0.97, 95% CI 0.95 – 0.98) and for all women with a DET (0.96, 95% CI 0.94 – 0.97) were calculated. When excluding all nulliparous women ORs were similar, therefore all nulliparous women were kept in de final model.

Limitations, reasons for caution: Information about miscarriages was derived from the women's questionnaires and therefore may have been prone to recall bias. However, this is not very likely, because women probably were not aware of a possible association between implantation rate and miscarriages. Contribution of quality of embryos transferred could not be assessed.

Wider implications of the findings: Our results show that lower implantation rates are associated with RPL. Therefore either multiple pregnancy after DET or RPL is not representing superfertility. In contrast, based on the current findings a theoretical consequence may be that women with miscarriages may undergo DET with less risk of developing a multiple pregnancy.

Trial registration number: Not applicable.

P-120 Limitations of radiological screening tests in detection of subtle incomplete septum or arcuate uterine anomaly in patients with recurrent pregnancy loss (RPL)

O. Abuzeid[1], A. Abdullah[2], A.S.Z. Moustafa[2], J. Hebert[3], F. Rocha[4], M.I. Abuzeid[5]
[1]*Hurley Medical Center, Obstetrics and Gynecology, Flint, MI, USA*
[2]*IVF Michigan Rochester Hills & Flint, PC, Research, Rochester Hills, MI, USA*
[3]*Hurley Medical Center, Obstetrics and Gynecology, Program Director, Flint, MI, USA*
[4]*Hurley Medical Center, Obstetrics and Gynecology, Division of Maternal Fetal Medicine, Flint, MI, USA*
[5]*IVF Michigan Rochester Hills & Flint, PC, and Hurley Medical Center, Practice Director of IVF Michigan Rochester Hills & Flint, PC and Hurley Medical Center, Department of Obstetrics and Gynecology, Division of Reproductive Endocrinology and Infertility, Rochester Hills and Flint, MI, USA*

Study question: Evaluate the accuracy of hysterosalpingogram (HSG), trans-vaginal 2D ultrasound (2D US), and trans-vaginal 3D US in detecting subtle uterine anomaly in patients with RPL.

Summary answer: None of the radiological screening tests used in this study, alone or in combination, are accurate enough in detecting such anomalies in patients with RPL.

What is known already: In 50% of patients with RPL the etiology is unexplained. Our group has previously postulated that in infertile patients routine radiological tests are not accurate in the diagnosis of subtle uterine septum (Abuzeid et al.; ASRM, 2015; Corrado et al.; ASRM, 2013; Kallia et al.; ASRM, 2011). There is limited data on the association of subtle uterine septum and RPL and on the best method for detecting such anomalies. Hysteroscopic correction of significant uterine septum is associated with improved reproductive outcome in both infertile patients and patients with RPL.

Study design, size, duration: This is a retrospective study. The study included 120 consecutive patients with RPL who were found to have incomplete uterine septum (n = 62, 51.7%) or accurate anomaly (n = 58, 48.3%) on diagnostic hysteroscopy in the period between 1992 and 2014.

Participants/materials, setting, methods: The study included 120 RPL patients who were referred to our reproductive medicine unit in Flint, Michigan. We compared the findings on diagnostic hysteroscopy with the findings on various radiological tests that were used in the screening for such anomalies. Seventy five patients underwent HSG (62.5%); 109 patients underwent 2 D US (90.8%); 70 patients underwent 3 D US (58.3%); 79 patients underwent saline infusion hysterosonogram (SIH) with 3 D US (65.8%) before diagnostic hysteroscopy.

Main results and the role of chance: The diagnosis of subtle uterine septum or arcuate uterine anomaly was made on HSG in only 41 patients (54.7%). When 2 D US was used the diagnosis was made in 52 patients (47.7%). 3 D US was accurate in making the diagnosis in 42 patients (60.0%), while when SIH with 3 D US was used the diagnosis was correct in 49 patients (62.0%). When both HSG and 2D US were used (n = 68) the diagnosis was correct in 46 (67.6%). When both 3D US and 3D US with SIH were used (n = 62) the diagnosis was correct in 48 (77.4%).

Limitations, reasons for caution: One of the limitations of this study is its retrospective nature with the inherent bias of such design. Therefore further prospective studies with larger sample size are required to confirm our findings.

Wider implications of the findings: The data in this study suggest that some patients with unexplained RPL may in fact have subtle uterine anomaly. Therefore in patients with a history of RPL and negative radiologic tests a diagnostic hysteroscopy is the only reliable method to rule out subtle congenital anomalies of the uterine cavity.

Trial registration number: N/A.

P-121 The prevalence of mycoplasma and ureaplasma related chronic endometritis in women with a history of recurrent pregnancy loss (RPL)

W.H. Kutteh[1], A. Truong[2], R. Ke[1], P. Brezina[1], A. Bailey[1]
[1]*Vanderbilt University Medical Center, Obstetrics and Gynecolocy, Memphis, Tennessee, USA*
[2]*Rhodes College, Biology, Memphis, Tennessee, USA*

Study question: To determine the frequency of *Mycoplasma hominus* and *Ureaplasma urealyticum* associated chronic endometritis in 1,583 women with RPL compared to 263 infertile controls attending the same clinic.

Summary answer: *M. hominus* and *U. Urealyticum* cultures were positive significantly more in women with RPL 315/1583 (19.9%) than from infertile controls 27/263 (10.3%) [$p < 0.0001$].

What is known already: Evaluation of known causal factors in women with RPL reveals a possible etiology in 55% of patients (Jaslow, 2010). Untreated chronic endometritis may contribute to recurrent miscarriage ((McQueen, 2015). *Mycoplasma* and *ureaplasma* positive cultures are strongly associated with preterm delivery (Goldenberg, 2008). Diagnosis and treatment of *mycoplasma* following a first or later pregnancy loss significantly reduces pregnancy loss in the next pregnancy (Quinn, 1983). *Mycoplasma* and *ureaplasma* infections have been a proven cause of bovine abortion for over 35 years (Doig, 1981).

Study design, size, duration: Single-center, retrospective cohort study of 1,846 women from 2005 to 2015. RPL cases (1,583) and infertile controls (263) were compared. RPL evaluation included karyotypes on both partners, uterine cavity evaluation, lupus anticoagulant, antiphospholipid antibodies, TSH, HgbA1c, progesterone, and Factor V Leiden. Infertile couples had a hysterosalpingogram, semen analysis, and documentation of ovulation. All women had endocervical cultures for *M. hominus* and *U. urealyticum* on selective media. Positive cultures were considered abnormal.

Participants/materials, setting, methods: All women attended the same reproductive center. They were matched 6:1 (cases = RPL to controls = infertile) based on age (mean 32.6 years; range 20 to 42 years), race (72% white, 26% African, 2% Asian and other), BMI (mean 27.1), and socio-economic status. All cultures were obtained in selective transport media and sent to the same laboratory. Positive cultures required treatment of both partners with doxycycline 100mg BID for 14 days with test of cure cultures after four weeks.

Main results and the role of chance:

Table.

	Infertile controls	Recurrent loss	*p* Value	Relative risk (95% CI)
Number	263	1583		
Positive *M. hominus*	1 (0.01%)	66 (4.2%)	0.0172	10.9 (1.53–78.7)
Positive *U urealyticum*	26 (9.89%)	249 (15.7%)	0.0147	1.59 (1.09–2.33)
Positive one or both	27 (10.3%)	315 (20.0%)	0.0005	1.94 (1.34–2.81)
Negative	236 (89.7%)	1268 (80.0%)	0.0005	1.94 (1.34–2.81)

Significantly more women with RPL (315/1583); 20.0%) were colonized with *mycoplasma* and/or *ureaplasma* than infertile controls (27/236; 10.3%) [$p = 0.0005$]. When both partners were treated with doxycycline for two weeks the test of cure four weeks later was negative over 90% of the time when treating *mycoplasma* and over 80% of the time when treating *ureaplasma*. Resistant patients were treated with levofloxacin or erythromycin to achieve a final cure rate of 95%. All others had a daily suppressive dose of erythromycin during pregnancy. The strengths of this study are that patients and controls are matched, attended the same clinic, had cultures obtained from the same laboratory, had standard evaluations for RPL and infertility. The study was powered with 95% confidence to detect a 5% difference in positive culture results.

Limitations, reasons for caution: Based on the power analysis, the role of chance is very small but present. The limitations of the study include: it was not prospective in design, all couples with a positive culture were offered treatment, however 40% of women did not complete treatment or were lost to follow up.

Wider implications of the findings: Women who are colonized with mycoplasma and/or ureaplasma generally do not have symptoms of vaginal irritation, discharge, rash, or odor. Cultures to identify these pathogens are readily available, easily and economically treated, and may provide an answer to many couples with previously unexplained RPL.

Trial registration number: Not applicable.

P-122 Immunomodulation of the endometrium using oral prednisolone in unexplained recurrent miscarriage and normal or high level of uterine natural killer cell density in the endometrium

K. Labib[1], M. Ghaleb[1], M. Ramadan[1], A. Abdelkader[1]
[1]*Ain Shams University, Cairo, Faculty of Medicine, Cairo, Egypt*

Study question: Are uterine Natural Killer (uNK) cells involved in the aetiology of unexplained recurrent miscarriage? And if so, is immunomodulation of the endometrium using prednisolone effective with unexplained recurrent miscarriage?

Summary answer: High uNk cell density is associated with recurrent miscarriage, prednisolone can be used as an immunomodulatory treatment in unexplained recurrent miscarriage to improve pregnancy outcome.

What is known already: Recurrent miscarriage is the loss of three or more consecutive pregnancies**.** Despite a wide range of investigations, no apparent cause is found in more than 50% of women with recurrent miscarriage and they are categorized as idiopathic or unexplained recurrent miscarriage**.** Uterine Natural Killer (uNK) cells are the most predominant leucocytes in the endometrium and their density varies throughout the menstrual cycle. UNK cell density increases in number towards the mid-luteal phase and peaks in early pregnancy if implantation occurs. Increased density of uNK cells in pre-implantation endometrium has been found in women with recurrent miscarriage compared to fertile controls

Study design, size, duration: A randomized controlled trial was conducted on two hundreds and four women with unexplained recurrent miscarriage during the period between January 2014 and December 2015.

Participants/materials, setting, methods: 204women were recruited from the Recurrent Miscarriage Clinic. Endometrial samples were taken for immunohistochemical assay uNK cells. Then divided into two groups according to the uNK cells density in the endometrium: -Group(I): women with uNK cells ≥5%. -Group(II): uNK cells < 5%.

Then follow up to 12 months, till they spontaneously got pregnant. Then they were randomized-Subgroup(A) received oral prednisolone in addition to the standard empiric treatment. -Subgroups(B) received the standard empiric treatment only.

Main results and the role of chance: 154 women had an uNK percentage ≥5%, while 50 had an uNK percentage < 5%. This means that increased density of uNK in pre-implantation endometrium is associated with recurrent miscarriage and may predict subsequent miscarriage. The rates of first-trimester miscarriage were comparable in women of subgroups Ia and Ib. This means similar risk of first-trimester miscarriage. The rates of live-birth were lower in subgroup Ia when compared to subgroup Ib; the difference was however, statistically insignificant. The rates of second trimester miscarriage were significantly higher in women of group II when compared to women of group I (threefold higher rate of second trimester miscarriage). Pregnancy-induced hypertension has similar rates between four subgroups. Also, the results showed that higher uNK cell density in preimplantation endometrium is associated with FGR and immunomodulation of the endometrium using oral steroids is associated with lower rate of FGR, although this association is not statistically significant. Also, the prevalence of gestational DM in our study is 6.5% ($n = 153$, 10 (6.5%)) which is consistent with its prevalence in a given population or ethnic group.

Limitations, reasons for caution: To our best knowledge, no more studies in the literature were found comparing oral prednisolone use in women with unexplained recurrent miscarriage with high or normal level of uNK cell density in the endometrium and the prognosis of pregnancy outcome which made our study results difficult to interprete.

Wider implications of the findings: We have demonstrated that high uNK cell density in preimplantation endometrium is associated with recurrent miscarriage and may predict subsequent miscarriage and administration of oral prednisolone in comparison to standard empiric treatment is not associated with significantly improving pregnancy outcome.

Trial registration number: We are in the process of registration on www.clinicaltrials.gov.

P-123 Recurrent pregnancy loss – what is the impact of consecutive versus non-consecutive losses?

O.B. Christiansen[1,2], P. Egerup[1], A.M. Kolte[1], E.C. Larsen[1], H.S. Nielsen[1]
[1]*Copenhagen University Hospital Rigshospitalet, Fertility Clinic 4071, Copenhagen, Denmark*
[2]*Aalborg University Hospital, Department of Obstetrics and Gynaecology, Aalborg, Denmark*

Study question: Is the prognostic impact of consecutive early pregnancy losses different from that of non-consecutive losses in women with secondary recurrent pregnancy losses (RPL)?

Summary answer: Only consecutive early pregnancy losses after the last live birth exhibit a statistically significant negative prognostic impact in women with secondary RPL.

What is known already: There is consensus that the risk for new pregnancy loss increases with the number of previous pregnancy losses in patients with RPL and that second trimester losses exhibit a stronger negative impact than early losses. It is unknown whether the sequence of early pregnancy losses plays a role for the prognosis in patients with a prior birth.

Study design, size, duration: Retrospective cohort study of pregnancy outcome in patients with unexplained secondary RPL included in three previously published Danish double-blinded placebo-controlled trials of intravenous immunoglobulin (IvIg) conducted from 1991 to 2014. No other treatment was given. In two of the trials only patients with a minimum of four previous pregnancy losses were included. Six patients with documented explained pregnancy losses (clinical ectopic pregnancies and aneuploid miscarriages) in the trials were excluded.

Participants/materials, setting, methods: Among a total of 168 patients included, 127 had secondary RPL of whom 52.8% had a subsequent pregnancy loss. Data were analyzed by multivariate analysis including the independent variables: age, number of early pregnancy losses before and after the last live birth, respectively; a second trimester pregnancy loss before or after the last live birth, respectively; number of live births and presence of stillbirth. The outcome variable was unexplained loss in the first subsequent pregnancy.

Main results and the role of chance: In women with secondary RPL both a late and each early loss happening before the last live birth did not significantly impact the risk of new pregnancy loss in the trials: RR 1.31 (95% CI 0.62–2.77, $p = 0.48$) and RR 0.88 (95% CI 0.70–1.11, $p = 0.29$), respectively. In

contrast, the impact on risk of pregnancy loss during participation in the trials conferred by a late and each early pregnancy loss happening after the live birth was significant: RR 2.15 (95% CI 1.57–2.94, $p < 0.0001$) and RR 1.14 (95% CI 1.04–1.24, $p = 0.002$), respectively. None of the other independent variables exhibited significant impact on pregnancy outcome.
Limitations, reasons for caution: Forty-eight percent of the patients were treated with IvIg, which could in principle influence the results. However, allocation to IvIg was completely random and prognostic variables were equally distributed in IvIg and placebo treated patients. The number of patients was limited.
Wider implications of the findings: The finding that a live birth eradicates the negative prognostic impact of pregnancy losses happening before the birth in patients with secondary RPL has importance for our understanding of the pathogenesis. It emphasizes that only consecutive pregnancy losses not intervened by a birth should count in the definition of RPL.
Trial registration number: In the third Ivig trial: NCT00722475.

P-124 Effect of JAR spheroids on endometrial stromal cell decidualization

L. Hu[1], G. Xiaoyi[1], S. Yingpu[1]
[1]*The First Affiliated Hospital of Zhengzhou University, Reproductive Center, Zhengzhou, China*

Study question: To study the cell cycle in endometrial stromal cell decidualization and the effect of JAR spheroids on endometrial cell decidualization.
Summary answer: Decidualized endometrial stromal cells break through the cell cycle arrest in S phase after co-cultured with JAR spheroids and prepare for embryo implantation.
What is known already: Decidualization is a critical step during embryo implantation and characterized by the differentiation of endometrial stromal cells (ESCs) into decidual cells. Estrogen and progestogen promote endometrial stromal cell exit from the cell cycle and enter differentiation. More cells arrest in G0/G1 phase. Cell cycle inhibitor P27, P57 expression are improved in decimalized endometrial stromal cells.
Study design, size, duration: The ESCs from normal proliferative endometrial tissues (five patients) were isolated from normal cycling women by endometrial biopsy at the time of diagnostic laparoscopy for fallopian tube obstruction. Histological examination revealed normal endometrium. All cells were used at the third passage.

After induced decidualization with 0.5 mM 8-Br-cAMP and 10^{-6} M MPA for four days, ESCs are co-cultured with JAR spheroids for 2h in a incubator with a shaking table to avoid the spheroids attachment.
Participants/materials, setting, methods: The ESCs from normal proliferative endometrial tissues (five patients) were isolated from normal cycling women by endometrial biopsy at the time of diagnostic laparoscopy for fallopian tube obstruction. Histological examination revealed normal endometrium.
Reproductive center: RT-PCR western blot, immunofluorescence.
Main results and the role of chance: After co-cultured with JAR spheroids, P27, P57 expression in endometrial stromal cell are decreased when compared with the decidualization group ($P < 0.05$) both in mRNA and protein level. The expression of LIF and integrin beta3 are improved when compared with the decidualization group. JAR spheroids induce decidualized ESCs break through the arrest of cell cycle and prepare for embryo implantation/JAR spheroids attachment.
Limitations, reasons for caution: JAR spheroids could not replace real embryos.
Wider implications of the findings: The mechanism of the embryo implantation is subtle, and decidualization of ESCs is critical. We explained the cell cycle change of ESCs before JAR spheroids attachment and might help with the exploration of the dialogue between embryos and ESCs.
Trial registration number: None.

P-125 Expression of TRPV4 exposed to estrogen in the pathophysiology of tubal ectopic pregnancy

C. Fung-Wei[1], G.J. Wu[1], R.J. Hsu[2]
[1]*Tri-Service General Hospital, National Defense Medical Center, Reproductive Medical Center, OBS&GYN, Taipei, Taiwan R.O.C.*
[2]*Tri-Service General Hospital, National Defense Medical Center, Pathology and Graduate Institute of Pathology and Parasitology, Taipei, Taiwan R.O.C.*

Study question: The role of estrogen in the motility of fallopian tube cilia may lead to tubal ectopic pregnancy.
Summary answer: High level of estrogen acting through the motility of cilia on fallopian tube, may potentially lead to tubal ectopic pregnancy.
What is known already: The role of estrogen in the pathophysiology of tubal ectopic pregnancy.
Study design, size, duration: Open-label, non-randomized trial. The fallopian tubes were collected from five women with tubal pregnancy and five multiparity women with tubal sterilization from 2013 to 2014.
Participants/materials, setting, methods: The fallopian tubes were collected from five women with tubal pregnancy and five multi-parity women with tubal sterilization. The TRPV family were measured by quantitative real time polymerase chain reaction. The mRNA and protein expressions of estrogen and progesterone receptor in the ectopic implantation site and chorionic villi were examined. Moreover, we investigated the biological effects of estrogen and progesterone on TRPV4 using epithelial ovarian cancer SKOV3 cells.
Main results and the role of chance: TRPV4 expression was significantly decreased in ectopic implantation site and chorionic villi compared with normal fallopian tube tissues. Lower expression of TRPV4 in SKOV3 cells was associated with the concentration of estrogen ($P < 0.05$). In contrast, TRPV4 expression was significantly increased in high level of progesterone.
Limitations, reasons for caution: Limitation: We substituted the epithelial ovarian cancer SKOV3 cells for the normal fallopian tube cells. The physiology of cells might be different.
Wider implications of the findings: Estrogen and progesterone signals might contribute to the pathology of tubal cilia function by the expression of TRPV4 and provide better understanding on their respective roles in fallopian tube physiology and tubal ectopic pregnancy pathophysiology and etiology.
Trial registration number: Not clinical trial.

P-126 Identifying maternal constraints on fetal growth and subsequent perinatal outcomes using a multiple embryo implantation model

N. Pereira[1], T. Cozzubbo[1], S. Cheung[1], Z. Rosenwaks[1], G.D. Palermo[1], Q.V. Neri[1]
[1]*Weill Cornell Medical College, Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, NY, USA*

Study question: We question whether adverse perinatal outcomes associated with assisted reproductive techniques (ART) occur as a result of epigenetic insults or due to maternal physiologic adaptations.
Summary answer: Our findings suggest that embryonic implantation sites during early gestation set the growth profile of each embryo, dictating later growth patterns and the gestational length.
What is known already: ART contributes to 1–2% of all live U.S. births annually. In recent years, there has been concern about the safety of ART, particularly *in vitro* fertilization (IVF). While the majority of singleton births after IVF are uncomplicated, studies have suggested that IVF pregnancies may be independently associated with increased risks of low birth weight (LBW), preterm birth, and perinatal mortality. These outcomes complicate multiple gestations as expected, but have also been reported in singleton conceptions. A multiple embryo implantation model allows for assessment of the early in utero environment, and therefore, assessment of any maternal constraints on developing fetuses.
Study design, size, duration: Retrospective, single-center study of ART cycles during a 16-year period were categorized according to the number of embryos transferred, those that implanted, and the actual number of live births. For each positive pregnancy test 10–15 days after embryo transfer, an ultrasonogram was performed to record the number of gestational sacs, fetal poles, and cardiac activity for each individual implanted embryo at 6–7 gestational weeks.
Participants/materials, setting, methods: Data from patients who were treated with ART, specifically intracytoplasmic sperm injection (ICSI), were collected. Controlled ovarian stimulation (COS), hCG trigger, oocyte retrieval and sperm injection were performed as per our standard protocols. First trimester implantation sites that resulted in live births were defined as "true" to distinguish them from those that spontaneously reduced called "virtual." All pregnancies with selective reduction were excluded. Birth outcomes analyzed included birth weight and gestational age at delivery.
Main results and the role of chance: A total of 17,415 cycles were analyzed. The average maternal age was 36.9 (±5.0) years. An overall fertilization rate of

73.4% generated approximately 48,708 good quality cleavage-stage embryos. In most patients (92.8%), an average of 3 embryos was transferred. The clinical pregnancy rate was 39.2% (n = 6,281). The overall occurrence of multiple gestations was 38.2% (n = 2,608) consisting of 2,038 twin, 511 triplet, and 59 quadruplet pregnancies. Of these multiple gestations, 18.6% of twin, 54.2% of triplet and 76.3% of quadruplet gestations spontaneously reduced. Failure of the implanted embryo to progress was not related to maternal age, embryo morphology or quality. Singleton newborns resulting from multiple implantation sites had lower birth weights (P < 0.01) and shorter gestational ages (P < 0.01) than those from a single implanted embryo. The number of embryos transferred did not affect the gestational length of singleton newborns. However, when more than one embryo implantation site was established, the proportion of births prior to 37 weeks of gestational age increased progressively (P < 0.01). Although the birth weights of singletons from multiple implantation sites (virtual singletons) were lower than true singletons, the birth weight of virtual singletons were comparable to the birth weights of true twin, triplet, and quadruplet live births.

Limitations, reasons for caution: While our study suggests that multiple embryo implantation is associated with lower birth weights and shorter gestational ages in singleton newborns, it must be noted that a myriad of maternal and uteroplacental factors ultimately determine in utero growth and development of fetuses.

Wider implications of the findings: Our study highlights that early in utero stress represented by multiple embryo implantations confers greater perinatal risk to the surviving fetus. Given the correlation between adverse perinatal outcomes and adult cardiovascular disease, diabetes, and dyslipidemia, avoidance of such stressors by reducing the number of embryos transferred assumes paramount importance.

Trial registration number: Not applicable.

P-127 The role of adjuvant treatment in unexplained recurrent miscarriage

S. Dobson[1], A. Dhanaliwala[2], M. Cook[2], E. Macowvic[1], J. Keeley[3], J. Moore[1], K. Jayaprakasan[4,5]
[1]*Nottingham City Hospital, Obstetrics and Gynaecology, Nottingham, United Kingdom*
[2]*Queen's Medical Centre, Obstetrics and Gynaecology, Nottingham, United Kingdom*
[3]*Nottinghamshire Healthcare, Primary Care, Nottingham, United Kingdom*
[4]*Derby Fertility Unit, Gynaecology, Derby, United Kingdom*
[5]*University of Nottingham, Division of Obstetrics and Gynaecology, Nottingham, United Kingdom*

Study question: To assess the role of adjuvant treatment on improving outcomes after recurrent miscarriage (RM).

Summary answer: Empirical adjuvant treatment for the management of unexplained RM does not appear to offer any benefit. Prognosis with early pregnancy support alone is good.

What is known already: RM affects 1% of couples and is associated with significant psychological distress. Based on the current evidence base, RM patients are investigated for anti-phospholipid syndrome, karyotyping, structural abnormalities of the uterus and for patients with second trimester losses, thrombophilia. While there is no definitive treatment that can be offered in unexplained RM, various treatments including progesterone, aspirin, low molecular weight heparin and corticosteroids are often prescribed by clinicians, despite a lack of supporting evidence. This is because of the fact that patients who suffer RM are a vulnerable population, often desperate to try any adjuvant treatments suggested.

Study design, size, duration: A review of all patients (N = 301) attending recurrent miscarriage clinic between May 2013 and January 2015, to allow a minimum of one year follow up, was undertaken at two large teaching hospitals in the UK. Inclusion criteria specified that only women who had suffered ≥3 consecutive miscarriages were included. Patients with <3 consecutive miscarriages or with incomplete follow up data were excluded leaving a cohort of 242 patients.

Participants/materials, setting, methods: Data including demographics, past medical history, results of screening tests, adjuvant treatments given and outcomes of subsequent pregnancies were collected from the hospital patient records and entered onto a spreadsheet database. A statistical Package for the Social Sciences was used to analyse the relationship between demographic data and the outcome data. Multiple logistical regression analysis was used to assess the effect of variables on future pregnancy outcomes. P-value of < 0.05 was statistically significant.

Main results and the role of chance: 33.1% of women had abnormal investigations and 66.9% had an unexplained recurrent miscarriage. While the chances of having a live birth in both the unexplained (74.2%) and explained (64.5%) groups were similar (P = 0.35), empirical adjuvant treatment for unexplained RM did not confer any benefit compared to expectant management alone (67.9% vs. 76.7% respectively; P = 0.5). The prevalence of antiphospholipid syndrome (lupus anticoagulant, anticardiolipin antibodies and anti-Beta2 glycoprotein-I antibodies), thrombophilia, thyroid disease, parental karyotype abnormalities and structural uterine abnormalities were 7.4%, 4.5%, 6.6%, 2.9% and 6.6% respectively. Among all the variables (age, number of previous miscarriages, smoking or ethnicity) analysed, age alone was the significant predictor of future live birth (OR: 0.94; 95% CI: 0.94; 0.888–0.997; P < 0.05) and of the possibility of pregnancy within one year of follow up (OR: 0.936; 95% CI: 0.936; 0.89–0.998; P < 0.05).

Limitations, reasons for caution: While the study design was an observational cohort study, it had a diverse population of patients from two large teaching hospitals. We were unable to adjust for confounding factors, with some patients being screened positive for more than one abnormal test and some taking more than one empirical adjuvant treatment.

Wider implications of the findings: More than three quarters of women with a history of unexplained RM will have a live birth in their subsequent pregnancy with conservative management alone. Patients should be informed of this and the practice of prescribing adjuvant treatment should be restricted except in the context of a large RCT.

Trial registration number: N/A.

P-128 Antimullerian hormone as predictor of miscarriage in unexplained repeat pregnancy loss women under 35 years old

G.S. Lee[1], J. Rhee[1], J. Kim[1], J. Park[1]
[1]*Keimyung University School of Medicine, Obstetrics and Gynecology, Daegu, South Korea*

Study question: The aim of this study was to evaluate if antimullerian hormone (AMH) was associated with pregnancy loss in young unexplained repeat pregnancy loss (RPL) women.

Summary answer: AMH values were not associated with repeat pregnancy loss in unexplained RPL women under 35 years old.

What is known already: Genetic cause, anatomic cause, and antiphospholipid syndrome are the only undisputed causes of RPL. Approximately 50% of cases of RPL are classified as unexplained. Advanced maternal age is related with miscarriages, which is predisposed to a greater risk of fetal aneuploidy. It has been proposed biological ovarian age is more important than chronologic age. AMH is well correlated with diminished ovarian reserve, readily used for predicting the oocytes' quantity in IVF cycle. Some studies regarding the relationship between AMH and miscarriage have been tried. However, the prospective study and evidence is still lack, especially in young women.

Study design, size, duration: Ninety nine women suffered three more miscarriage were consecutively registered as unexplained RPL after excluding the genetic, anatomic, endocrinological cause from January 2014 through December 2015. After excluding women over 35 years, 69 women diagnosed as unexplained RPL were enrolled.

Participants/materials, setting, methods: Maternal serum AMH levels were defined as low (< 1.0 ng/ml), normal (1.0–3.5 ng/ml) and high (> 3.5 ng/ml). To compare other etiological causes, Natural killer cell proportion, protein C activity, protein S activity, antithrombin III, homocystein and plasminogen activator inhibitor-1 (PAI-1) were evaluated. Pregnancy rate and miscarriage rate were compared among the groups. All spontaneous abortus were performed the cytogenetic study for checking the aneuploidy.

Main results and the role of chance: Mean age of each groups were not different as 33.75 ± 1.26 in low AMH, 31.95 ± 1.83 in normal AMH, and 31.02 ± 2.95 in high AMH group. Parity and previous miscarriage number were not different among the groups either. Natural killer cell proportion was elevated in 34 women. 8 cases of protein S deficiency and 3 cases of hyperhomocysteinemia were found. No significant difference was among the groups. And also, mean value of NK cell proportion, protein C activity, protein S activity, antithrombin

III, homocystein and PAI-1 were similar. Pregnancy rate in normal AMH group was 9/21 (42.9%), similar with 19/44 (43.2%) of high AMH group. Miscarriage rates were also similar between normal and high AMH group such as 33.3%, and 36.8% respectively. In low AMH group, only one women could be pregnant and suffered miscarriage again. Among total 11 abortus, 4 fetus were revealed as aneuploidy.

Limitations, reasons for caution: Because of the limited number of this study, further longitudinal studies with larger sample sizes are required.

Wider implications of the findings: The relationship of AMH and miscarriage is still unclear. It is important to find that the preconceptinal biological marker to predict the risk of miscarriage in a future pregnancy. It could be used for family planning and counselling.

Trial registration number: NO 12-262

P-129 Serum and tissue concentration of vascular endothelial growth factor (VEGF) in ampullary ectopic pregnancy and the depth of trophoblastic invasion

D.R.K. Teshima[1], F.R. Cabar[1], P.P. Pereira[1], R. Schultz[2], L. Antonangelo[3], R.P. Francisco[1]

[1]Faculty of Medicine, University of São Paulo, Department of Obstetrics and Gynecology, São Paulo, Brazil

[2]Faculty of Medicine, University of São Paulo, Department of Pathology, São Paulo, Brazil

[3]Faculty of Medicine, University of São Paulo, Department of Pathology and Medical Research Laboratory 03, São Paulo, Brazil

Study question: To evaluate the correlation between serum concentration and tissue expression of VEGF and to associate the depth of trophoblastic invasion into the tubal wall with tissue VEGF in ampullary pregnancies

Summary answer: The depth of trophoblastic penetration into the tubal wall is not associated with tissue VEGF expression. Serum VEGF do not show correlation with tissue expression

What is known already: The implantation site in the tubal wall is different from well-vascularized endometrium and the concentration of VEGF seems to be elevated in ectopic pregnancy to accommodate to this unfavorable environment. Previous studies showed that higher serum VEGF concentrations is related to deeper invasion of trophoblastic tissue into the tubal wall.

Since there is greater expression of VEGF in ectopic pregnancy implantation site and that higher serum levels of VEGF are found in pregnancies with deeper trophoblastic invasion and, VEGF tissue concentration would also be correlated with the depth of trophoblastic invasion into the wall of the oviduct.

Study design, size, duration: A prospective study was conducted on patients with a diagnosis of tubal pregnancy in the ampullary region who were submitted to salpingectomy between July 11th, 2012 and August 19th, 2013.

Inclusion criteria were spontaneous conceived singleton pregnancies, diagnosis of tubal pregnancy in ampullary portion, radical surgical treatment (salpingectomy), and measurement of serum VEGF.

Exclusion criteria were: not ampullary pregnancy, impossibility of collecting blood sample, impossibility of either anatomopathological or tissue VEGF analysis.

Participants/materials, setting, methods: 63 cases were recorded. Forty two patients fulfilled the inclusion criteria and then 8 were excluded. Blood samples were collected to determine serum VEGF concentration with Luminex. Histologically, trophoblastic invasion into the tubal wall was classified as grade I when limited to the tubal mucosa, grade II when reaching the muscle layer and grade III when comprising the full thickness of the tubal wall. Tissue VEGF expression was measured by immunohistocemistry and point counting technique.

Main results and the role of chance: Histological analysis showed that 8 patients (23.5%) had stage I tubal infiltration, 7 (20.6%) had stage II, and 19 (55.9%) had stage III. The gestational age ranged from 28 to 95 days (53.2 ± 14.5 days), and there was no significant difference in mean gestational ages among the three histological groups ($p = 0.604$).

Serum VEGF concentrations on the day of surgery ranged from 0.36 to 205.16 pg/mL (median 14.77 pg/mL) and the median tissue VEGF percentage was 16.07 (range, 3.44–50.14). According to Kruskal-Wallis' test, the difference between the percentage of tissue VEGF was not significant in relation to the degree of trophoblastic invasion ($p = 0.621$).

Serum levels of VEGF did not show any correlation to its tissue expression. The Spearman's coefficient (Rho = –0.057) presented a weak correlation between these two variables ($p = 0.748$).

Multivariate logistic regression analysis was performed and the variable tissue VEGF was included in order to compare its performance as a predictive factor of depth of trophoblastic invasion into oviduct wall. Grade I versus II and III ($p = 0.321$) were compared and III versus I and II ($p = 0.230$). We observed that tissue VEGF showed no statistical difference for prediction of both degrees of trophoblastic invasion

Limitations, reasons for caution: no limitation or reasons for caution.

Wider implications of the findings: The percentage of tissue VEGF was similar in the three degrees of trophoblastic invasion. Different from previous studies, this finding suggests that VEGF at the site of tubal implantation appears not to be related to trophoblastic invasion and maybe other still unknown growth factors may contribute to this process.

Trial registration number: no trial registration number.

P-130 Abnormal human chorionic gonadotropin (hCG) trends in viable singleton pregnancies after transfer of multiple embryos

P. Brady[1], L. Farland[1,2], S. Missmer[1,2,3], C. Racowsky[1], J. Fox[1]

[1]Brigham and Women's Hospital, Obstetrics, Gynecology and Reproductive Biology, Boston, USA

[2]Harvard School of Public Health, Epidemiology, Boston, MA, USA

[3]Brigham and Women's Hospital, Channing Division of Network Medicine, Department of Medicine, Boston, MA, USA

Study question: Among viable singleton pregnancies, is the incidence of an abnormal early hCG rise increased following transfer of multiple embryos compared to single embryo transfer (ET)?

Summary answer: Abnormal hCG rises were significantly more common in singleton pregnancies after transfer of two or more embryos.

What is known already: Serial serum hCG levels are used to monitor early pregnancies following *in vitro* fertilization (IVF) treatment. An abnormal hCG trend, commonly defined as a rise less than 66% in 2 days, is concerning for a failing or ectopic pregnancy. This finding generates significant patient anxiety and may result in interventions that could interrupt a viable pregnancy. To our knowledge, no previous studies have assessed the association between the number of embryos transferred and abnormal hCG trends during very early pregnancy.

Study design, size, duration: Retrospective cohort study of 2001 successful IVF/ICSI cycles resulting in singleton live births (629 cycles with single ET and 1372 cycles with transfer of two or more embryos), between 2005 and 2014. First hCG levels were checked approximately 12 days after ET (range 7–20 days), with subsequent values checked at 2 day intervals whenever possible.

Participants/materials, setting, methods: Fresh or frozen autologous IVF/ICSI cycles with day 3 or day 5 ET were included if only one gestational sac was detected on ultrasound with a singleton live birth beyond 24 weeks of gestation. Logistic regression models were adjusted for oocyte age to estimate the Odds Ratio of having an abnormal hCG rise (<66% in 2 days).

Main results and the role of chance: The mean initial hCG values among patients receiving a single embryo or multiple embryos were 381.0 and 382.5 mIU/mL, respectively. Among patients receiving two or more embryos, 6.1% ($n = 84$) had abnormal rises between the first and second hCG measurements, compared to 2.7% ($n = 17$) of patients undergoing single ET ($p = 0.005$, OR 2.16, 95% confidence interval 1.26–3.71). Addition of the following variables to the base model did not significantly alter the association of embryo number and odds of an abnormal hCG rise: Maternal age at ET, reproductive history, infertility diagnosis, body mass index, day of ET, fresh versus frozen embryos, embryo quality, use of ICSI or assisted hatching, or endometrial thickness. Among patients with abnormal rises between the first and second hCG measurements, 89% had third hCG levels measured. In this group, normal hCG rises (>66% in 2 days) were observed between the second and third levels in 73% of patients who underwent single ET and 77% of patients who received multiple embryos.

Limitations, reasons for caution: In 20% of patients, initial hCG levels were not checked 2 days apart (range: 1–9 days); these measurements were log transformed to calculate the 2-day percent rise, in accordance with previous studies demonstrating a log-linear increase in early hCG. These findings may not be applicable to pregnancies conceived without IVF.

Wider implications of the findings: Patients with multiple embryos transferred who deliver singletons are more likely to have suboptimal early hCG rises, potentially due to transient implantation of other non-viable embryo(s). While useful for counseling, these findings should not change standard management of abnormal hCG rises following IVF. Third hCG measurements may clarify pregnancy prognosis.
Trial registration number: N/A.

P-131 Supplementation of hMG decreases early pregnancy loss in the rFSH GnRH antagonist cycles complicated with low LH levels in both young and older ages

P.K. Yang[1], J.H. Yang[1], C.D. Chen[1], M.J. Chen[1], S.U. Chen[1], Y.S. Yang[1]
[1]National Taiwan University Hospital, Obstetrics and Gynecology, Taipei City, Taiwan R.O.C.

Study question: Whether the addition of hMG for patients complicated with low LH during COS using GnRH antagonist protocol achieves better pregnancy outcome compared to rFSH-alone in patients of different age groups.
Summary answer: Patients with low LH levels during rFSH antagonist protocols, addition of hMG reduces spontaneous abortion rates compared to rFSH-alone in both young and old ages
What is known already: The role of LH during COS remains controversial, and there has been no consistent proof that the addition of LH supplements during COS results in improvements in outcomes. Although LH deficiency has been reported in the past with varying sequelae in specific populations, it has been assumed that the LH levels in the general population receiving GnRH antagonist cycles are adequate. Our previous study have related a low cycle LH nadir with an increase in spontaneous abortion rate. It has not been shown if the addition of LH activity is associated with an improvement in outcome in young patients.
Study design, size, duration: This is a retrospective cohort comprising of 284 patients with low LH levels that were drawn from 1356 patients receiving COS using antagonist protocol between 2011 and 2014. LH levels were examined on day 2 of the cycle, 4 days after and then every 1–3 days until day of hCG. There is no loss of follow-up for the primary endpoint, which is implantation rate, pregnancy rate, and early pregnancy loss rate.
Participants/materials, setting, methods: The 1356 patients receiving GnRH antagonist protocols using rFSH or rFSH-hMG with fresh transfers were recruited. Patients with polycystic ovarian disease, hypogonadotropic hypogonadism, hyper-responders or poor responders had been excluded. The low LH is defined by a nadir ≦ 0.8 mIU/mL during COS. In the 284 patients with low LH, 174 patients received rFSH only and 110 received supplementation with hMG. Pregnancy rates, implanation rate, and spontaneous abortion rates were compared between the two groups.
Main results and the role of chance: A total of 1356 patients were recruited for analysis. We found that at least one episode of low serum LH, defined by LH ≦ 0.8 mIU/mL during COS, occurred in 284 (20.9%) patients. An analysis of the risk factors showed that age is related to the occurrence of low LH, and exhibits a decreasing trend with age (OR: 0.858, $P = 0.036$). In these 284 patients with low LH, pregnancy outcomes were compared between those receiving rFSH ($n = 174$) and those receiving rFSH-hMG ($n = 110$). The rFSH-hMG group was associated with decreased incidence of spontaneous abortions (11.5% vs. 26.7%, $P = 0.045$). The improvements in early pregnancy loss were particularly significant in younger patients (≦37 years) (4.8% vs. 20%, OR: 0.20, $P = 0.036$) and those with the occurrence of low LH before use of GnRH antagonist (3.3% Vs. 29.0%, OR: 0.08, $P = 0.012$).
Limitations, reasons for caution: The limitation of the study is in the retrospective nature of the study. Our study population is limited to the normal population and excludes polycystic ovarian disease, hypogonadotropic hypogonadism, hyper-responders and poor responders. A prospective analysis is warranted.
Wider implications of the findings: Analysis of the risk factors of low LH levels in GnRH antagonist protocol showed that younger age is related to higher occurrence of low LH. In patients receiving rFSH GnRH antagonist, it is prudent to follow LH levels to optimize cycle outcome for each patient, not limiting to older age.
Trial registration number: Nil.

P-132 Analysis of 1287 patients having unexplained spontaneous miscarriage: search for a possible etiology

B.N. Chakravarty[1], P. Chakraborty[2], S.K. Goswami[1], R. Chattopadhyay[1], S. Ghosh[1], G. Ganguly Mukherjee[2], M. Chakravarty[2], S.N. Kabir[3]
[1]Institute of Reproductive Medicine, ART, Calcutta, India
[2]Institute of Reproductive Medicine, Infertility, Calcutta, India
[3]CSIR-Indian Institute of Chemical Biology, Reproductive Biology Research, Kolkata, India

Study question: Is there any hidden etiology underlying unexplained spontaneous miscarriage (USM)?
Summary answer: Higher risk of USM in women with polycystic ovary syndrome (PCOS) is possibly due to high prevalence of hyperhomocysteinemia (HHcy) irrespective of number of miscarriages.
What is known already: Apparently-unexplained miscarriage is frustrating to the couple and perplexing to the clinicians. Moreover, the background etiology if not explored and treated at the outset, similar mishaps are likely to recur, eventually leading to well recognized clinical situation of recurrent USM. It is widely accepted that high prevalence of obesity and insulin resistance (IR) are directly related to miscarriage. A number of studies document a close association between IR and HHcy, the later being a frequent finding in our study. However, the importance of single unexplained miscarriage and the possibility of its recurrence have not been widely studied.
Study design, size, duration: A five-year prospective study including one thousand two hundred and eighty-seven women having the previous history of USM was conducted at Institute of Reproductive Medicine, Kolkata, India during November 2010–December 2015. Presence or absence of PCOS as judged by Rotterdam consensus was the initial dividing criteria while the number of miscarriage (1–2: category A; 3–4: category B, and ≥5: category C) and the presence of HHcy, IR or obesity were the basis of subsequent stratifications.
Participants/materials, setting, methods: The subjects were evaluated for uterine defects, karyotyping, thyroid disorder, HHcy, obesity, IR, thrombophilic (anticardiolipin), and infective (toxoplasma and rubella) disorders. Log-linear regression was used to determine the relative risk (RR) of USM for HHcy, IR and obesity. Student's *t*-test was used to test the difference between PCOS and non-PCOS groups while multivariate logistical regression model was used to assess the effect of homocysteine and other confounding factors like PCOS and body mass index (BMI).
Main results and the role of chance: Of the 1287 subjects, 694 had PCOS. The representation of different categories of USM in PCOS sub-population was A: 50.72% ($n = 352$), B: 36.45% ($n = 253$) and C: 12.82% ($n = 89$) as compared to A: 71.83% ($n = 426$), B: 23.10% ($n = 137$), and C: 5.06% ($n = 30$) in the non-PCOS population. The incidence of HHcy, IR and obesity was 45.67% ($n = 317$), 52.16% ($n = 362$), and 29.11% ($n = 202$), respectively, in PCOS population, which was significantly higher as compared to the non-PCOS set (HHcy: 27.65% ($n = 164$; $p < 0.04$); IR: 6.74% ($n = 40$; $p < 0.0001$); obese: 10.96% ($n = 65$; $p < 0.01$)). Hyperhomocysteinemic (RR: 0.65; 95% confidence interval (CI): 0.51–0.82), IR (RR 0.73; 95% CI: 0.51–1.02) and obese women (RR: 0.87, 95% CI: 0.74–1.03) had significantly higher chances of miscarriage. No correlation was found between miscarriage and genetic, metabolic, thrombophilic, infective and anatomical aspects. Serum homocysteine had an individual strong association with USM [odds ratio (OR): 2.01, 95% CI: 1.13–3.58) among all categories in the PCO cohort irrespective of number of miscarriages. However, using multivariate logistic regression analysis this effect was reduced to a non-significant level after adjusting for serum homocysteine [OR = 1.10, 95%CI 0.85–1.36] and all other confounding factors considered (OR = 0.98, 95% CI 0.75–1.28).
Limitations, reasons for caution: Despite including a large number of patients and using the statistical adjustment for confounding variables as homocysteine levels, PCOS, and BMI, the prospective observational analysis could not adjust for many known potential confounders, e.g., age, previous miscarriage, and infection.
Wider implications of the findings: It seems rational to diagnose the cause of the first pregnancy loss and offer treatment for better prognosis of recurrent USM. The possible involvement of HHcy, particularly in women with PCOS, may be taken into account in this direction.
Trial registration number: Not applicable.

P-133 Hyperhomocysteinemia induced soluble fms like tyrosine kinase overactivity leads to pregnancy loss in rats

P. Chakraborty[1], S. Yasmin[1], S.K. Goswami[2], M. Pal[3], B. Ghosh[2], S. Ghosh[2], R. Chattopadhyay[2], B.N. Chakravarty[2]
[1]*Institute of Reproductive Medicine, Infertility, Calcutta, India*
[2]*Institute of Reproductive Medicine, ART, Calcutta, India*
[3]*Vidyasagar College, Department of Zoology, Kolkata, India*

Study question: Does hyperhomocysteinemia (HHcy) influence placental thrombosis and what is the possible mechanism of action?
Summary answer: Increased soluble fms-like tyrosine kinase (sFlt-1) inhibits vasculo-endothelial growth factor (VEGF) leading to placental thrombosis and pregnancy loss in hyperhomocysteinemic rats.
What is known already: Mild-to-moderate HHcy, a risk factor for arterial and venous thrombosis, has been suggested as a possible threat to women with habitual abortions or placental abruption. Pathogenesis of vascular disease associated with homocysteine induces oxidative stress (OS) and thereby endothelial dysfunction. A hypothesis of endothelial dysfunction by excess placental secretion of sFlt-1 has recently been proposed which inhibits VEGF in the vasculature. Though HHcy, OS and thrombosis are interrelated, the directionality of that association is unclear. A better understanding of how HHcy effects pregnancy loss may help improve diagnosis in HHcy associated miscarriage.
Study design, size, duration: 40 female Sprague-Dawley rat of 5–6 week of age were mated to control males. Post pregnancy, they were divided into two groups comprising 20 female each. Pregnant control group remained sedentary. HHcy was induced in the other set by dissolving homocysteine in drinking water at a concentration of 53 mg/dL from d1 to d15 of pregnancy.
Participants/materials, setting, methods: Placental sections of homocysteine-treated and control rats were stained with hematoxylin-eosin. Circulating sFlt-1 and homocysteine concentrations were measured using commercial ELISA kits. For confirmation of OS in placenta we quantified placental heat shock protein (pHSP) by immunohistochemistry (IHC) and subsequently hypoxic inducible factor (HIF-1α) by western blot (WB). VEGF expression was evaluated by WB. Quantitative real-time PCR (qRT-PCR) was applied to determine apoptotic biomarkers in placental tissues with or without homocysteine treatment.
Main results and the role of chance: Serum homocysteine increased significantly ($p < 0.01$) in homocysteine treated cohort. Hyperhomocysteinemic rats showed reduced placental weight in comparison to control. Presence of thrombus has been observed in chorionic plate vessel with a decreased area of spongiotrophoblasts and labyrinth in the former. An increased expression of pHSP by IHC in spongiotrophoblast of experimental group and HIF-1α ($p < 0.02$) suggested fetal hypoxia and decreased oxygen supply through the placenta in HHcy. VEGF protein expression was however decreased significantly ($p < 0.01$) in hyperhomocysteinemic group. Pregnant control animals had a significantly lower level ($p < 0.0001$) of sFlt-1 (114 ± 11 pg/ml) than homocysteine treated animals (239 ± 17 pg/ml). mRNA expression of selected genes were significantly ($p < 0.01$) affected by homocysteine treatment. While survivin and Bcl-2 were found to be down-regulated, expressions of caspase 9, Bax, Bid, p21, CIDEA, HRK were up-regulated by at least threefold. Caspase-8 expression was however unaltered. This opens up a novel mechanism by which over-activity of sFlt-1 initiates the intrinsic pathway for apoptosis and fetal hypoxia, thereby inducing pregnancy loss.
Limitations, reasons for caution: Supplementary research is required to confirm this study's findings using human placental tissue. With further trials in the future in both the animal and human models, a more definitive conclusion may be arrived at.
Wider implications of the findings: A significant association between elevated homocysteine levels and pregnancy loss was observed through augmenting placental thrombosis. Over-activity of sFlt-1 may switch on OS thereby initiating the intrinsic pathway for apoptosis. Further studies of the molecular and cellular mechanisms underpinning the connection between disordered homocysteine metabolism and thrombosis are warranted.
Trial registration number: Not applicable.

P-134 Care management of patient with early recurrent miscarriages: Embryo transfer strategy

L. Delaroche[1], C. Dupont[1], F.X. Aubriot[2], F. Lamazou[2], C. Yazbeck[2]
[1]*Laboratoire d'AMP Eylau Unilabs de la clinique Pierre Cherest, AMP, Neuilly sur seine, France*
[2]*Clinique Pierre Cherest, AMP, Neuilly sur seine, France*

Study question: Is the transfer at blastocyst stage a better strategy to avoid pregnancy loss and increase live birth rate in patients with recurrent miscarriages?
Summary answer: The transfer at blastocyst stage does not significantly improve live birth rate and does not significantly decrease pregnancy loss in patients with recurrent miscarriages.
What is known already: Early recurrent pregnancy loss is defined by two or more miscarriages. Different etiology are involved: immunologic, anatomic, endocrinologic, genetic disorders. When no factor is identified, the most relevant hypothesis is the production of aneuploid embryos. After embryo transfer without PGS, the miscarriage rates vary between 26% to 64%.

Embryo transfer at blastocyst stage is associated with better implantation rates and increases chances of live birth rate in general infertile populations. Extended culture leads to better embryo selection by self-correction of certain chromosomal abnormalities. Nevertheless, compared to day 3 transfer, it does not reduce miscarriage risk when euploid embryos are transferred.
Study design, size, duration: This retrospective study was conducted at our ART clinic from January 2010 up February 2015. 8681 cycles of IVF/ICSI were analyzed and couples with a history of 2 or more early miscarriages were included. The outcomes of patients who underwent fresh early cleavage embryo replacement on day 2/3, were compared to the outcomes of patients who underwent fresh blastocyst transfers (day 5/6).
Participants/materials, setting, methods: 279 (3.2%) couples fulfilled the inclusion criteria. 218 patients received an early embryo transfer and 61 a blastocyst transfer. Confounding factors, miscarriage per clinical pregnancy and live birth rate were analysed.

Clinical and biological characteristics were compared using chi-squared test and Student t-test, and IVF/ICSI outcomes were studied accordingly. Confounding factors were evaluated by a logistic regression model. The *P* value was considered significant when <0.05. The results were expressed by mean ± SD or percentage.
Main results and the role of chance: No significant differences were found between the cleavage stage transfer group and the blastocyst stage transfer group respectively in terms of female age (38.06 ± 4.04 vs. 37.65 ± 3.44), female body mass index (23.45 ± 4.38 vs. 24.03 ± 4.66), percentage of female smokers (14.36% vs. 15.09%), percentage of IVF vs. ICSI (56.88% vs. 52.46%) and the duration of ovarian stimulation.

However, less oocytes were retrieved in the cleavage stage transfer group (7.67 vs. 10.11, $p = 0.0006$) but more embryos were transferred in this group (1.94 vs. 1.70, $p = 0.009$).

No statistically significant difference of live birth rate was observed between the early transfer group and the blastocyst transfer group (8.96% vs. 16.39%, $p = 0.43$). Miscarriages per clinical pregnancy were similar in both groups (37.78% vs. 37.50%, $p = 0.69$).

After adjustment on female age, number of oocytes retrieved, fertilization technique and number of embryos transferred, a logistic regression analysis did not observe significant difference in live birth rate related to embryo transfer strategy (OR = 1.08; 95% CI: 0.87–1.34).
Limitations, reasons for caution: This study is a preliminary retrospective study, and should be confirmed by future prospective randomized studies.
Wider implications of the findings: Since PGS is not available in our country, extended culture could have been an alternative for embryo selection with reduced chromosomal abnormalities. We found that extended culture was not able to reduce miscarriages in this specific population, or to better select euploid embryos in case of underlying genetic causes.
Trial registration number: NA.

P-135 Combined first trimester risk assessment for trisomy 21 in women with recurrent pregnancy loss (RPL)

K. Husby[1], J. Malchau Lauesgaard[2], C. Ekelund[3], A. Tabor[3], A.M. Kolte[1], O.B. Christiansen[1], H.S. Nielsen[1]
[1]*Copenhagen University Hospital Rigshospitalet, Fertility Clinic and Recurrent Pregnancy Loss Unit, Copenhagen, Denmark*
[2]*Copenhagen University Hospital Roskilde Sygehus, Department of Obstetrics and Gynecology, Roskilde, Denmark*
[3]*Copenhagen University Hospital Rigshospitalet, Center of Fetal Medicine and Pregnancy, Copenhagen, Denmark*

Study question: Is the performance of combined first trimester screening for trisomy 21 different in women with RPL compared to women in the general Danish population?
Summary answer: The proportion of women, who are screen positive, is significantly higher in women with RPL compared to the background population (8.7% vs. 4.5%).
What is known already: First trimester risk assessment for trisomy 21 is based on maternal age, nuchal translucency thickness (NT) and the maternal serum markers Pregnancy Associated Plasma Protein A (PAPP-A), and free **β-hCG. In Denmark** women with a risk above 1:300 are offered an invasive diagnostic test, with a procedure related miscarriage risk of 0.5%. We hypothesized that more RPL women are screened positive in the first trimester screening based on clinical experience from a national RPL unit. This has only previously been investigated in one small study including 64 pregnancies of women with RPL – reporting no difference.
Study design, size, duration: A retrospective study based on the Danish RPL Database with RPL related data since 1986 and the Danish Fetal Medicine Database (DFMD) that covers 99.5% of the 90% of pregnancies in Denmark attending first trimester screening. DFMD includes subsequent procedures and outcomes based on data from National Birth Register, National Patient register and National Cytogenetic Register. Included are 774 singleton pregnancies of women with RPL and 268,342 population based singleton pregnancies in the period 2008–2013.
Participants/materials, setting, methods: The women included from the RPL database all have three or more pregnancy losses. Women included from the Danish Fetal Medicine Database represent 90% of Danish singleton pregnancies. Cross-linking between several of the National databases was possible after permission from the Danish Data Protecting Agency and is based on the women's unique personal registration number.
Main results and the role of chance: In total 8.7% (67/774) women with RPL were given a risk above 1:300, thus screened positive which is significantly more than the 4.5% (12,202/268,342) in the Danish population, $p < 0.0001$. The women with RPL were older (34y vs. 30y), median of PAPP-A MoM was lower (0.98 vs. 1.02), and NT was larger (1.70mm vs. 1.64mm) compared to the background population; factors resulting in higher screen positive rate. However, median of β-hCG MoM was lower (0.97 vs. 1.03) which reduce the screen positive rate.

The RPL women had significantly higher rate of fetuses with abnormal karyotypes compared to the background population (1.55% vs. 0.61%). No difference was found between the fraction of chromosomal abnormalities of the karyotyped fetuses in the RPL women 12.8% (12/94) and the Danish population 10.9% (1337/12278), $p = 0.61$.

We found higher screen positive rate and a higher proportion of fetuses with abnormal karyotypes in our cohort of RPL women. The RPL women are older, which may explain these findings. Further analyses are required to identify if the biomarkers used in the risk assessment also clinically contribute to the higher screen positive rate among RPL women.
Limitations, reasons for caution: Although this is the largest study on first trimester screening in RPL women it is still unknown if the high screen positive rate is driven alone by age or if the other biomarkers and possible other RPL related factors contribute independently.
Wider implications of the findings: It seems advantageous to inform RPL women at first trimester screening of a higher risk of being screened positive but also of chromosomal abnormalities.

More research is needed to understand the possible increase in NT and lower PAPP-A in order to individualize and optimize the first trimester screening for RPL women.
Trial registration number: The study is approved by the Danish Data Protection Agency with registration number 30-1140.

P-136 Early onset gestational diabetes (GD) as the cause for recurrent spontaneous miscarriages (RSA): RSA, pregestational metformin treatment and pregnancy outcome

M. Sick[1], S. Fill Malfertheiner[1], D. Gutknecht[1], A. Eder[1], C. Reißmann[1], M. Bals-Pratsch[1]
[1]*Profertilita, Reproductive Medicine, Regensburg, Germany*

Study question: Objective of the study was to obtain a prevalence of impaired glucose tolerance, insulin resistance and early onset GD in association with RSA and analyze pregnancy outcome in this population.
Summary answer: Impaired glucose tolerance, insulin resistance show a high prevalence (98.2%) in women diagnosed with RSA. GD was diagnosed in 45.8% of women in subsequent pregnancy.
What is known already: Gestational diabetes is associated with RSA. A non diagnosed GD is a risk factor for recurrent spontaneous miscarriage. Further it is known that infertility is associates with a high prevalence of early onset GD. The efficacy of pregestational metformin treatment is supported by the observation that the rates of RSA and GD are reportedly lower among women with polycystic ovarian syndrome who conceive while taking metformin.
Study design, size, duration: Retrospective, monocentric analysis of 59 women diagnosed with RSA. Recruitment period 07/2011 to 12/2013.
Participants/materials, setting, methods: Fifty-seven women with confirmed RSA and subsequent pregnancy are included in the analysis. In all subjects a basic 75g oral glucose tolerance test (OGTT) and insulin sensitivity testing was performed prepregnancy. All RSA-patients with and without disturbed glucose metabolism or IR received metformin treatment (standard dose 3 × 500mg). As soon as pregnancy was confirmed a second 75g OGTT was performed. If impaired glucose tolerance or GD was diagnosed treatment was initiated according to the current guidelines.
Main results and the role of chance: 98.2% of the study population showed a prepregnancy disturbed glucose metabolism and/or a insulin resistance (IR). In 45.8% a GD was diagnosed in the following pregnancy. Of women diagnosed with GD 77.8% received metformin treatment prepregnancy. After initiation of metformin treatment 40 women became pregnant, all with a positive pregnancy outcome.
Limitations, reasons for caution: Retrospective Analysis, Monocentric study.
Wider implications of the findings: The high incidence of prepregnancy disturbed glucose metabolism, IR and GD indicates that glucose metabolism has more influence in miscarriage than assumed. If impaired GM/IR is not diagnosed and treated before conception or in early pregnancy, it is likely to have a negative impact on the vasculogenesis during implantation period.
Trial registration number: No conflict of interest.

P-137 Molecular karyotyping of products of conception – evaluation of performance and capacity

L. Volozonoka[1], V. Fodina[2], L. Kornejeva[1]
[1]*IVF Riga, Genetics Laboratory, Riga, Latvia*
[2]*IVF Riga, Reproductology Unit, Riga, Latvia*

Study question: Significant part of products of conception (POC) meant for investigation remain without conclusion because of classical cytogenetic testing shortcomings.
Summary answer: Chromosomal microarray analysis (CMA) is an alternative to trophoblast karyotyping capable to overcome shortcomings of the cytogenetic analysis substantially increasing investigated POC sample portion.
What is known already: Each case of miscarriage requires an in-depth investigations to determine given event etiology, pathogenesis and predict future management. About 50% of all early pregnancy loss cases are due to fetal chromosomal aberrations, which are classically analyzed cytogenetically, e.g., karyotyping which prerequisite is presence of choroidal tissues in sample. Main POC karyotyping failure reasons are tissue viability loss, inappropriate transportation conditions and time from the fetal death till testing. Molecular karyotyping – POC analysis by aCGH (array comparative genomic hybridization) can surpass cytogenetic testing because substrate for aCGH is gDNA, which can be extracted also from unviable tissue and paraffin blocks.
Study design, size, duration: Study was performed retrospectively to access applicability and effectivness of diagnostic test: molecular karyotyping of products of conception by aCGH on 37 samples received in IVF Riga clinic (Riga, Latvia) from May 2015 till January 2016. Inclusion criteria was collected (first trimester) *missed abortion* sample after medical/surgical treatment of pregnancy. aCGH for POC was validated for chromosomal aneuploydies by standart chorion villus karyotyping.
Participants/materials, setting, methods: A total of 37 POC samples were analyzed, average women age was 30.5 ± 6.3 years. In all but four investigated samples choroidal villi were clearly visualized. DNA was isolated from primary biological samples or paraffin blocks. CMA was performed following the standard protocol for aCGH (24Sure, Illumina). Resulted copy number karyotype were interpreted. To ensure that the DNA extracted from choroidal villi is free of maternal DNA three samples were STR tested.

Main results and the role of chance: Chromosomal abnormalities were found in 16 samples out of 37 (43%) (mean women age 30.5 ± 6.3). Three samples had 69, XXY karyotype, seven had autosomal trisomies by chromosomes 2, 13, 15 (2x), 16, 19 (one full and one mosaic) and 22, four were classified as X monosomies, one sample had mosaic form of monosomy by chromosome 19. Seven samples showed normal male karyotype – 46, XY and the remaining 15 exhibited balanced female aCGH profile (five of them showed no trophoblast). STR analysis test for three samples extracted from choroidal villi showed no maternal contamination in two cases but in one case low level of contamination had taken place, but its CMA profile was undoubtedly defined as chromosome 13 trisomy. POC STR analysis indicates that the DNA isolated from the visualized choroidal villi can be safely used for further analysis.

Limitations, reasons for caution: At the moment conventional POC analysis by BAC aCGH is validated for whole chromosome copy number changes. Structural chromosomal aberration (including submicroscopical) testing should be further validated. Low level mosaicism, balanced translocations and balanced polyploidies, i.e., 69,XXX and 92,XXXX cannot be detected by conventional aCGH.

Wider implications of the findings: Until now such type of testing was not available in Latvian population, but its application has substantial clinical significance. Most efficient way would be developing cost-effective strategy for POC testing, applying CMA in cases when cytogenetic testing is impossible and performing DNA contamination test in cases where no trophoblast visualized.

Trial registration number: –

P-138 Biochemical pregnancy loss is unrelated to embryo stage of development and euploidy at transfer: evidences from 2452 warming cycles

A. Vaiarelli[1], L. Rienzi[1], A. Capalbo[1], S. Colamaria[1], D. Cimadomo[1], N. Barnocchi[2], M. Giuliani[1], B. Iussig[3], P. Patrizio[4], F.M. Ubaldi[1]
[1]*Clinica Valle Giulia, G.EN.E.R.A., Centre for Reproductive Medicine, Rome, Italy*
[2]*Studio Associato Ostetrico Ginecologico – PMA Umbria, G.EN.E.R.A., Centre for Reproductive Medicine, Umbertide, Italy*
[3]*Salus, G.EN.E.R.A.-Centre for Reproductive Medicine, Marostica, Italy*
[4]*Yale University Fertility Center, Fertility Center, New Haven, CT, USA*

Study question: Is biochemical pregnancy loss (BPL) decreased in cryopreserved euploid blastocyst transfers after preimplantation genetic diagnosis for comprehensive chromosomal testing (PGD-A) compared to untested cleavage-stage embryos and blastocysts?

Summary answer: Biochemical losses have similar incidence in PGD-A and untested embryo/blastocyst warming transfers suggesting no causative relationship with duration of in-vitro culture and chromosome aneuploidies.

What is known already: Biochemical pregnancy loss, defined as β-hCG levels decline after a short period of positivity, has not known underlying causes. Embryonic chromosome anomalies have been advocated as the main cause. However, no direct evidences have been reported showing that biochemical losses occur as a consequence of a primary aneuploidy in the embryo. Blastocyst stage PGD-A has been indicated as an efficient approach to accurately identify euploid embryos. The comparison of pregnancy outcomes between warming IVF cycles with or without PGD-A represents a powerful approach to directly investigate causative relationships between chromosome aneuploidies, duration of *in vitro* culture and pregnancy losses.

Study design, size, duration: A retrospective single center cohort study including all consecutive embryo transfer cycles from 2008 to 2015 was performed. Only warming cycles were analysed to avoid the potential for confounding due to hormonal imbalances deriving from ovarian stimulation. Furthermore, cleavage and blastocyst stage transfers were also evaluated separately. Three different groups were thus analysed: cleavage stage transfers without PGD-A (group A), blastocyst stage transfers without PGD-A (Group B) and blastocyst stage transfer with PGD-A (Group C).

Participants/materials, setting, methods: β-hCG was always measured on days 16th after ovulation/progesterone's administration. BPL was defined as β-hCG levels ≥10IU/L in >1occasions, but not sustained and in the absence of ultrasonographic intrauterine/extrauterine pregnancy. For group A and B, the number of embryos transferred was decided on the basis of medical and biological data, while for group C elective single euploid embryo transfers were performed. Logistic regression was used to test association between the 3groups and other cycle's/patient's covariates with BPL.

Main results and the role of chance: 2452 warming cycles involving 3241 embryos (mean per transfer = 1.32 ± 0.56) were performed in natural (74.4%) or hormone replacement cycles (25.6%) on an endometrium ≥7mm and with a level TSH ≤2.5mU/L. Mean female age at treatment was 36.25 ± 3.9, 35.4 ± 3.9, 37.4 ± 3.5 for group A, B and C, respectively (NS). 1062 (43.3%;95%CI:41.4–45.3) positive pregnancy tests were recorded, 217/637 (34.1% 95%CI:30.4–37.9; mean number of embryos transferred = 1.84 ± 0.67) following warming cleavage stage embryos, 412/1026 (40.2; 95%CI:37.1–43.2, mean number of embryos transferred = 1.3 ± 0.45) following warming blastocyst stage embryos and 433/789 (54.9%; 95%CI:51.3–58.4, mean number of embryos transferred = 1.0 ± 0.13) following euploid blastocyst transfers. Overall, 161 biochemical pregnancy losses per positive β-hCG value were observed (15.2%; 95%CI = 13.0–17.5). Biochemical pregnancy loss rate was 19.3% (42/217;95%CI = 14.3–25.2), 13.8% (57/412; 95%CI = 10.6–17.5), 14.3% (62/433; 95%CI = 11.2–18.0) for cleavage stage, blastocyst and euploid blastocyst, respectively. Logistic regression analysis showed no significant association for all covariates tested to biochemical loss incidence. In particular, blastocyst stage with PGD-A did not modify the risk (OR = 0.98; 95%CI = 0.67–1.45; $p = 0.93$) as well as the stage of transfer, cleavage or blastocyst, showed no effect (OR = 1.36; 95%CI 0.83–2.22; $p = 0.18$). Female age, male age, sperm factor, stimulation protocol, endometrial preparation protocol, coagulation factors, autoimmunity factors, were all unrelated to the risk for biochemical losses.

Limitations, reasons for caution: BPL was evaluated only from day 16 onwards. More information about the incidence of subclinical pregnancy losses and related causative factors could derive from earlier evaluations. The retrospective nature of the study is also a reason for caution. Embryo's mosaicism could not be ruled out from the analysis.

Wider implications of the findings: This study provides evidences that biochemical losses are not due to aneuploidies. Furthermore, no association with extended *in vitro* culture and other patient and cycle's characteristics were observed. Future studies looking at other genetic (non-chromosomal) and uterine factors are needed to unravel mechanisms underlying this relatively frequent adverse event reproduction.

Trial registration number: none.

P-139 Role of G-CSF treatment in recurrent pregnancy loss in TREGblood levels and expression of FOXP3, VEGF, VEGF-R2 and C-KIT in first trimester pregnancy specimens

M. Sbracia[1], F. Scarpellini[1]
[1]*Hungaria, Cerm, Rome, Italy*

Study question: Which is the mechanism of action for G-CSF treatment in Recurrent Pregnancy Loss?

Summary answer: G-CSF in women with Recurrent Miscarriage increases Treg cells in the peripheral blood and in the decidua, and VEGF, VEGF-R2 and c-kit expression on trofoblast

What is known already: We used successfully G-CSF in the treatment of Recurrent Miscarriage, as well as in recurrent implantation failure. We previously showed that G-CSF may be useful in the treatment of recurrent miscarriage. The G-CSF is a cytokyne promoting leukocyte growth, but also troflobast development. However, there not data on the mechanism of action of G-CSF on pregnancy.

Study design, size, duration: An immunohistochemical and FACS studies for FoxP3, VEGF, VEGF-R2 and c-kit in first trimester placentas and blood samples of women with RPL was conducted. Tissue from 8 abortive first trimester pregnancies with RPL treated during the pregnancy with G-CSF and controls of 10 first trimester voluntary pregnancy terminations and Blood samples of 10 women with RPL treated with G-CSF and in 10 phisiological pregnancies, were collected at 7/8 week of gestation

Participants/materials, setting, methods: Immunohistochemistry was performed on tissue sections to assess FoxP3, VEGF, VEGF-R2, c-kit, with commercially available monoclonal antibodies, and nn avidin-biotin-peroxidase detection system was used.. Leukocytes extractedfrom peripheral blood samples were stained for Flow cytometric analysis using FACScalibur (BectonDickinson). All antibodies used were purchesed eBioscences. Treg cells were the CD4+CD25+Foxp3+. Statistical analysis was performed using unpaired t test.

Main results and the role of chance: In the decidua of women with recurrent pregnancy loss treated with G-CSF a significant increase in the number of cells positive to Foxp3 with respect to controls was observed (HSCORE 167+46 vs. 79+24: $P < 0.01$). VEGF expression in trophoblast of specimens of women treated with G-CSF was statistically significant higher than controls (HSCORE 156+39 vs. 70+19: $P < 0.01$) VEGF-R2 expression in trophoblast of specimens of women treated with G-CSF was statistically significant higher than controls (HSCORE 148+37 vs. 81+28: $P < 0.01$). The c-kit expression in trophoblast of specimens of women treated with G-CSF was statistically significant higher than controls (HSCORE 1417+34 vs. 72+21: $P < 0.01$) Treg levels in peripheral blood of women treated with G-CSF during pregnancy were statistically significant higher than in women with RM treated with placebo and in women with phisiological pregnancy ($P < 0.001$and $P < 0.01$ respectivelly). The other populations of lymphocytes did not show statisticaly significant differences.
Limitations, reasons for caution: Data showed that G-CSF administration in pregnant women with RPL increases the Treg cells in decidua and the VEGF, VEGF-R2 and c-kit expression on trofoblast. as well as Treg levels in peripheral blood of these women These findings show that G-CSF treatment acts on both trophoblast and maternal immune system
Wider implications of the findings: These may be the of the mechanism of action in the positive effect of G-CSF on the pregnancy outcome in these women.
Trial registration number: none.

P-140 Paternal influence of sperm transcripts and DNA damage in recurrent implantation failure

V. Dhawan[1], M. Kumar[1], N. Malhotra[2], N. Singh[2], R. Dada[1]
[1]*All India Institute of Medical Sciences, Anatomy, New Delhi, India*
[2]*All India Institute of Medical Sciences, Obstetrics & Gynaecology, New Delhi, India*

Study question: Does sperm transcriptome affect early embryogenesis?
Summary answer: Sperm delivers selective paternal transcripts supportive of implantation and early embryogenesis to the oocyte contributing to transcriptome of embryo prior to activation of embryonic genome.
What is known already: Spermatozoa are terminally differentiated transcriptionally inactive cells, capable of post-meiotic production of functionally viable transcripts which can translate proteins involved in critical process related to stress response, embryogenesis and implantation. Sperm with DNA damage are capable of fertilizing an oocyte, but result in high rate of pre and post implantation losses. Sperm nuclear DNA fragmentation has been positively correlated with lower fertilization rates, reduced cleavage rates and rate of blastocyst development, increased embryo fragmentation and impaired implantation rates.
Study design, size, duration: A case control study of 25 men from infertile couples undergoing ART and 20 controls at AIIMS, New Delhi, India. Study duration was 9 months.
Participants/materials, setting, methods: Semen samples from men undergoing ART were analyzed for DNA damage by assessing DNA fragmentation index (DFI) and ROS (reactive oxygen species) levels (RLU/sec/million sperm) by sperm chromatin structure assay (SCSA) and Chemiluminiscence assay respectively. q-PCR analysis was performed on the semen specimens after reverse transcribing the RNA isolated from the samples. The relative quantification of target genes was calculated with $2\Delta\Delta^{Ct}$ method after normalization to β-actin.
Main results and the role of chance: The mean DFI of men undergoing ART was significantly higher (40.8 ± 5.1 vs. $22.3 \pm 6.4\%$; $P < 0.0001$) in cases as compared to controls. Seminal ROS levels were also seen to be significantly higher (452.8 ± 152.6 vs. 23.5 ± 10.7) in cases with respect to controls. The cut-off values for DFI and ROS levels were taken as <30% and <25 RLU/sec/million sperm respectively. The transcript levels of RPS6, RPL10A, RBM9, EIF5A and TOMM7 genes were correlated with DFI and ROS levels.
Limitations, reasons for caution: A potential limitation for this ongoing study is low sample size. Contributions of other confounding factors for the study namely various environmental and female factors also have the potential to influence early embryonic development and implantation.
Wider implications of the findings: The analysis of spermatozoal transcripts is important for our understanding of sperm differentiation, fertilization and early embryonic development. Correlation with oxidative stress may help in regulation of transcript levels by normalizing ROS levels. It may help to explore the diagnostic potential and assess the fecundity of spermatozoa in ART
Trial registration number: N/A.

P-141 Guideline-based quality indicators in Early Pregnancy Assessment Units

M. van den Berg[1], E. van den Boogaard[2], F. Mol[1], F. van der Veen[1], P. Hajenius[2], M. Goddijn[1]
[1]*Academic Medical Centre, Centre for Reproductive Medicine, Amsterdam, The Netherlands*
[2]*Academic Medical Centre, Obstetrics and Gynaecology, Amsterdam, The Netherlands*

Study question: What are valid quality indicators to measure actual care in Early Pregnancy Assessment Units (EPAUs)?
Summary answer: We identified eleven guideline-based indicators, covering four general, one patient, four logistic and two doctor aspects of care, to assess actual care in EPAUs.
What is known already: The Association of Early Pregnancy Units, Royal College of Obstetricians and Gynaecologists, the National Institute for Health and Care Excellence (UK) and the Ministry of Health, Australia have developed guidelines for setting up and running of EPAUs. A recent study showed, by using surveys, that there is considerable variation between EPAUs according to access to services and quality of care provided. To improve quality of care valid quality indicators – measurable elements of practice performance based on consensus – are needed. Quality indicators to measure the quality of care delivered by an EPAU are still lacking.
Study design, size, duration: We used the systematic RAND-modified Delphi method to develop an indicator set from these four available guidelines. This stepwise method consists of four expert consensus rounds with independent expert ratings and repetitive feedback. The expert panel comprised a representative diversity of 11 experts in the field and clinical guideline users working at academic and teaching hospitals in the UK, Australia, Denmark and The Netherlands.
Participants/materials, setting, methods: We divided the recommendations extracted from the guidelines into four domains, i.e., general, patient, logistic and doctor, and translated these into a questionnaire presented to the expert panel. Every member scored each recommendation on a nine-point Likert scale. The panel prioritized the recommendations using a top-five ranking system per domain. We selected those >75th percentile as key recommendations, A second questionnaire with the member's scores presented the ranking of recommendations.
Main results and the role of chance: We extracted 119 recommendations from the guidelines of which 37 general, 13 patient, 51 logistic and 18 doctor aspects of care. Ten out of 11 questionnaires (91%) were returned by the expert panel and fully completed. The highly scored recommendations were selected for the set of potential key recommendations. These key recommendations are: (1) available protocols for daily practice, (2) all treatment options available for miscarriage, (3) all treatment options available for ectopic pregnancy, (4) a standard system to register ultrasound findings, (5) good quality ultrasound equipment, (6) access to urine pregnancy testing, (7) access to serum hCG assay, (8) a designated examination room to provide privacy, (9) a designated senior staff member responsible for the clinical area, (10) recognized ultrasound training for the staff and (11) a system taking care that women referred to an EPAU are seen promptly. No new recommendations were suggested by the expert panel.
Limitations, reasons for caution: A limitation can be the selection of the expert panel. This can influence the accuracy and validity of the procedure. On the other hand, there is no good alternative for this.
Wider implications of the findings: Guideline-based quality indicators can help clinicians to establish and run an high quality evidenced based EPAU. Furthermore, indicators enable the measurement of actual care and guideline adherence in and between various EPAUs. Further research can focus on barriers and facilitators for guideline dissemination to further optimise the quality of care.
Trial registration number: Not applicable.

P-142 Maternal & perinatal outcome of pregnancies threatening to miscarry

S. Agrawal[1]
[1]*Kota, India*

Study question: The purpose is to study maternal and perinatal outcome in women with threatened miscarriage**.**

Summary answer: There is need to monitor patients after a threatened miscarriage to minimise the complications and, such pregnancies demand more serious prenatal care.
What is known already: These pregnancies are at a higher risk but there is no definitive evidence.
Study design, size, duration: RCT: A large, prospective, multiinstituional study was conducted over a period of 36 months in two tertiary care centers in Northern India.746 Pregnant patients with a history of threatened miscarriage during first twenty weeks of pregnancy. They were registered, followed at antenatal clinics and delivered. Ultrasonogram was performed for diagnosis, calculation of gestational age and to detect the presence of subchorionic hepatoma. Controls, without a history of threatened miscarriage were similarly scanned and followed throughout pregnancy.
Participants/materials, setting, methods: The patients registered, followed up prospectively at antenatal clinics and delivered in same hospital. Ultrasonogram was performed for diagnosis, calculation of gestational age and to detect the presence of subchorionic hematoma. The patients were followed up regularly. In patients with subchorionic hematoma, scans were repeated weekly until resolution of hematoma. All women (controls and cases) were matched for age, parity, social class, BMI and gestational age at booking.
Main results and the role of chance: The overall adverse pregnancy outcomes were significantly higher in women with threatened miscarriage than the control group. Out of 746 cases, 179 (24%) patients spontaneously aborted after diagnosis of threatened miscarriage. Low lying placenta on USG at the initial scanning before 20 weeks was significantly more in study group than control group ($p = 0.02$). But at term the difference was not significant which can partially be explained by theory of trophotropism of placenta.

The incidence of preterm labor, PROM, low birthweight was significantly higher among the cases amd more in patients with heavy bleed. The mean birthweight and mean gestational age at birth was significantly less among females with threatened miscarriage. A high percentage of patients had subchorionic hemorrhage on early USG in the study group while none in the control group had it. The incidence of spontaneous miscarriage was significantly higher in patients with hematoma ($p = 0.01$). This was also dependent on the size of hematoma.
Limitations, reasons for caution: Subjectivity in amount of bleeding and USG interpretation.
Wider implications of the findings: The identification of these high risk groups should enable better management protocols and new therapeutic protocols to improve neonatal outcome. The most encouraging aspects of our study were that it was a prospective study, women were booked very early in pregnancy, multiple fetal as well as maternal outcomes were studied.
Trial registration number: Not applicable.

POSTER VIEWING SESSION

EMBRYOLOGY

P-143 Blastocyst collapse is not an independent predictor of reduced live birth: a time-lapse study

D. Bodri[1], T. Sugimoto[1], J. Yao Serna[1], R. Kato[1], K. Satoshi[1], M. Tsunekazu[1]
[1]*Kobe Motomachi Yume Clinic, Assisted Reproduction Unit, Kobe, Japan*

Study question: Is blastocyst collapse, observed by time-lapse monitoring (TLM), independently associated with live birth in a cohort of unselected infertile patients undergoing single blastocyst transfer?
Summary answer: Blastocyst collapses (including multiple ones) occurred frequently in almost half of the cohort, but they were not independent predictors of reduced live birth.
What is known already: In a recently published retrospective study (Marcos et al., 2015), (mostly single) blastocyst collapse, precisely observed by TLM, was associated with a reduced rate of implantation (35 versus 48.5%). The authors strongly recommended against transferring such blastocysts (if any alternative is available) and encouraged to include this marker as an additional criterion in existing time-lapse embryo selection models.
Study design, size, duration: All consecutive infertile patients whose embryos were submitted to prolonged embryo culture and reached expanded blastocyst stage ($n = 501$) in a TLM incubator (EmbryoScope, Vitrolife) between 2012 and 2014, subsequently undergoing vitrified-warmed embryo transfers ($n = 291$) until August 2015 were included in this retrospective analysis. Fourteen cases involving zona pellucida-free embryos were excluded because blastocyst collapse could not be evaluated in them. The outcome of embryo transfers was followed-up until live birth occurred (including 4 ongoing pregnancies).
Participants/materials, setting, methods: Early, late and interval morphokinetic parameters were scored according to published consensus criteria. Blastocyst collapses were defined as instances when the surface of the trophoectoderm cells separated >50% from the inner side of the zona pellucida. The entire cohort was divided into three subgroups: "no collapse", "single collapse" or "multiple collapses". The association between blastocyst collapse and live birth was evaluated by a multivariate logistic regression analysis including categorical morphokinetic variables and other confounders.
Main results and the role of chance: During the study period 277 single blastocyst transfers were performed (female age 38.4 ± 3.9, range: 28–47 years). The overall live birth rate per embryo transfer was 30% (82/277). One or more blastocyst collapse(s) occurred in 46% (127/277) of the examined embryos; in 22% (61/277) of the cases only a "single collapse" was observed whereas in 24% (66/277) "multiple collapses" were seen. In the "multiple collapse" subgroup an average number of 2.9 collapses were registered (range: 2–9). Live birth rates per single blastocyst transfer decreased progressively between subgroups (36, 31 and 14%, respectively, $p = 0.004$) but statistically significant differences were only observed between the "multiple collapse" and the other two subgroups ($p = 0.0009$ and 0.02). Unadjusted odds ratios showed that only "multiple collapse" was associated with a decreased probability of live birth (OR: 0.28 95%CI: 0.12–0.59, $p = 0.001$). After adjusting for 8 categorical TLM variables and 7 patient-, and cycle-related confounders the previously seen association for the "multiple collapse" subgroup has disappeared. In the resulting model only $texpB_2$ (time to reach expanded blastocyst size of 160 microns) (aOR 4.67 95%CI: 1.62–14.9, $p = 0.006$), t2 (aOR 2.44 95%CI: 1.27–4.78, $p = 0.008$) and female age (aOR 0.87 95%CI: 0.79–0.96, $p = 0.006$) remained significantly associated with live birth.
Limitations, reasons for caution: The main limitation was the moderate number of 277 blastocyst transfers included. Furthermore our unselected cohort was biased towards advanced-aged, poor-prognosis patients undergoing mild IVF treatment coupled with vitrified-warmed single blastocyst transfer exclusively. This might limit generalizibility to other less infertile populations or to centres which use different treatment protocols.
Wider implications of the findings: Blastocyst collapse patterns should not be evaluated alone without taking into account other cleavage- or blastocyst-stage morphokinetic variables (such as $texpB_2$ and t2) that are stronger predictors of reproductive outcome.
Trial registration number: n/a.

P-144 A hierarchical model combining cleavage-stage morphokinetic variables predicts blastocyst formation rate

J. Yao Serna[1], D. Bodri[1], T. Sugimoto[1], R. Kato[1], S. Kawachiya[1], T. Matsumoto[1]
[1]*Kobe Motomachi Yume Clinic, Embryology, Kobe, Japan*

Study question: Which cleavage-stage morphokinetic variables are the most predictive of expanded blastocyst formation rate in order to establish a hierarchical model based on the strongest predictors?
Summary answer: In a multivariate analysis three cleavage-stage variables (t2, t9, and s3) were associated with blastocyst formation permitting the establishment of a simple, combined hierarchical score.
What is known already: In recent years increasing number of time-lapse monitoring (TLM) studies focused on finding morphokinetic variables that could be predictors of blastocyst formation, succesfully identifying several (early) cleavage-stage variables that were consistently associated with it. However, only a recent study (Motato et al., 2015) has managed to estabilish a four-category hierarchical score (including tM = time to morula and s3 = t8–t5) predicting blastocyst development which showed a good discrimination ability (AUC: 0.849). It is arguable however, whether including tM is really useful if a blastocyst prediction model would be used in a clinical setting to select day 3 embryos for prolonged culture.

Study design, size, duration: All consecutive infertile patients from a single centre whose cleavage-stage embryos were submitted to prolonged culture (n = 1137) in a TLM incubator (EmbryoScope, Vitrolife) between 2012 and 2014 were included in this retrospective analysis.
Participants/materials, setting, methods: Early (PNf, t2–9) and interval (cc2a-b, s2–3) morphokinetic parameters were scored according to consensus criteria and standardized to pronuclear fading. Detailed histograms for all morphokinetic variables were examined to determine the existence of ranges with high, medium and low rates of blastocyst development. Subsequently continuous TLM variables were converted into categorical ones. The association between blastocyst formation and categorical morphokinetical variables was evaluated by multivariate logistic regression analysis also including other patient-, and cycle-related confounders.
Main results and the role of chance: The average rate of expanded blastocyst formation was 44% (501/1137). In a univariate analysis all twelve cleavage-stage morphokinetic variables and also eight patient- (female age, parity, history of previous IVF treatment, partner age, duration of marriage as a proxy for infertility duration), and cycle-related confounders (stimulation type, current cycle rank, number of retrieved mature oocytes) were associated with blastocyst formation. In a multivariate analysis however, only three cleavage-stage (t2, t9 and s3) and two patient-related confounders (female age and duration of marriage) remained statistically significant. Combining the two strongest morphokinetic predictors (t2 and s3) resulted in a simple, five-category (from "E" to "A") hierarchical model, representing 16, 17, 23, 28, and 16% of the entire cohort of cultured embryos, respectively. The model effectively distinguished between embryos of increasing blastocyst development potential (11, 23, 43, 62 and 72% from category "E" through "A", $p < 0.0001$). The AUC value of the hierarchical model was higher (0.744) than for any of the two combined cleavage-stage variables alone (0.669 for t2 and 0.696 for s3).
Limitations, reasons for caution: Our unselected cohort was biased towards advanced-aged, poor-prognosis patients undergoing mild IVF treatment coupled with single vitrified-warmed blastocyst transfer. This might limit generalizibility to other less infertile populations or to centres which use different treatment protocols.
Wider implications of the findings: Our study suggests that both early (t2) and late (s3 as t8–t5) cleavage-stage morphokinetic parameters are associated with development until the expanded blastocyst stage. A simple, hierarchical model effectively distinguished between day 3 cleavage-stage embryos of low, intermediate and high blastocyst development potential permitting their ranking before starting prolonged culture.
Trial registration number: None.

P-145 What are pregnancy chances after the transfer of day 5 vitrified/warmed compacted morulæ and early blastocysts as compared to late blastocyst?

D. Montjean[1], V. Pauly[2], A. Beltran Anzola[1], M.J. Gervoise-Boyer[1], C. Geoffroy-Siraudin[1], P. Boyer[1]
[1]*Hopital Saint Joseph, Médecine et Biologie de la Reproduction, Marseille, France*
[2]*Aix-Marseille Université, Faculté de médecine, Département de Santé Publique et Maladies Chroniques, Unité de recherche EA 3279, Marseille, France*

Study question: Is it worth cryopreserving compacted morula and early blastocyst stage embryos?
Summary answer: Compacted morula, early blastocyst and late blastocyst stage embryos show equal transfer rate, implantation rate and pregnancy rate after warming.
What is known already: The excellent results reported on embryo vitrification at day 5 were based on the selection of top embryos which implies that lower quality embryos are ruled out from transfer. However it is of common knowledge that Day 5 embryo cohorts obtained after *In vitro* culture often show heterogeneous embryo stages ranging from compacted morula to late blastocysts based. These dissimilarities reflect individual embryo dynamics that provide different success chances. Day 5 embryos displaying typical morphology may be cryopreserved. However, the prognosis in terms of transfer, implantation and pregnancy rates for each embryo grade has not yet been investigated.
Study design, size, duration: 543 evolving embryos obtained at day 5 were vitrified over a four-year period: Category 1, either compacted morula or blastocyst with early forming blastocoele (n = 257), Category 2, early blastocyst with clear blastocoele that occupies less than half of the embryonic volume (n = 233) and Category 3, late blastocysts displaying a blastocoele occupying more than half the volume of the embryo and/or increased size (n = 53). Transfer, implantation and pregnancy rates were assessed and compared between each category.
Participants/materials, setting, methods: The 543 embryos were vitrified either for delayed embryo transfer (freeze-all strategy) or for the preservation of surpernumerary embryo. Embryos were individually cryopreserved (Cryotop®) and warmed using the Kitazato vitrification/warming kit. Morphology was assessed using the simplified Gardner grading system and recorded prospectively in an image database before vitrification and after warming. Transfer, implantation and pregnancy rates were assessed for each embryo category and compared using SPSS (Statistical Package for the Social Sciences) software.
Main results and the role of chance: 404 couples enrolled in infertility treatment program benefitted embryo vitrification at day 5. The main objective of the study was to assess and to compare post-warming embryo transfer, implantation and pregnancy rates in the 3 different day 5 embryo categories obtained after *In Vitro* Fertilization, Intra Cytoplasmic sperm injection using fresh or vitrified/warmed oocytes. The major outcome of the present investigation is that, after warming, day 5 embryos belonging to the 3 categories described above show equal success rates: category 1, 2 and 3 embryos have comparable chances to be transferred after warming (88.3%, 88.3%, 93.0%, respectively, [p = 0.55]), they have similar implantation rates (n fetal sac/n embryo transferred) (15.8%, 14.4%, 26.3%, respectively, [p = 0.21]) and provide equivalent early pregnancy chances (n clinical pregnancy/n transfer) (16.3%, 15.9%, 26.4%, respectively [p = 0.17]). Miscarriage rate encountered after embryo transfer is statistically not different in the 3 categories (9.1%, 15.8%, 6.3%, respectively, [p = 0.12]). Our data show that the technique used for fertilization does not affect embryo post-warming transfer rate (p = 0.99), implantation rate (p = 0.65), clinical pregnancy rate (p = 0.65) nor miscarriage rate (p = 0.56).
Limitations, reasons for caution: Category 3 embryos are commonly transferred in priority during fresh cycle. Therefore, the number of vitrified embryos belonging to this category is much smaller than others leading to a loss of power of statistical analyses. Larger group of category 3 embryos is required to draw final conclusion.
Wider implications of the findings: Our observation shows that as long as an evolving embryo reaches day 5 and displays typical morphology, it constitutes a chance to achieve a pregnancy. Therefore, it is worth cryopreserving pre-blastocyst and early blastocyst. We believe that interest should be borne at such embryos that are unfortunately often discarded.
Trial registration number: None.

P-146 Algorithms for the prediction of blastocyst formation and implantation: the predictive value of oocyte and cleavage-stage embryo morphological criteria

R.C.S. Figueira[1], A.S. Setti[2,3], D.P.A.F. Braga[2,3,4], R.C. Ferreira[1], A. Iaconelli Jr.[3,5], E. Borges Jr.[3,5]
[1]*Fertility Medical Group, IVF Laboratory, Sao Paulo/SP, Brazil*
[2]*Fertility Medical Group, Scientific Research, Sao Paulo/SP, Brazil*
[3]*Instituto Sapientiae – Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific Research, Sao Paulo/SP, Brazil*
[4]*Universidade Federal de São Paulo UNIFESP, Disciplina de Urologia – Área de Reprodução Humana – Departamento de Cirurgia, Sao Paulo/SP, Brazil*
[5]*Fertility Medical Group, Clinical Department, Sao Paulo/SP, Brazil*

Study question: Are there algorithms, based on oocyte and embryo morphological criteria assessed under light microscopy, which can predict blastocyst achievement and implantation potential in ICSI cycles?
Summary answer: This study characterized variables with independent predictive value and provided algorithms for the prediction of blastocyst formation and implantation potential in ICSI cycles.
What is known already: A prospective and individual determination of whether an extended embryo culture strategy would improve the chance of pregnancy is challenging. This challenge becomes more complicated when we consider our inability to predict whether (or which) cleavage stage embryos will form viable blastocysts. In order to define cycles that would benefit from extended embryo culture and result in higher chances of implantation, it is important to determine (i) which cleavage-stage morphological criteria would be able to predict blastocyst formation, and (ii) which of these criteria would be able to assist in blastocyst selection for transfer.

Study design, size, duration: This transversal study included data from 743 ICSI cycles performed from July 2011 to June 2014 in a private fertility centre. Inclusion criteria were as follows: patients undergoing ICSI with fresh embryo transfer performed on day 5 of development. A total of 5850 individually cultured embryos were evaluated regarding independently identified oocyte dimorphisms, pronuclear score and embryo morphological scores on days 2 and 3.
Participants/materials, setting, methods: Associations between these variables and the probability of the achievement of a blastocyst or of an ongoing implantation were checked and candidate predictors were considered for the construction of a multivariable prediction model to rank embryos according to their blastocyst formation and implantation potential. The characteristics of the cycle, couple and treatment were also included in the model.
Main results and the role of chance: Based on the bivariate analysis, 43 potential predictive variables for blastocyst formation potential and 20 for blastocyst implantation potential were selected for the establishment of prediction models using binary multiple logistic regression. The final prediction model included 14 independent predictive factors for blastocyst formation: Female age, oocyte yield, large perivitelline space in the oocyte, morphological features on day 2 (cleavage rate, blastomere asymmetry, blastomere multinucleation, multinucleation in more than 25% of the blastomeres, and absence of a nucleus in at least one blastomeres), morphological features on day 3 (number of blastomeres, cleavage rate, blastomere asymmetry, fragmentation, blastomere multinucleation, and the number of blastomeres with no apparent nucleus). The final prediction model included four independent predictive factors for the blastocyst implantation potential model: female age and morphological features on day 2 (blastomere asymmetry, multinucleation, and absence of a nucleus in at least one blastomere). The prediction models for blastocyst formation potential and implantation potential achieved accuracy rates of 71.7% and 80.1%, respectively.
Limitations, reasons for caution: In most laboratories, embryo selection for transfer is still based on morphological parameters evaluated by light microscopy. The subjectivity of the morphological evaluation, as well as the wide diversity of embryo classification systems used by different centers implies contrasting results, making the implementation of consensus a difficult task.
Wider implications of the findings: These models provide a tool for clinics and embryologists that predicts the best time for embryo transfer without the use of time-lapse technology. The optimization of embryo selection, considering morphological criteria from early stages, represents the potential to increase treatment success rates while minimizing the chances of a multiple pregnancy.
Trial registration number: N/A.

P-147 A simple, hierarchical model combining cleavage- and blastocyst-stage time-lapse variables successfully predicts live birth following vitrified-warmed single embryo transfer

T. Sugimoto[1], D. Bodri[2], J. Yao Serna[2], R. Kato[2], S. Kawachiya[2], T. Matsumoto[2]
[1]*Kobe Motomachi Yume Clinic, Clinical Genetics, Kobe, Japan*
[2]*Kobe Motomachi Yume Clinic, Assisted Reproduction, Kobe, Japan*

Study question: Which early/late morphokinetic time-lapse variables are the most predictive of live birth in order to establish a hierarchical model based on the strongest predictors?
Summary answer: In a multivariate analysis one cleavage- and one blastocyst-stage morphokinetic variable was associated with live birth permitting the establishment of a simple, combined hierarchical score.
What is known already: In recent years increasing number of time-lapse monitoring (TLM) studies focused on finding morphokinetic variables that could be predictors of embryo implantation. Most of these studies involved cleavage-stage embryos only (between 84 to 754 "KID" embryos with so-called known implantation data) and succesfully identified several early cleavage-stage morphokinetic variables (such as t3, t5, cc2, s2 and cc3) that were consistently associated with successful implantation. On the other hand, so far there is a lack of published studies involving time-lapse monitored blastocysts and morphokinetic parameters extracted from later stages (morula, early and expanded blastocyst) of embryo development are still under investigation.
Study design, size, duration: All consecutive infertile patients from a single centre whose embryos were submitted to prolonged embryo culture and reached the expanded blastocyst stage (n = 501) in a TLM incubator (EmbryoScope, Vitrolife) between 2012 and 2014, subsequently undergoing vitrified-warmed embryo transfers (n = 291) until August 2015 were included in this retrospective analysis. The outcome of embryo transfers was followed-up until live birth occurred (n = 86) (including 4 still ongoing pregnancies).
Participants/materials, setting, methods: Early, late and interval morphokinetic parameters were scored according to published consensus criteria and standardized to pronuclear fading. Subsequently, histograms for all morphokinetic variables were examined to determine the existence of "optimal live birth ranges". Those TLM variables where such an optimal LB range could be observed were converted into categorical ones. The association between live birth and categorical morphokinetical variables was evaluated by multivariate logistic regression analysis including other patient-, and cycle-related confounders.
Main results and the role of chance: The examination of detailed histograms revealed that areas with a significantly higher proportion of live births ("optimal LB ranges") existed for five cleavage-stage (t2, t3, t4, cc2a and cc2b) and three blastocyst-stage variables (tBfull, texpB_1 and $_2$) thus permitting the conversion of these morphokinetic variables from continuous (hours) to categorical (inside/outside) ones. After adjusting all eight morphokinetic parameters and seven patient- and cycle-related confounders among each other, only two TLM variables remained highly significant (t2: aOR 2.42 95%CI: 1.29–4.57, p = 0.006 and texpB_2: 4.37 95%CI: 1.62–12.94, p = 0.005). Combining these two strongest predictors resulted in a simple, three-category ("A", "B" and "C") hierarchical model. Category "A", "B" and "C" blastocysts represented 22, 49 and 29% of the total cohort, respectively. The model effectively distinguished between blastocysts of increasing live birth potential (category "C": 11%, category "B": 30%, category "A": 54%, $p < 0.0001$). Compared to the middle category "B" group, "A" and "C" blastocysts had a significantly higher (OR 2.72 95%CI: 1.47–5.10, p = 0.00015) and lower (OR 0.25 95%CI: 0.10–0.55, p = 0.00009) LB potential, respectively. The AUC value of the hierarchical model was higher (0.70) than for any of the two combined variables alone (0.61 for t2 and 0.66 for texpB_2).
Limitations, reasons for caution: The main limitation is the moderate number of 291 single blastocyst transfers included. Furthermore our unselected cohort was biased towards advanced-aged, poor-prognosis patients undergoing mild IVF treatment coupled with single blastocyst transfer exclusively. This might limit generalizibility to other less infertile populations or to centres which use different treatment protocols.
Wider implications of the findings: Our study suggests that blastocyst-stage morphokinetic parameters might be better predictors of clinical outcome than previously published cleavage-stage ones (higher odds ratios for texpB_2 compared to t2). A simple, hierarchical model effectively distinguishes between low, medium and high implantation potential blastocysts permitting their ranking before future embryo transfers.
Trial registration number: n/a.

P-148 Oocytes with smooth endoplasmic reticulum clusters originate blastocysts with impaired implantation potential

A.S. Setti[1,2], R.C.S. Figueira[3], D.P.A.F. Braga[1,2,4], E. Ono[2], M.C. Azevedo[3], A. Iaconelli Jr.[2,5], E. Borges Jr.[2,5]

[3]*Fertility Medical Group, IVF Laboratory, Sao Paulo/SP, Brazil*
[4]*Universidade Federal de São Paulo UNIFESP, Disciplina de Urologia – Área de Reprodução Humana – Departamento de Cirurgia, Sao Paulo/SP, Brazil*
[5]*Fertility Medical Group, Clinical Department, Sao Paulo/SP, Brazil*

Study question: Are embryos derived from oocytes presenting smooth endoplasmic reticulum clusters (SERc) less likely to develop into blastocysts and implant?
Summary answer: In this study, although oocytes displaying SERc normally reached the blastocyst stage, no blastocysts derived from SERc+ oocytes implanted.
What is known already: The Alpha Scientists in Reproductive Medicine and ESHRE Special Interest Group of Embryology recently recommended not inseminating oocytes affected by SERc, since they might be associated with an increased risk of abnormal outcome. Several reports focusing specifically on SERc+ oocytes have indeed shown negative outcomes in terms of fertilization, embryo development and pregnancy rates as well as compromised obstetric and neonatal outcomes. However, a more recent publication demonstrated that healthy babies could result from SERc+ oocytes. Therefore, information regarding the clinical significance of SERc+ oocytes is still controversial.

Study design, size, duration: This transversal study included data from patients undergoing their first or second ICSI cycle, from July 2011 to June 2014, in a private fertility centre. Inclusion criteria were as follows: patients undergoing ICSI with fresh embryo transfer performed on day 5 of development.
Participants/materials, setting, methods: The obtained oocytes were split between the SERc+ group, which consisted of oocytes presenting SERc, and the SERc-group, which consisted of oocytes free of SERc. The ICSI cycle outcomes were compared between the SERc+ and SERc-groups. Additionally, the implantation rate was compared between the groups. For the investigation of implantation, only cycles in which none (0%) or all the embryos transferred had implanted (100%) were included in the analysis.
Main results and the role of chance: Seven hundred and forty-three ICSI cycles performed were analyzed. A total of 7609 oocytes were morphologically evaluated and 167 oocytes presented SERc. Maternal age and the total dose of FSH administered were not associated with the occurrence of SERc. However, the number of follicles and retrieved oocytes were determinants of the increased odds of SERc occurrence (OR: 1.03; CI: 1.02–1.04 and OR: 1.03; CI: 1.01–1.04, respectively). A total of 5705 zygotes were obtained. There were no significant differences between the SERc+ and SERc-groups regarding the fertilization rate and high-quality embryo rate on days 2 and 3. On day 5 of embryo development, 3147 blastocysts were obtained. Similar blastocyst formation rates and number of transferred embryos were observed between the groups. Out of 1639 embryos transferred, 767 blastocysts were transferred to patients who had a 0% or 100% implantation rate. A total of 618 blastocysts were transferred in the 0% implantation rate group and 149 blastocysts were transferred in the 100% implantation group. The mean implantation rate in the SERc-group was 20.5% whereas no blastocyst derived from SERc+ oocytes implanted.
Limitations, reasons for caution: Approximately 5% of ICSI cycles show at least one SERc+ oocyte. The relatively rare occurrence of SERc in oocyte cohorts limits the experimental analysis of this dysmorphism. Additionally, a bias might have been introduced since oocyte morphology in this study was punctually accessed by light microscopy.
Wider implications of the findings: The birth of healthy babies from SERc+ oocytes might lead to a revision of the current consensus in the future. In the meanwhile, if transfers of embryos derived from SERc+ oocytes are performed, they should be approached with caution and only when no alternative embryos of sufficient quality are available.
Trial registration number: N/A.

P-149 Freeze-all, oocyte vitrification or fresh embryo transfer? Lessons from an egg-sharing donation program

D.P.A.F. Braga[1,2,3], A.S. Setti[1,2], E. Ono[2], R.C.S. Figueira[4], L.S. Vingris[4], E.G. Lo Turco[3], A. Iaconelli Jr.[2,5], E. Borges Jr.[2,5]
[1]Fertility Medical Group, Scientific Research, Sao Paulo/SP, Brazil
[2]Instituto Sapientiae – Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific Research, Sao Paulo/SP, Brazil
[3]Universidade Federal de São Paulo UNIFESP, Disciplina de Urologia – Área de Reprodução Humana – Departamento de Cirurgia, Sao Paulo/SP, Brazil
[4]Fertility Medical Group, IVF Laboratory, Sao Paulo/SP, Brazil
[5]Fertility Medical Group, Clinical Department, Sao Paulo/SP, Brazil

Study question: Which approach leads to better results, embryo vitrification, oocyte vitrification, or fresh embryo transfer in controlled ovarian stimulation (COS) cycles?
Summary answer: Better clinical outcomes result when using embryo vitrification, followed by oocyte vitrification. Fresh embryo transfer in COS cycles leads to poorer results.
What is known already: The cryopreservation of oocytes is a popular technique that is useful in oocyte donation. It has been reported that COS is associated with impaired endometrial receptivity. In frozen–thawed cycles, when COS is not performed, pregnancy rates have been reported to be higher than in fresh cycles. Considering this, the freeze-all policy has emerged as an alternative to fresh embryo transfers. However, while it has been suggested that embryo transfer in natural or endometrium-prepared cycles is a better approach than the transfer during a COS cycle, the question about vitrification of oocytes or embryos remains under debate.
Study design, size, duration: This case-control study included 8,075 oocytes from 425 oocyte donors that were submitted to intracytoplasmic sperm injection (ICSI), from Jan/2014 to Dec/2014. The oocytes were used for the donors' own cycles (n = 5440/4585 oocytes/embryos, the Fresh_Oocytes_Group) or were cryobanked (n = 2635/2128 oocytes/embryos, the Vitrified_Oocytes_Group) for 425 recipients. Concerning the Fresh_Oocytes_Group, the embryos were either cryopreserved and transferred during a subsequent cycle (Freeze_all_Group, n = 297 cycles, 3209 embryos) or transferred during a fresh cycle (Fresh_Transfer_Group, n = 128 cycles, 1307 embryos).
Participants/materials, setting, methods: The study was performed at a private assisted reproduction centre and enrolled oocyte donor patients undergoing ICSI cycles using fresh oocytes, vitrified oocytes, or vitrified embryos. Mature oocytes were vitrified three hours after collection and cryo-stored. Embryos were vitrified on day three of development. Both the vitrification and warming procedures were performed using the Cryotop method. On day five, for both the fresh and cryopreservation protocols, one or two embryos were transferred.
Main results and the role of chance: The fertilisation rate (85.4 ± 14.4 vs. 80.2 ± 18.2, $p < 0.001$) and number of transferred embryos (1.6 ± 1.0 vs. 1.8 ± 1.1, $p < 0.001$) was lower for the Vitrified_Oocytes_Group compared to the Fresh_Oocytes_Group. In addition, the high quality embryo rate on days two (43.2% vs. 31.5%, $p < 0.001$) and three (38.6% vs. 30.7%, $p < 0.001$) and the blastocyst formation rate (41.1% vs. 36.6%, $p < 0.001$) were lower for embryos derived from vitrified oocytes compared to embryos derived from fresh oocytes. When the Fresh_Oocytes_Group was split into the Freeze_all_Group and the Fresh_Transfer_Group and these groups were compared with the Vitrified_Oocytes_Group, a significant difference in the clinical outcomes was noted: the Freeze_all_Group had the highest pregnancy (71.4% vs. 49.6% vs. 39.8%, $p < 0.001$) and implantation rates (67.3% vs. 43.0% vs. 37.2 $p < 0.001$), followed by the Vitrified_Oocytes_Group, while the Fresh_Transfer_Group had the lowest rates of pregnancy and implantation. No significant differences were noted when miscarriage rates were compared among the groups (10.8% vs. 12.8% vs. 9.4%, $p = 0.679$).
Limitations, reasons for caution: For the present study, the oocytes were obtained from an egg-sharing donation program; therefore, they originated from infertile couples. Moreover, the limited number of subjects may be a reason for caution in the present study.
Wider implications of the findings: Embryo vitrification is a better approach than oocyte vitrification. However, when compared to fresh embryo transfers, embryos derived from warmed oocytes and transferred into a "more receptive endometrium" result in better clinical outcomes. This supports the value of oocyte vitrification for cryobanking in oocyte donation programs.
Trial registration number: N/A.

P-150 Treatment with ionomycin improves pregnancy rates in poor responders

J.S. Koo[1], H. Lee[1], H.S. Moon[1], S.E. Moon[1], S.H. Park[1], S.H. Min[1]
[1]Good Moonhwa Hospital, Center of Reproduction Medicine, Busan, South Korea

Study question: Does ionomycin treatment improve embryo developmental competence and pregnancy rate of poor responders?
Summary answer: Application of ionomycin treatment leads to increased rates of cleavage to 8-cell stage and clinical pregnancy.
What is known already: Ionomycin can induce Ca^{2+} influx by altering the plasma membrane permeability or can act directly on intracellular organelles which release Ca^{2+}. Studies in somatic cell nuclear transfer bovine oocytes showed that ionomycin is a more potent and more specific Ca^{2+} ionophore than A23187. When ionomycin is used as an assisted oocyte activation agent, the reported fertilization rates are usually higher than with the use of A23187. In humans, calcium fluctuations were detected with a peak shortly before cell division. Interestingly, these calcium oscillations disappeared in arrested embryos.
Study design, size, duration: This prospective study was performed between October 2014 and December 2015 at a reproductive center. All patients involved gave written consent, and institutional review board approval was granted. This study includes 21 non-treatment and 22 treatment couples.
Participants/materials, setting, methods: A prospective study was conducted including patients with a poor responders following conventional ICSI in our center. In the treatment cycles, all metaphase II-oocytes were exposed to a commercially available ready-to-use 0.5 μM ionomycin for 5 min immediately after ICSI. After a three-step washing procedure, *in vitro* culture was performed as in the control cycles, when possible up to 8-cell stage. Cleavage and clinical

pregnancy rates were compared, *p*-value of <0.05 was considered statistically significant.

Main results and the role of chance: The average female age, number of oocytes retrieved, embryo developmental stage and number of embryos transferred did not vary significantly amongst the groups. Fertilization rate did not differ (75.4 versus 73.2%); however, further cleavage to 8-cell stage was significantly higher ($P < 0.001$) in the ionomycin group (98.5%) when compared with the control cycles (91.9%). Most importantly, clinical pregnancy rates were higher ($P < 0.01$) in the ionomycin treatment group (44.4%) when compared to the control group (20.8%).

Limitations, reasons for caution: Poor responders exhibit advanced age, previous ovarian surgery or pelvic adhesions, all of which can contribute to reduced oocytes and embryo quality in comparison with normal responders. This study is still not powered to exclude possible associations between take home baby rate and perinatal outcomes on babies born.

Wider implications of the findings: The findings of this study indicate that ionomycin treatment improves the rates of cleavage to 8-cell stage and clinical pregnancy in poor responders. However, this treatment does not seem to completely resolve the poor responders. Further investigations are necessary to determine the effects of ionomycin treatment of the culture conditions.

Trial registration number: NA.

P-151 Prostaglandin-Endoperoxide Synthase 2 and Versican expression levels in cumulus cells are associated with *in vitro* fertilization pregnancy outcomes

A. Ocampo-Bárcenas[1,2], J. Pedraza[3], L. Porchia[1], E. Hernández[2], F. Camargo[1,2], E. Lopez-Bayghen Patiño[1,4]

[1]*Instituto Ingenes, Laboratorio de Investigación y Diagnósotico Molecular, Mexico DF, Mexico*

[2]*Universidad Autónoma Metropolitana, Doctorado en Ciencias Biológicas y de la Salud, México-DF, Mexico*

[3]*Instituto Ingenes, Laboratorio FIV, Mexico DF, Mexico*

[4]*Cinvestav-IPN, Departamento de Toxicología, México DF, Mexico*

Study question: Is expression of Prostaglandin-Endoperoxide synthase 2 (PTGS2) and Versican (VCAN) in Cumulus cells' (CC) correlated with embryo pregnancy potential?

Summary answer: Is expression of Prostaglandin-Endoperoxide synthase 2 (PTGS2) and Versican (VCAN) in Cumulus cells' (CC) correlated with embryo pregnancy potential?

What is known already: Many reports have established the association between CCs gene expression profiles and oocyte competence, embryo quality, and pregnancy outcomes. For example, PTGS2 expression was associated with germinal vesicle to metaphase II stage transitions, development of higher quality embryos, and good embryo morphology. Moreover, VCAN, a major component of the extracellular matrix of the cumulus-oocyte complex, has been associated with oocyte quality, key steps of oocyte maturity, embryonic development, cumulus expansion, and higher probability of pregnancy and live births, making PTGS2 and VCAN gene expression plausible markers of ideal oocytes for IVF procedures.

Study design, size, duration: A retrospective study design was utilized for one complete IVF cycle. One hundred and ninety-eight women that suffer from infertility undergoing IVF in Mexico City, Mexico were selected for this study. Some subjects were lost due to not returning for follow-ups appointments, failure to produce viable oocytes/embryos, failure to collect sufficient RNA from the CCs for analysis, or chose not to be included. Forty-two women healthy were included (age: 29–46 years; BMI = 25.5 ± 5.0 kg/m^2).

Participants/materials, setting, methods: Patients were subjected to a controlled ovarian stimulation protocol with GnRH. CCs were isolated during oocyte retrieval and RNA was isolated using Trizol per the manufacture's suggestions. The expression of PTGS2, VCAN, and L19 were measured by using quantitative PCR. The PVL index [$(PTGS^{2+}VCAN)*L19_{normalized}$] was determined for each oocyte. After fertilization, only embryos with high morphological scores were implanted. Clinical pregnancy was confirmed by βhGC or the presence of a fetal heartbeat.

Main results and the role of chance: 8.2 ± 3.4 oocytes were collected per patient, of which 47.7 ± 29.5% of the collected oocytes had PVL scores ≥58. There was no correlation between PVL index and morphological scores. 2.3 ± 0.8 embryos were implanted per a patient. Using a modified equation proposed by Ekart et al., we calculated the probability of pregnancy for each treatment. The presence of at least one embryo with a PVL index score was associated with a greater chance of achieving clinical pregnancy (odds ratio=5.464, 95%CI: 1.01–29.54). However, 13 subjects presented endometriosis and, when excluded, the chance associated with achieving clinical pregnancy increased (odds ratio=14.00, 95%CI: 1.42–137.32).

Limitations, reasons for caution: Due to regulations in Mexico, only few women received single embryo transfers. A majority of women received three embryos; however, the number of embryos with PVL index scores of ≥58 ranged from one to three per cycle. We cannot be sure which embryo led to a clinical pregnancy.

Wider implications of the findings: Here, we provide evidence that using embryos with PVL index scores ≥58 could improve IVF outcomes. This result was found in Mexicans; however, it is possible the index can be implemented in other ethnicities.

Trial registration number: None.

P-152 Ultrastructure and cytogenetic analysis of bull-eye inclusions and granular vesicles in human oocytes with evaluation of embryological, clinical and newborn outcomes after ICSI

M. Sousa[1], C. Soares[1], A.R. Azevedo[1], M.J. Pinho[2], C. Almeida[2], J. Silva[3], M. Cunha[3], P. Viana[3], A. Gonçalves[4], C. Osório[4], E. Oliveira[1], R. Sá[1], J. Teixeira da Silva[5], C. Oliveira[5], A. Barros[6]

[1]*Institute of Biomedical Sciences Abel Salazar, UMIB, Univ. Porto, Microscopy, Lab. Cell Biology, Porto, Portugal*

[2]*Faculty of Medicine, University of Porto, Department of Genetics, Porto, Portugal*

[3]*Centre for Reproductive Genetics Alberto Barros, IVF, Porto, Portugal*

[4]*Centre for Reproductive Genetics Alberto Barros, IVF-Spermiology, Porto, Portugal*

[5]*Centre for Reproductive Genetics Alberto Barros, Clinics, Porto, Portugal*

[6]*Department of Genetics, Faculty of Medicine, University of Porto, Centre for Reproductive Genetics Alberto Barros, Clinics Director, Porto, Portugal*

Study question: To determine if the presence of bull-eye inclusions and granular vacuoles in human oocytes affects the clinical outcomes after intracytoplasmic sperm injection (ICSI).

Summary answer: Transfer of embryos derived from dimorphic oocytes were associated with a significant decrease in clinical pregnancy (CP), live birth delivery (LBDR) and newborn (NB) rates.

What is known already: Several oocyte dimorphisms were related to poor ICSI outcomes: indented zona pellucida was associated with lower fertilization (FR), embryo cleavage (ECR) and blastocyst (BL) rates; large refractile bodies were associated with lower FR and BL rates; marked central dark granulation were associated with lower implantation (IR) and ongoing pregnancy (OP) rates and increase in embryo aneuploidy; single or multiple vacuoles were associated with lower FR; large aggregates of smooth endoplasmic reticulum tubules (aSERT) were associated with lower FR, ECR, BL, CP, OP, IR and LBDR rates, and NB deficiencies. The bull-eye inclusions and granular vacuoles have not been previously described.

Study design, size, duration: In this retrospective study we analysed all consecutive ICSI cycles (4099 cycles) performed during the period 2005–2013. Three groups were established: controls were those ICSI cycles whose oocytes showed no dimorphisms (3877 cycles, 3352 embryo transfers and 1218 NB); cycles with the presence of the bull-eye dimorphism (11 cycles, 0.27%, 10 embryo transfers and 5 NB); and cycles with the presence of the granular vacuole dimorphism (211 cycles, 5.15%, 203 embryo transfers and 75 NB).

Participants/materials, setting, methods: At a private ART clinic, patients were fully evaluated including karyotyping. Ovarian stimulation was mainly performed with a GnRH antagonist and rFSH, and HCG for oocyte trigger. Gamete and embryo handling followed previous descriptions. For luteal support we used progesterone, and estradiol and progesterone in cases where an agonist was used for oocyte trigger. Results were analysed by indicated statistics. Donated dimorphic oocytes were processed for transmission electron microscopy and in-situ fluorescence hybridization.

Main results and the role of chance: The ultrastructure of the bull-eye inclusion revealed a round prominent structure delimited by lipid droplets and made of small vesicles. As the ooplasm was devoid of large smooth endoplasmic reticulum vesicles and aSERT, it possibly to corresponds to an abnormal trapping

of SER. There were no significant differences to controls regarding demographic, stimulation, embryological, clinical and NB outcomes. There was 1 cycle with mixed embryo transfer (ET) with 1 NB and 1 cycle with pure ET (no NB).

The ultrastructure of the granular vacuole revealed a vesicle with a double membrane containing dense vesicles and lipid droplets. The presence of a double membrane raised the suspicion of micronucleus and in-situ fluorescence hybridization was performed, which revealed the presence of chromosomes. There were 141 cycles with ET of normal embryos (61 NB), 52 cycles with mixed ET (12 NB) and 10 cycles with pure ET (2 NB). There were no significant differences to controls regarding demographic, stimulation, embryological, clinical and NB outcomes. However, with intragroup analysis, mixed ET revealed lower CP (42.9% vs 7.9%), LBDR (32.5% vs 5.4%) and NB (32.5% vs 5.9%). Similarly, pure ET revealed lower CP (42.9% vs 2.0%), LBDR (32.5% vs 1.0%) and NB (32.5% vs 1.0%).

Limitations, reasons for caution: The limitation refers to the low number of cases with these dimorphisms. However, this is because they represent a rare event, with 0.3% of cycles exhibiting oocytes with bull-eye inclusions and 5.2% of cycles with granular vesicles, which occurred occurring during 10 years where there were 4099 consecutive ICSI cycles.

Wider implications of the findings: The presence of micronuclei would have a negative impact on embryo cleavage and implantation due to embryo aneuploidies. Absence of NB abnormalities in these cycles whose oocytes display granular vesicles might be linked to micronuclei chromosome degradation. Nevertheless, couples should be advised on the low probability of reaching a pregnancy.

Trial registration number: Not applicable.

P-153 DNA methylome analysis in mouse germ cells and early embryos

T. Kono[1], H. Kobayashi[2], T. Koike[1], A. Sakashita[1], H. Tsuno[1], S. Kumamoto[1], T. Wakai[1], S. Sano[1]
[1]*Tokyo University of Agriculture, BioScience, Tokyo, Japan*
[2]*Tokyo University of Agriculture, NODAI Genome Research Center, Tokyo, Japan*

Study question: Single resolution DNA methylome of mouse zygotes, blastocysts, and the primitive streak stage embryonic tissues has not been analyzed.

Summary answer: We performed DNA methylome analysis of mouse mature germ cells, zygotes, blastocysts, and post-implantation embryonic tissues.

What is known already: Recent studies proposed that demethylation occurs during the embryogenesis and gametogenesis via two different mechanisms, which may be passive or active mechanism. Both the events are thought to be essential for proper development; however, few details are available pertaining of demethylation.

Study design, size, duration: To understand epigenetic reprogramming that occurs after fertilization, we examined the genome-wide methylation profiles in mouse zygotes, blastocysts, and the primitive-streak-stage embryonic tissues by using Illumina sequencing libraries (n=2–5). A new whole-genome shotgun bisulfite sequeicing (WGSBS) library, termed the PBAT method, which accurately quantifies whole-genome methylation levels at a single-base resolution. The deep-sequencing data (average depth: 4.5~15.7) of each sample were obtained and analyzed.

Participants/materials, setting, methods: All gametes, zygotes and embryos were collected from C57BL/6N mice. Zygotes and normal blastocysts were produced by IVF. Successful fertilization and pronuclear stages were checked by Hoechst DNA staining. The polar bodies were removed by pipetting, and all samples were subjected to PBAT library construction and sequencing by Illumina HiSeq 2500. The sequenced reads were mapped to GRCm38/mm10 reference using Bismark.

Main results and the role of chance: Whole-genome DNA methylome maps of mouse germ cells and early embryos were generated by using amplification-free whole-genome bisulfite sequencing method (PBAT). Non-CpG methylation was observed in oocytes, zygotes, and epiblasts; however, the methyl cytosine (mC) distribution in epiblasts was different from that in oocytes, and was completely absent in the blastocyst stage (the non-CpG demethylation may take place via a passive process). Both parental genomes undergo global CpG demethylation during preimplantation development; however, marked demethylation of the paternal genomes was observed compared to the modest demethylation of the maternal genomes, and demethylation of PGC genomes is more intensive. Most of the known imprint control regions show the moderate mCpG levels in zygotes, blastocysts, and post-implantation embryos (via a highly orchestrated process that involves demethylation and *de novo* methylation during embryogenesis) due to the maintenance of their parent-of-origin methylation, and such regions (among the gdDMRs) are very rare.

Limitations, reasons for caution: Shown only one species, mice.

Wider implications of the findings: Our data could serve as a platform for future studies to elucidate the role of epigenetic modifications in the development and function of germline and stem cells.

Trial registration number: The trial number is 2 to 5.

P-154 Reduced early pregnancy loss of day 4 blastocysts transferred in artificial FET on P+5

K. Ozgur[1], H. Bulut[2], M. Berkkanoglu[1], K. Coetzee[1]
[1]*Antalya IVF, Antalya IVF, Antalya, Turkey*
[2]*Ozel Antalya Tup Bebek Merkezi Antalya IVF Center, IVF, Antalya, Turkey*

Study question: To investigate the reproductive outcomes of blastocysts that developed on day 4 of *in vitro* culture transferred on P+5 or P+6 of artificial FET cycles.

Summary answer: Transferring day 4 blastocysts on P+5 of FET results in excellent pregnancy and clinical pregnancy rates, and lower early pregnancy loss rates.

What is known already: Conventional embryo developmental milestones are important indicators of embryo competence, with fast or slow developing embryos having increased aneuploidy and consequently reduced implantation, however, fine-tuning of culture media and incubation technologies maybe changing the timing of some of these embryo developmental milestones. These changes may have important consequences for embryo-endometrium synchronization and optimal implantation.

Study design, size, duration: In this pilot study to a prospective randomized control trial, we retrospectively investigated cycles where blastocysts were vitrified on day 4 of embryo culture, between May 2015 and December 2015. The cycles were divided into two cohorts according to the day of embryo transfer, P+5 (d4-d4 group, $N = 53$) or P+6 (d4-d5 group, $N = 23$).

Participants/materials, setting, methods: SAGE 1-Step™ media (Origio, Denmark) was used for embryo culture and incubation conditions set at 6% CO_2, 5% O_2 and 37.0°C (K-Systems, Denmark). All inseminations were performed using ICSI. On day 4, embryos were checked at 92 hours and 100 hours. Vitrification and warming of blastocysts were performed using ultra-rapid technologies (Cryotop, Kitazato BioPharma Co. Ltd, Japan). In the artificial FET cycles endometrium-embryo synchronization was performed using progesterone supplementation (Crinone, Merck Serono, Turkey).

Main results and the role of chance: Since May 2015, an increasing number of patients have had blastocysts vitrified after 100 hours on day 4 of embryo culture. The following parameters were comparable between the d4-d5 group and the d4-d4 group, the mean patient age (31.5 ± 6.4 vs 31.5 ± 4.8 years), antral follicle count (16.9 ± 13.5 vs 17.8 ± 9.3), and number of blastocysts transferred (1.26 ± 0.45 vs 1.34 ± 0.48). The pregnancy and clinical pregnancy rates of the two groups were non-significantly different, 82.6% versus 84.9% ($p = 0.912$) and 69.6% versus 81.1% ($p = 0.835$), respectively. However, the early pregnancy loss rate was significantly higher ($p < 0.001$) in the d4-d5 group, 15.8% versus 4.4%, respectively.

Limitations, reasons for caution: A retrospective observational analysis.

Wider implications of the findings: In the subsequent RCT the reproductive outcomes of day 4 blastocysts may help to establish whether implantations are negatively affected by *in vitro* culture or whether the transfer of blastocysts on P+5 results in better embryo-endometrium synchronization – allowing implantation to occur within the optimal time of endometrial receptivity.

Trial registration number: N/A.

P-155 Standard blastocyst morphology is not a golden predictor of euploid embryos by correlation with preimplantation trophectoderm biopsies in women older than 35 during ICSI cycles

W.J. Yang[1], C.H. Chen[2], L. Fan[3], W.H. You[4], W.R. Wang[4]
[1]*M.D.-Ph.D., Reproductive Medicine, Zhubei, Taiwan R.O.C.*
[2]*B.S, Reproductive Medcine, Zhubei, Taiwan R.O.C.*
[3]*M.D., Reproductive Medicine, Zhubei, Taiwan R.O.C.*
[4]*B.S, Reproductive Medicine, Zhubei, Taiwan R.O.C.*

Study question: Is conventional blastocyst morphological evaluation golden predictor of euploid embryos for women older than 35 in ICSI cycle by correlation with preimplantation trophectoderm (TE) biopsies?
Summary answer: There was no statistic correlation between the blastocysts morphology and euploid embryos by preimplantation trophectoderm biopsies in women older the 35.
What is known already: TE biopsy and comprehensive chromosome screening (CCS) is considered to be a promising approach to select euploid embryos for transfer. To kwon the role of morphology in blastocyst stage preimplantation genetic screening (PGS) cycles might be helpful in further IVF/ICSI cycles.
Study design, size, duration: This is a observational study performed between January 2014 and December 2014 in the reproductive center of Taiwan IVF group center, Taiwan. The study includes the data analysis of 581 blastocysts with conclusive CCS results obtained from 97 patients of 114 ICSI cycles.
Participants/materials, setting, methods: Preimplantation genetic screening was offered to infertile patients of advanced maternal age (>35 years) and/or with a history of unsuccessful IVF treatments or previous spontaneous abortion. Blastocyst morphology was assessed and categorized in three groups (excellent, average and poor). Linear regression models were used to test the relationship between blastocyst morphology and developmental rate CCS data and FET cycle outcomes of euploid blastocysts.
Main results and the role of chance: A total of 97 patients with 114 PGS cycles were included. There were 581 embryos analyzed. The overall euploid rate was 42.34% ($n = 246$). The implantation rate was 62.27%). In the excellent embryo group ($n = 314$), the euploid rate was 52.55% ($n = 165$); in the average embryo group ($n = 232$), the euploid rate was 31.47% ($n = 73$). In the poor embryo group ($n = 35$), the euploid rate was 22.86% ($n = 8$). There was no statistic difference between these three groups ($P > 0.05$). Also, there was no correlation between embryo morphology and embryonic euploid rate by CCS data ($P > 0.05$). In the present study, we found that the standard blastocyst morphology was not a golden predictor of euploid embryos in women older than 35 years old during ICSI cycles
Limitations, reasons for caution: The study is limited by its retrospective study. A larger sample size or a prospective randomized design could be used in future studies to corroborate the current findings.
Wider implications of the findings: This study provides knowledge that the standard blastocyst morphology evaluation are not good enough indicators to selection among euploid embryos in women older than 35 years old. Accordingly, all poor morphology and slower growing expanded blastocysts should be biopsied due to the similar chance of euploid embryos.
Trial registration number: None.

P-156 Effect of female age on early embryonic developmental speed before 1st cleavage

Y. Kida[1], K. Nakayama[2], E. Asano[3], M. Kojima[3], S. Kounogi[2], N. Fukunaga[2], Y. Asada[2]
[1], Nagoya, Aichi, Japan
[2]Asada Ladies Clinic Medical Corporation, Asada Ladies Nagoya Clinic, Aichi, Japan
[3]Asada Ladies Clinic Medical Corporation, Asada Ladies Kachigawa Clinic, Aichi, Japan

Study question: Does female age have an impact on early embryonic development prior to 1st cleavage?
Summary answer: Female age was found to affect the tPNf and time interval of PNa-PNf. tPNf was faster and PNa-PNf was shorter with increasing female age.
What is known already: There are many reports about early development events predicting blastocyst formation after 1st cleavage, but knowledge of the most relevant biomarkers predicting blastocyst formation before 1st cleavage is still limited. Moreover, there is no information on the impact of female age on early embryonic developmental patterns prior to 1st cleavage.
Study design, size, duration: This prospective study examined 288 embryos resulting from normal fertilization in 45 patients undergoing ICSI over a 5 month period. Embryonic events were analysed in three age categories, less than 30 years old (Group A); 30–34 years old Group B), 35–39 years old (Group C).
Participants/materials, setting, methods: All embryos were cultured in the EmbryoScope® time lapse incubator, in droplets of 30µl of Continuous Single Culture Medium (Irvine Scientic, USA) until day 7. Time of 2nd polar body extrusion (tPB2), appearance (tPNa) and fade (tPNf) of pronuclei were analyzed. For defining tPNa, the time of maternal pronuclei appearance was used. The following intervals were calculated: PB2-PNa, PNa-PNf. Tukey test was used for comparison of mean timings. *P*-values < 0.05 were considered significant.
Main results and the role of chance: Regarding the average times of tPB2, tPNa and PB2-PNa, there was no significant difference between three groups. However for the average times of tPNf and PNa-PNf, there was a significant difference between Group A and C (24.4 h vs 22.8 h) (19.0 h vs 17.3 h) ($P < 0.05$). Moreover, analysing only those embryos which went on to form blastocysts, significant differences were observed between all 3 age groups for PNf and PNa-PNf (23.7 h vs 22.9 h vs 21.9 h)(18.4 h vs 17.5 h vs 16.6 h) ($P < 0.05$). Furthermore, significant differences in tPNf and the PNa-PNf timings were found between embryos which formed blastocysts and those which did not ($P < 0.05$). Within these 2 groupings, it was also observed that there was a significant difference in the tPNf and PNa-PNf between Group B and C ($P < 0.05$).
Limitations, reasons for caution: This study was limited to the analysis of embryos from Asada Ladies Clinic patients. Developmental speed of embryos can also be impacted by the culture environment, therefore these findings apply only to this patient group.
Wider implications of the findings: Patient age seems to be an important variable to consider when scoring embryo development events through time-lapse technologies.
Trial registration number: Not applicable.

P-157 Cryopreservation of oocytes for freeze-all policy in women at risk of ovarian hyperstimulation syndrome (OHSS): preliminary results.

P. Boyer[1], D. Montjean[1], A. Amar-Hoffet[1], C. Geoffroy-Siraudin[1], M. Gervoise-Boyer[1], F. Audibert[1]
[1]Hôpital Saint-Joseph, Laboratoire de Biologie de la Reproduction, Marseille Cedex 08, France

Study question: Can "oocyte freeze all" be proposed with satisfactory results for freeze-all strategy in cases at risk of OHSS?
Summary answer: Oocyte vitrification is rarely used in IVF programs although it appears from biological to ethical points of view an alternative to exclusive "embryo-freeze-all" policy.
What is known already: OHSS is the second complication of hormonal *in vitro* fertilization treatment. OHSS may happen during ovarian stimulation treatment or after embryo implantation. Late OHSS may be prevented avoiding pregnancy by freezing all embryos, also known as freeze-all policy. So far, this strategy proved its superiority to fresh embryo transfer in terms of clinical and obstetrical outcomes. For a majority of patients and professionals, oocyte cryopreservation appears to be ethically more acceptable than embryo freezing. However, "oocyte freeze all" remains still rarely used. Futhermore the efficiency of freeze-all strategy involving only oocytes has not yet been assessed
Study design, size, duration: Some expected complications of HOSS did permit embryo transfer. Since 2012, in cases at risk of OHSS, ovulation was triggered using either hCG or GnRH agonist and pregnancy was avoided by cryopreserving the entire cohort of mature oocytes. Oocyte warming cycles were proposed when clinical context allowed a pregnancy to occur. Embryos obtained after fertilization of warmed oocytes were replaced in context of spontaneous or using hormonal replacement therapy allowing better endometrial receptivity.
Participants/materials, setting, methods: 56 women (Mean age: 32.4 years ± 5.1) at risk of OHSS (Mean oestreadiol level: 3171.7 pg/ml ± 1358.0, mean number of mature oocytes vitrified: 19.0 ± 7.4) had the entire mature oocytes cohort cryopreserved using Kitazato vitrification kit. Among the women included in this study, 4% were at severe risk of HSO and 96% of moderate HSO. 50 of these women were proposed at least one oocyte warming cycle using Kitazato warming kit, corresponding to 100 warming cycles and 93 embryo transfers.
Main results and the role of chance: No hospitalisation or complication of OHSS was reported in the included patients. A total of 1063 oocytes were vitrified and to date 532 were warmed. 87(±18.5)% of warmed oocytes survived and underwent intracytoplasmic sperm injection (ICSI). A mean of 70(±20.7)% of injected oocytes showed 2 pronuclei 16–18 hours after ICSI. In 53.4% of the case embryo transfer was performed at embryo culture Day 5. Mean

number of embryo transferred was 1.6 resulting in early pregnancy rate per transfer (βHCG blood measurement>100UI/l) of 35.5% and clinical pregnancy rate (foetal heartbeat detected) of 32.3%. 2 miscarriages were reported before 12 weeks of gestational age. To date 11 deliveries gave birth to 13 healthy children and 17 pregnancies are still ongoing. It is important to note that 531 oocytes are still cryopreserved and available for warming cycle which provides supplementary pregnancy chances.
Limitations, reasons for caution: A larger cohort is needed to draw any definitive conclusion. Moreover, the present data obtained with oocyte vitrification need to be compared with the strategy involving only embryos.
Wider implications of the findings: These encouraging results may bring a tremendous change in freeze all policy giving an alternative to exclusive embryo freeze-all. Furthermore, the major advantage of oocyte vitrification is to give couples the opportunity to have more than only one ICSI cycles allowing fresh embryo transfer without ovarian stimulation and its complications.
Trial registration number: None.

P-158 Anti-oxidative effect of 6,9,12-hexadecatrienoic acid on *in vitro* development of pre-implantation embryos

Y. Kai[1], H. Yamada[2], M. Hakozaki[2], Y. Mio[1]
[1]*Mio Fertility Clinic, Fertility Research Centre, Yonago, Japan*
[2]*Iwate Biotechnology Research Center, Department of Bioresource Sciences, Kitakami, Japan*

Study question: Does supplementation of culture media with 6,9,12-hexadecatrienoic acid improve *in vitro* development of pre-implantation embryos under oxidative stress?
Summary answer: 6,9,12-hexadecatrienoic acid supplementation may rescue embryos under oxidative stress by inhibiting reactive oxygen species (ROS) production and increasing mitochondrial membrane potential (MMP).
What is known already: Oxidative stress, especially ROS, has detrimental effects on embryo development. Although supplementing culture media with antioxidants such as melatonin, vitamin E and pyruvate has been reported to improve the quality and developmental rate of animal embryos, these substances are not widely used in clinical settings. Recently, eicosapentaenoic acid, a type of polyunsaturated fatty acid (PUFA), was shown to prevent tetrachlorodibenzodioxin-induced oxidative stress in HepG2 cells. In a preliminary study, 6,9,12-hexadecatrienoic acid, a type of PUFA, also improved *in vitro* development of mouse embryos under oxidative stress.
Study design, size, duration: We studied 167 pre-implantation mouse zygotes and 20 donated pre-implantation 4-cell human embryos *in vitro*. Mouse zygotes were pre-incubated with 6,9,12-hexadecatrienoic acid in dimethyl sulfoxide (treated group, $n = 57$) or dimethyl sulfoxide alone (negative controls, $n = 54$) before H_2O_2-induced oxidative stress, or not exposed to 6,9,12-hexadecatrienoic or oxidative stress (non-treated controls, $n = 55$). Human embryos were treated with 6,9,12-hexadecatrienoic acid (treated group, $n = 10$) or not exposed to 6,9,12-hexadecatrienoic acid (non-treated controls, $n = 10$).
Participants/materials, setting, methods: 6,9,12-hexadecatrienoic acid was purified from pacific krill (*Euphausia pacifica*). We used morphological and cytochemical analysis to assess embryo development and ROS production, respectively. We also analyzed MMP at the morula stage, total cell number at the blastocyst stage, and the ratio of inner cell mass (ICM) to trophoectoderm (TE) at the blastocyst stage. Fluorescence of ROS production and MMP were calculated using Image J software. Values are expressed as mean ± standard error of mean.
Main results and the role of chance: Under H_2O_2-induced oxidative stress, the rate of blastocyst formation in mouse zygotes treated with 6,9,12-hexadecatrienoic acid was higher than in negative controls (58.8% v 25.0%; non-treated controls, 70.6%). For ROS, relative fluorescence intensity per embryo 24 hours after H_2O_2 exposure was lower in the treated group than in negative controls (9.9 ± 1.0 v 11.6 ± 0.5; non-treated controls, 7.9 ± 0.5). For MMP, relative fluorescence intensity per embryo (measured using tetramethylrhodamine methyl ester) was higher in the treated group than in the negative controls at the morula stage (1.083 ± 0.08 v 1.008 ± 0.07; non-treated controls, 1.000 ± 0.08). The total cell number and the ICM:TE ratio at the blastocyst stage was not significantly different between groups. The rate of blastocyst formation did not differ between the treated and non-treated human embryos (80.0% v 70.0%), but the hatching rate for the human embryos was much higher in the treated group (70.0% v 20.0%).
Limitations, reasons for caution: Further investigations with larger samples are needed to confirm our results. The molecular mechanism that underlies the antioxidant effect of 6,9,12-hexadecatrienoic acid is unclear.
Wider implications of the findings: 6,9,12-hexadecatrienoic acid could be used as a safe and effective functional food ingredient, and might become a useful supplement for reducing oxidative stress during *in vitro* culture of embryos and while obtaining viable embryos for assisted reproductive technology.
Trial registration number: NA.

P-159 Embryonic estrogen receptors: do they have a role in the implantation and post-implantation development?

F.J. Huang[1], Y.D. Hsuuw[2], W.H. Chan[3], K.C. Lan[1], H.Y. Kang[4], P.Y. Lin[1], K.E. Huang[5]
[1]*Kaohsiung Chang Gung Memorial Hospital, Department of Obstetrics and Gynecology, Niao, Sung District, Kaohsiung, Taiwan R.O.C.*
[2]*National Pingtung University of Science and Technology, Department of Life Science, PingTung, Taiwan R.O.C.*
[3]*hung Yuan Christian University, Department of Bioscience Technology and Center for Nanotechnology, Chung Li, Taiwan R.O.C.*
[4]*Chang Gung University College of Medicine, Graduate Institute of Clinical Medical Science, Kaohsiung, Taiwan R.O.C.*
[5]*Chang Gung University College of Medicine, Department of Medicine, Kaohsiung, Taiwan R.O.C.*

Study question: Do estrogenic hormones in the blastocysts have a physiological role in the implantation and post-implantation development?
Summary answer: The implantation and post-implantation development of mouse blastocysts *in vitro* were adversely affected by blocking estrogen receptors (ER) using ER blockers.
What is known already: The effects of estrogen depend on the existence of their specific receptors. ER mRNA was found in oocytes and fertilized eggs. The message level began to decline at the two-cell stage and reached its lowest level at the five- to eight-cell stage. ER mRNA reappeared at the blastocyst stage. The embryonic expression of ER genes in the blastocyst suggests a possible functional requirement for ER at this stage of development. These results provide a basis for determining the direct role of estrogen in pre-implantation embryos.
Study design, size, duration: The physiological function of the ER was evaluated by using the ER blockers. Mice blastocysts were cultured for 8 days to evaluate the morphological development. 1000 blastocysts were collected from the ICR female mice for the *in vitro* culture. 100 blastocysts were collected for the immunocytochemical assay to detect the ER in the pre-implantation embryos.
Participants/materials, setting, methods: This was an *in vitro* experimental study involving the use of mouse blastocysts and the model of in-vitro 8-day culture. Under the tamoxifen (ER-α blocker) or ICI182,780 (ER-α/-β blocker) r PHTPP (ER-β blocker) treatment, implantation and post-implantation development were evaluated daily. The ER proteins in the pre-implantation and post-implantation embryos were detected through the immunocytochemical assay.
Main results and the role of chance: The ER-α and β were noted in the blastocyst and early post-implantation embryos (implanted blastocysts and early egg cylinder stage embryos). However, only ER-β was noted in the late egg cylinder stage embryos. Differential expression of ER in the post-implantation embryos was shown in the study. At the concentration of 10^{-7}M or more, tamoxifen impaired the development of the late egg cylinder stage and early somite stage. Furthermore, at the concentration of 10^{-5}M, the adverse effects occurred earlier at the stage of early egg cylinder embryos. Similar effects of ICI182,780 were found at the concentration of 10^{-8}M to 10^{-6}M. Furthermore, the development from implanted blastocysts to early somite embryo was completely affected adversely at the concentration of 10^{-5}M of ICI182,780. PHTPP did not impair the development of implantation and early egg stage embryos. However PHTPP at the concentration of 10^{-7}M to 10^{-5}M impair the development of late egg cylinder stage embryo. In conclusion, the dose-dependent adverse effects of ER blocker on the implantation and post-implantation development were demonstrated clearly. Reviewing the literatures, this is the first piece of evidence that physiological role of ER in the blastocysts and post-implantation were demonstrated in the study.
Limitations, reasons for caution: Considering the ethical and technical limitations inherent to the use of human embryos for implantation studies, the mouse

model was used as an approach for exploring the potential role of embryonic ER on the implantation and post-implantation embryo development. Nevertheless, the extrapolation of these results to humans requires further investigation.
Wider implications of the findings: This study presents clear evidence on the potential role of embryonic ER on the implantation and post-implantation embryo development. These new findings could contribute to the physiological knowledge of human embryo culture for the clinical applications in in-vitro – fertilization protocol.
Trial registration number: The study has been supported by grants from the National Science Foundation of Taiwan (NSC-101-2314-B-182A-110, NSC-102-2314-B-182A-085 and NSC-103-2314-B-182A-108). There is no competing interest.

P-160 Time-lapse imaging provides further evidence that planar arrangement of blastomeres is abnormal

T. Ebner[1], P. Oppelt[1], E. Radler[1], M. Puchner[1], R.B. Mayer[1], O. Shebl[1]
[1]*Kepler Universitätsklinikum, Gynecology, Obstetrics, and Gynecological Endocrinology, Linz, Austria*

Study question: Are developmental kinetics of planar human embryos different from tetrahedral ones?
Summary answer: Planar embryos are associated with both a significant increase in irregular cleavage as well as a remarkable delay in preimplantation development.
What is known already: Normal day-2 embryos show a tetrahedral arrangement of four cells with three blastomeres lying side by side. Cleavage anomalies include embryos that are characterized by a particular planar constellation of four blastomeres with presumed incomplete cleavage. The fact that such embryos show a reduced implantation capacity led an experienced time-lapse user group to recommend the annotation of a planar arrangement of cells on observation (tPA). However, to date no information on morphokinetics of planar embryos is available.
Study design, size, duration: Within a 5-month study period (August to December 2015) all consecutive patients were prospectively screened for day-2 planar embryos. Planar embryos were annotated according to generally acknowledged and novel time-lapse variables. Morphokinetic parameters of the sibling embryos showing normal cleavage pattern served as a control.
Participants/materials, setting, methods: A total of 210 patients frequented an university-affiliated clinic in the study period. The rate of affected patients (exclusively ICSI cases) and embryos was 12% and 4%, respectively. All embryos were cultured in a novel time-lapse incubator in a tri-gas milieu until day 5. A 5-minute picture interval was set to optimize annotation.
Main results and the role of chance: Significantly more ($P > 0.001$) planar embryos showed morphological (e.g., bi- and multi-nucleation) and morphokinetic (trichotomous mitosis, cell fusion, embryo rolling) anomalies as compared to tetrahedral embryos. Time-lapse imaging allowed to deselect 45% of the planar and 13% of the normal embryos (this information would have been missed using static observation). Morphokinetics were unaffected up to 4-cell stage, thereafter planar embryos cleaved significantly slower (3–4 h) as indicated by t5 to t8.
Limitations, reasons for caution: This is the first study using a time-lapse incubator with individual incubation chambers. It is not clear to what extent morphokinetic variables may differ from those assessed with alternative time-lapse-incubators. It should be kept in mind that, theoretically, patients generating one or more planar embryos could have an intrinsic problem.
Wider implications of the findings: Time-lapse imaging of human day 2 planar embryos ultimately confirms what has been hypothesized based on static observations of the same. Increased presence of multinucleated blastomeres and irregular cleavage behavior strongly indicate that planar embryos are abnormal and should be deselected.
Trial registration number: None.

P-161 No differences in development/quality of embryos cultured in sequential and single-step medium regarding of female age and method of *in vitro* fertilization: prospective study

L. Bacer Kermavner[1], M. Stimpfel[1], J. Kmecl[1], B. Valentincic Gruden[1], J. Mivsek[1], E. Vrtacnik-Bokal[1], B. Pozlep[1], I. Virant Klun[1]
[1]*University Medical Centre Ljubljana, Reproductive Unit, Department of Obstetrics and Gynaecology, Ljubljana, Slovenia*

Study question: What is the difference in embryo development and quality after prolonged *in vitro* culturing to the blastocyst stage in sequential media and single-step medium?
Summary answer: No differences in the development of embryos to the blastocyst stage and their quality were found after culturing in sequential media and single-step medium.
What is known already: Sequential media protocols are sufficient but not necessary to support the complete *in vitro* development of human preimplantation embryos. It has already been published that human embryos can be successfully cultured from day 0 onward in single-step medium without renew it on Day 3. In spite of this, there is still some scepticism about the single-step medium maybe to be sufficient for embryo development to the blastocyst stage.
Study design, size, duration: In this prospective, sibling zygote/embryo study, we compared the development and quality of embryos, cultured in sequential media and single-step medium, regarding of female age and method of *in vitro* fertilization (IVF or ICSI). A total of 581 normally fertilized (2PN) zygotes from 96 IVF/ICSI cycles in 96 couples were randomly allocated to two culture systems: sequential media (285 zygotes) and single-step medium (296 zygotes) to compare the embryo development and quality.
Participants/materials, setting, methods: In each couple, a half of embryos was cultured in Sydney IVF COOK sequential media (Cleavage medium (Day 1–3) and Blastocyst medium (Day 3–5/6) and another half of embryos in SAGE 1 single-step medium (Origio) from Day 1 to Day 5/6 to compare the blastocyst rate and the quality of derived blastocysts according to Gardner (2000). The collected data were analyzed using Chi-Square test. Statistical significance was set up at $P < 0.05$.
Main results and the role of chance: The derived blastocysts were assigned to one of three quality groups in terms of development and morphology of embryoblast and trophectoderm: 1) good-quality (≥3AA), 2) fair-quality (≥3AB and BA), or 3) poor-quality (1–6 BB, CC) blastocyst. The blastocyst rate and the proportion of good-quality blastocysts, developed in sequential media, were not significantly different from those, developed in single-step medium (43.6 vs. 44.8% and 48.3 vs. 48.1%, respectively). There were no statistically significant differences in the proportion of fair-quality blastocysts (13.9 vs. 17.5%) and poor-quality blastocysts (37.7 vs. 34.3%) between the two culture systems. In addition, there was approximately the same proportion of morulae (17.5 vs. 17.1%) and arrested embryos (38.9 vs. 38%) in both culture systems. And finally, there was no statistically significant differences in blastocyst quality between the two culture systems regarding of female age (≤36/>36 years) and method of *in vitro* fertilization (IVF, ICSI).
Limitations, reasons for caution: The differences in groups failed to reach statistical significance. We have to put attention on implanted embryos and the outcome of pregnancy in the future.
Wider implications of the findings: The results of this study indicate that the sequential media are quite comparable to single-step medium in terms of embryo development and quality. Therefore the sequential media can be replaced by single-step medium to culture embryos to the blastocyst stage in daily clinical practice.
Trial registration number: 0.

P-162 Egg age modulates calcium signaling pattern, specific histone modification and embryonic development outcome in the mouse

B. Li[1], S. Chen[1], X. Xiao[1], J. Huang[1], L. Li[1], Z. Hengde[1], Z. Cao[1], J. LV[1], X. Wang[1]
[1]*Tangdu Hospital, the Fourth Military Medical University, Department of Obstetrics and Gynecology, Xi'an-Shaan'xi, China*

Study question: Egg age is a crucial factor affecting embryo quality, and thus closely associated with the outcome of embryo development. However, it is unclear how egg age affects the embryo development.
Summary answer: Egg age affects the pattern of calcium signaling at fertilization, epigenetic modifications and sperm chromatin decondensation, and thus may modulate the fetal and placental development.
What is known already: In mammals, ovulated eggs arrested at MII stage are normally fertilized soon after ovulation. If fertilization does not occur within the narrow optimal window, unfertilized eggs that remain in the oviduct would lead to aging. egg age is one of the key factor affecting the egg's quality and embryo's developmental potential after fertilization.

Study design, size, duration: Mature mouse eggs were collected from oviducts at 11–12 h, 14–15 h, 19–20 h after hCG injection. Then, eggs were fertilization by fertilized by intracytoplasmic sperm injection (ICSI). The relationship between egg age and embryonic development, the pattern of calcium signaling at fertilization, the timing of pronuclear formation, and epigenetic modifications were analysed.
Participants/materials, setting, methods: CD1 strain mice (6–8 weeks old) were used. Intracytoplasmic injection of spermatozoa was performed using a Leica Inverted Microscope equipped with a pair of manually operated pressure microinjector (IM-6 Narishige) and Piezo-system (PMM Controller, Model PMAS-CT150). The cytoplasmic Ca^{2+} of mouse eggs was measured using a Mira-Cal Ratio Vision digital fluorescence imaging system. H3K9 acetyl, H3K9 methyl, H4K16 acetyl, H3T11 phos were analysed by immunofluorescence staining.
Main results and the role of chance: 1) egg age significantly decreased blastocyst formation rate, blastocyst total cell number, the normal fetuses rate, and placental weight; 2) aged eggs had an abnormal pattern of calcium signaling at fertilization, significant increased eggs showing only 1–2 calcium spike in comparison with young eggs; 3) egg age affected the timing of pronuclear formation; 4) H4K16 acetylation in aged eggs decreased significantly quickly in sperm chromatin following fertilization; 5) aged eggs showed a significantly reduction in sperm chromatin decondensation by judging the area of sperm nucleus.
Limitations, reasons for caution: This study was carried out using a mouse model. Whether egg age affects the fertilization events in human and affect the development of human fetal and placental development need further study.
Wider implications of the findings: Egg age affects the development of mouse embryonic development partly via the variation of calcium signaling pattern and specific histone modification.
Trial registration number: Basic animal research.

P-163 Clinical outcomes and development of children born from vitrified oocytes for azoospermic patients

Y. Nakamura[1], H. Hattori[1], C. Sasaki[1], M. Takahashi[1], Y. Tanaka[1], H. Inoue[1], M. Koizumi[1], K. Kyono[1]
[1]*Kyono ART Clinic, Department of Obstetrics and Gynecology, Sendai, Japan*

Study question: The aim of this study was to assess the effect of oocyte vitrification on clinical outcomes and development of childlen compared to fresh oocytes.
Summary answer: There were no significant differences in clinical results or child development between fresh and vitrified oocytes.
What is known already: Vitrification has been reported to be a simple, cost effective, efficient method for cryopreservation of mammalian and human oocytes. Many studies have shown more positive results with oocyte vitrification than with slow freezing procedures.
Study design, size, duration: Retrospective study. Subjects were 438 couples with 924 oocyte-retrieval cycles for azoospermic patients from Dec., 1996 to Sep., 2015. Children were born from vitrified oocytes (68 from 66 pregnancies) and fresh oocytes (230 from 196 pregnancies). Singleton and multiple pregnancies from the husband's sperm and donated sperm were included.
Participants/materials, setting, methods: Oocyte vitrification by the Cryotop method has been performed in our clinic since 2003. We assessed the cumulative pregnancy rate, neonatal conditions at birth, and development of movement and language between the two groups from ages 1 to 6 years old.
Main results and the role of chance: In the vitrified group, the survival rate of oocytes after warming was 87.2% (909/1043). Mean women's ages were 33.6 ± 4.8 and 33.1 ± 6.6 at oocyte retrieval and mean men's ages were 35.7 ± 4.9 and 34.9 ± 5.8 in the vitrified and fresh groups, respectively. No differences were found between the two groups in pregnancy rate (35.2%:93/264 vs. 36.5%:364/996), gestational age at delivery (39.4 weeks vs. 39.2 weeks), birth weight (3.070 g vs. 3.067 g), birth height (39.4 cm vs. 39.2 cm). In the vitrified group, there were no cases of congenital abnormality. In the fresh group, there were two cases of congenital abnormality: one of polymelia and one of atrial septal defect. There were no differences in movement and language development between the two groups.
Limitations, reasons for caution: None.
Wider implications of the findings: Regarding oocyte vitrification, many studies have shown more positive results than with slow freezing procedures. In this study, there are no significant differences between fresh and vitrified oocytes for azoospermic patients. The use of vitrified unfertilized oocytes should be recommended for wide medical treatment.
Trial registration number: None.

P-164 The utilization of different gonadotrophin preparations induces significant differences in the generation of high quality embyos as measured by time lapse technology

N. Galindo[1], M. Munoz[1], V. Legidos[1], G. Leon[1], I. Perez-Cano[1], M. Meseguer[2]
[1]*IVI Alicante, Reproduction, Alicante, Spain*
[2]*IVI Valencia, Reproduction, Valencia, Spain*

Study question: To evaluate if different protocols of stimulation influence embryo morphology dynamics and implantation rates in patients undergoing IVF/ICSI for the treatment of infertility.
Summary answer: Different gonadotrophin protocol induces significant differences in the generation of high quality embryos. The higher proportion of high quality embryos is observed with r-FSH + r-LH.
What is known already: The impact of protocols of stimulation on the quality of the embryos generated is a topic of continuous discussion. Most studies comparing gonadotrophins, assess embryo quality and implantation potential utilizing single point morphological evaluations which are subjective and may change between different IVF settings. To be able to identify the best protocol of stimulation for each patient and maximize the production of high quality embryos, it is of outmost importance to be able to assess quality with an objective technology based on time-lapse.
Study design, size, duration: Retrospective cohort study. We examined 650 *in vitro* fertilization-intracytoplasmic sperm injection (IVF/ICSI) cycles in patients with controlled ovarian stimulation utilizing different gonadotrophin protocols by combining two recombinant gonadotrophins (r-FSH+r-LH) (n = 91), only r-FSH (n = 331) or with hMG (n = 228). A total of 3128 embryos were cultured in single step medium and recorded from zygote to blastocyst stage analyzed in Embryoscope™ time-lapse technology (Vitrolife, Sweeden). The study period were between October 2011 and November 2015.
Participants/materials, setting, methods: Ovarian stimulation of patients analyzed were performed with three different gonadotrophin protocols as described before. After ICSI, oocytes and embryos. High quality embryos were defined as those with optimal morphokinetic development and high implantation potential, as described by Vermilyea et al. (2014). The variables analyzed by multiple logistic regression included the duration and the synchrony of the second embryo cell cycle together with the number of oocytes retrieved, maternal age and body mass index (BMI).
Main results and the role of chance: Descriptive characteristics of the patients in the stimulation protocols groups included in the analysis revealed no differences maternal age and BMI. Also Estradiol and Progesterone levels on the day of hCG administration were comparable together with similar days of stimulation. On the contrary the number of oocytes retrieved were 12.9 (12.4–13.5, r-FSH), 9.1 (CI95% 8.3–9.9, hMG), 9.9 (8.8–8.11.0, r-FSH+r-LH) and Metaphase II oocytes 7.7 (CI95%7.1–8.3), 9.8 (CI95%9.3–10.3) and 7.9 (CI95%7.0–8.9) respectively for r-FSH, hMG and r-FSH+r-LH. Different gonadotrophin protocols of stimulation induces significant differences in the proportion of high quality embryos observed (r-FSH = 7.35%, hMG = 7.86%, r-FSH+r-LH = 12.18%; p = 0.016). Multiple logistic regression analysis revealed significant effect produced by gonadotropin protocol on the production of high quality embryos (r-FSH+r-LH vs hMG, odds ratio (OR) = 1.876 (CI95%1.17–3.02) p = 0.010). The multivariable analysis also revealed that the number of oocytes recovered, maternal age and BMI did not prove to be an influential factor on embryo quality. There were also relevant differences on implantation rate related with stimulation protocols (r-FSH 33.3%, hMG 27.1%, r-FSH+r-LH 35.7%), but these differences were not significant, probably due to the still reduced sample size.
Limitations, reasons for caution: Although the multiple regression analysis is controlling all the potential confusing factors that may bias the current data the retrospective nature of the present study should take our conclusions with precaution. Future prospective randomized studies would be ideal to confirm significant differences in embryo quality and implantation rate.
Wider implications of the findings: The outcome of our study suggest that different gonadotrophin protocols induces significant differences in the

generation of high quality embryos. Customized stimulation protocols adapted to the clinical features of our patients may lead us with the generation of higher proportion of good quality embryos enhancing reproductive outcome.
Trial registration number: None.

P-165 Computer-automated time-lapse analysis can be use with two distinct levels of oxygen concentration

E. Olaya[1], A. Guijarro[2], L. Ortega[1], C. Luna[1], S. Cortés[1], R. Nuñez[1], P. Caballero[3]
[1]*Clinica Tambre, Embriology Laboratory, Madrid, Spain*
[2]*Hospital Virgen de la Luz, Gynecology, Cuenca, Spain*
[3]*Clinica Tambre, Gynecology, Madrid, Spain*

Study question: The aim of this study was to analyse if computer-automated prediction scores for embryo development potential also correlate to patient pregnancy using two different levels of oxygen concentration.
Summary answer: Eeva High and Medium embryos have a significantly higher likelihood of get a pregnancy than Eeva Low embryos irrespective of the oxygen concentration used.
What is known already: The Eeva™ Test (Early Embryo Viability Assessment) is a prognostic test based on automated detection and analysis of time-lapse imaging information and it has been shown to benefit embryo selection specificity when used adjunctively with traditional morphology. The classification model was based on two cell division timing parameters, both of which have been shown to consistently correlate to embryo development. However, the methods above have not yet been validated using incubators with different oxygen concentration.
Study design, size, duration: This is a retrospective study including 349 embryos from 49 patients who were undergoing fresh *in vitro* fertilization (IVF) treatment. 26 patients used their own eggs (53.1%) embryos and 23 patients used donor eggs (46.9%). All of them consented to have their embryos imaged using the Eeva System from January 2015 to December 2015.
Participants/materials, setting, methods: Computer-automated assessment of 349 embryos was performed using the Eeva Test. 222 embryos (63.6%) were cultured with a 5% Oxygen concentration and 127 (36.4%) with a 20% oxygen concentration. The relationship between such computer-derived outputs (High, Medium, Low scores), and clinical pregnancy were examined at 5% and 20% oxygen tension
Main results and the role of chance: The EEVA result were: 63 (18.1%) No Result, 147 (42.1%) Low, 58 (16.6%) Medium and 81 (23.2%) High. There were no significant difference with the EEVA Score when we studied the eggs source (chi2 *p*:0.796) neither oxygen concentration of the incubator we used (chi2 *p*:0.202).

We transferred a total of 75 embryos, from which 21 (28%) were Low, 19 (25.3%) were Medium and 35 (46.7%) were High. When we applied an univariate analysis we found a positive linear correlation (*p*: 0.037) between scores and pregnancy, 54.3%, 52.6%, 23.8% pregnancy rates to High, Medium and Low Scores respectively. Moreover, if we limit the Eeva score in two categories, High-Medium and Low, the statistic significance in pregnancy rate will increase to 53.7% vs 23.8%.

In our case a binary logistic regression multivariate model helped us to discard the concomitant effect of confusion factors and we could check that eggs source and Eeva score were two independent forecasts factors each other and with the confusion factors introduced at model.

Considering this confusion factors, the donor eggs give us more probability to achieve a pregnancy with a OR 6.379 (*p*:0.003) and also the embryo transfer with a High or Medium Score with a OR 3.933 (*p*:0.035).
Limitations, reasons for caution: The different oxygen concentration is a choice that the laboratories have to do, and many studies demonstrate that this concentration varies the morphokinetic parameters of embryos. However, in our study we have not observed difference. Obviously, this study needs more cases to be consolidated.
Wider implications of the findings: Our results show that it's the same oxygen concentration and the Eeva results doesn't vary whith donor or patient eggs. According with our results, it's possible to unify High and Medium Eeva Score like some years, but with wide time limits, we have the risk to do a misclassification.
Trial registration number: No clinical trial.

P-166 Is day 5 transfer still necessary in the time-lapse era?

F. Gagsteiger[1], D. Zhu[2], Z. Szabó[2], N. Reeka[1], K. Eibner[1], J. Koglin[1], K. Bundschu[1], N.L. Sandi-Monroy[2]
[1]*Kinderwunschzentrum Ulm, Reproductive Medicine, Ulm, Germany*
[2]*Kinderwunschzentrum Ulm, IVF Labor, Ulm, Germany*

Study question: Are there differences in morphokinetics between embryos that did not implant and those resulting in live births?
Summary answer: Embryos resulting in live births presented significant morphokinetic differences in the first three days of culture in comparison with not implanting embryos.
What is known already: Time-lapse imaging allows exact observation of morphokinetic characteristics of embryos during its culture. Several studies have developed algorithms to predict embryo blastulation, implantation or aneuploidy. Many authors reported better pregnancy and implantation rates, as well as less miscarriage. However, as far as we are concerned, no study has ever compared the morphokinetics of embryos in extended *in vitro* culture resulting in live births with those not implanted.
Study design, size, duration: This was a retrospective study of 272 embryos from 168 patients attending a private fertility clinic in Germany between April 2012 and June 2013. Embryos were divided into two groups – no implantation (IF, $n = 222$) or 100% implantation and live birth (LB, $n = 52$). For analysis, 23 morphokinetic parameters were selected and compared among the embryos.
Participants/materials, setting, methods: Only fresh stimulated ICSI cycles were included in the analysis. Embryos were cultured in the EmbryoScope after intracytoplasmic sperm injection (ICSI, time zero) in sequential media at low oxygen concentration. Embryo transfer (ET) was performed on day 2 to 6 depending on the number of available embryos. Selection of embryos for ET was based solely on morphology before ET. Kruskal-Wallis or Mann Whitney test were used and $p < 0.05$ was considered significant.
Main results and the role of chance: To discard a possible effect of age on morphokinetics, embryos were divided according to female age in three groups (≤ 34, 35–39 and ≥ 40 years) but no significant differences among the groups could be seen. On the other side, when analyzing the morphokinetics of IF and LB embryos, we could observe that seven parameters differed significantly between the groups. Results are presented as mean of hours post ICSI ± standard deviation. Firstly, syngamy in IF embryos occurred later than in LB embryos, 24.09 ± 3.49 versus 22.92 ± 2.81 ($p = 0.0196$), respectively. Secondly, time to reach the 2-cell stage (t2), a well established good prognosis marker before time lapse, also differed slightly between IF and LB embryos (26.96 ± 3.87 versus 26.27 ± 4.78, respectively, $p = 0.0313$). Additionally, embryos in the IF group seemed to be slower than in the LB group in their development regarding time to reach the 5-, 6- and 7-cell stage (t5, $p = 0.0193$; t6, $p = 0.0032$; t7, $p = 0.0002$). Thus, the duration of the third round of embryonic cleavage (cc3) was also longer in the IF than LB group ($p = 0.0015$). Furthermore, start of blastulation (tFB) occurred earlier in the LB group (100.4 ± 5.72) than in the IF group (103.4 ± 7.323, $p = 0.0015$).
Limitations, reasons for caution: This is a retrospective analysis in a small group of patients. Possible confounding factors, such as length of infertility, were not adjusted when doing the analysis. Furthermore, the use of algorithms for embryo selection still requires further studies before being applied in routine practice.
Wider implications of the findings: *In vitro* culture has been suggested to affect not only later embryo development but also perinatal outcomes. Developing an algorithm that allows successful embryo selection within three days of culture could minimize possible negative effects by reducing culture period and also reduce costs for patients.
Trial registration number: Not applied.

P-167 Low oxygen tension may increase implantation potential by enhanced expression of hypoxia and antioxidant genes in mouse blastocyst cultured *in vitro*

Y.Y. Ma[1], C.H. Chen[1], J.W. Wang[1], C.R. Tzeng[1]
[1]*Center for Reproductive Medicine & Sciences, Department of Obstetrics & Gynecology, Taipei City, Taiwan R.O.C.*

Study question: How low O_2 tension affect the embryo viability, and gene expression profile cultured *in vitro*?

Summary answer: The lower O_2 tension improve embryo viability by increased antioxidant enzymes and LIFR to increase implantation ability, enhanced mitochondrial activity during implantation period.
What is known already: In human IVF, the oxidative stress appears to jeopardize *in vitro* embryo development. Many studies showed lower oxygen concentration had as a better result as well as addition of antioxidants to culture media. However the mechanisms of beneficial effects of reduced oxygen tension in embryogenesis remain unclear.
Study design, size, duration: A prospective RCT of experimental animal study in a university hospital.
Participants/materials, setting, methods: The 2-cell ICR mouse embryos were cultured to blastocyst stage under 3% O_2(n = 330) tension and 20% O_2(n = 317) tension. The expression of antioxidant genes (MnSOD and PRDX5) were analyzed by real-time RT PCR and validated by Immunofluorescence. The apoptosis, mitochondrial membrane potential (mtMP) and ROS level were assessed by TUNEL, stain with JC-1 and DCFDA, respectively.
Main results and the role of chance: The blastocyst formation and hatching rate increased significantly in 3% O_2 group when compared to 20% O_2 group (P < 0.5). The transcription levels of MnSOD and PRDX5 were also significantly increased seven to eight fold in 3% O_2 group, compared to 20% O_2 group (P < 0.05). Immunofluorescence staining showed the intensity of HIF-2α, MnSOD and LIFR was higher in 3% O_2 than 20% O_2 group, respectively. Apoptosis and ROS levels was significantly higher in 20% O_2, compared with 3% O_2 group (P < 0.05). The 3% O_2 blastocyst also showed a significantly higher mtMP compared with 20% O_2 group.
Limitations, reasons for caution: Our study was based in mouse model and further studies on implantation ability or birth rate are required to confirm our findings.
Wider implications of the findings: This study provided new evidence of a beneficial effect of 3% oxygen tension in embryonic competence and may improve further implantation; it may also assist in developing best culture condition for IVF.
Trial registration number: NA.

P-168 Effect of timing of oocyte denudation after oocyte retrieval on fertilization and pregnancy outcome following cleavage stage single embryo transfer

H. Terasawa[1], S. Ueno[1], K. Uchiyama[1], A. Yabuuchi[2], T. Okuno[3], T. Kobayashi[3], K. Kato[3]
[1]Kato Ladies Clinic, Department of IVF Laboratory, Tokyo, Japan
[2]Kato Ladies Clinic, Department of Research and Development, Tokyo, Japan
[3]Kato Ladies Clinic, Department of Gynecology, Tokyo, Japan

Study question: Does denuding timing of cumulus-ooycte complexes after oocyte retrieval (OR) for ICSI influence fertilization rate and pregnancy outcomes following single embryo transfer?
Summary answer: Fertilization and clinical pregnancy rates were significantly declined as duration between OR and oocyte denuding became longer.
What is known already: It has been hypothesized that cumulus cells secrete paracrine factors which promote post-ovulatory oocyte aging. This event potentially concur with the entry of cumulus cells into apoptosis. Additionally, previous findings that the degree of apoptosis in cumulus cells in matured oocytes influence the fertilization rate suggest the possible correlation between timing of oocyte denudation after OR and pregnancy outcomes. Currently, in ART, little is known regarding the effect of duration between OPU and oocyte denudation on fertilization and pregnancy outcomes. Therefore further IVF laboratory based studies were required to clarify the hypothesis.
Study design, size, duration: A retrospective cohort study of 302 IVF cycles (566 oocytes) was conducted in single center from March 2015 to November 2015. The timing of denudation after OR was classified into three groups: less than 2 hours (Group A, n = 80), 2–3 hours (Group B, n = 165) and 3 hours and over (Group C, n = 57). Fertilization rate after ICSI and clinical pregnancy rate with gestational sac following single cleavage stage embryo transfer (SET) were compared among the groups.
Participants/materials, setting, methods: This cohort fulfilled the following criteria: woman's age at egg retrieval was 33–39 years, less than 3 times of repeated cycle and the less than 5 oocytes for ICSI. The oocytes were retrieved by minimum stimulation or natural cycles. Spindle position was checked prior to ICSI by a polarized light optical system. Outcome measures were fertilization rate (2PN), abnormal fertilization rate and clinical pregnancy rate following SET in 163 SET cycles.
Main results and the role of chance: There were significant differences in fertilization rate (2PN) between Group A and Group C (A: 91.2% 114/125, B: 87.3% 288/330 and C: 82.0% 91/111, p < 0.05). Abnormal fertilization rate was similar among the groups (A: 1.6% (3/125), B: 2.4% (8/330) and C: 4.5% (5/111)). However, abnormal fertilization rate was tended to increase as duration between OR and denuding became longer. Clinical pregnancy rates following subsequent SET were not significantly different between groups (A: 38.9% 23/59, B: 26.9% 21/78, C: 23.0% 6/26), yet, there was a tendency to improve the clinical pregnancy rate in earlier denuding group.
Limitations, reasons for caution: The main limitation of the present study is related to its retrospective nature and to a relatively small sample size.
Wider implications of the findings: Our finding that normal fertilization and clinical pregnancy rates were improved as duration between OPU and oocyte denuding became earlier suggests that timing of oocyte denuding could influence the fertilization and pregnancy outcomes. Therefore, cumulus-oocyte complexes are recommended to be denuded early after OR in the case of ICSI.
Trial registration number: None.

P-169 The assessment of metaphase-I (MI) oocytes retrieved from COH by time-lapse imaging

H.J. Kim[1], H.J. Yoon[1], J.M. Jang[1], W.D. Lee[2], S.H. Yoon[3], Y.K. Shin[4], K.H. Kim[5], J.H. Jung[3], J.H. Lim[3]
[1]Maria Fertility Clinic, Research Center, Seoul, South Korea
[2]Maria Fertility Clinic, Ob/Gyn, Seoul, South Korea
[3]Maria Medical Foundation, Research Center, Seoul, South Korea
[4]Ilsan Maria Fertility Clinic, Ob/Gyn, Goyang-si, South Korea
[5]Bucheon Maria Fertility Clinic, Ob/Gyn, Bucheon-si, South Korea

Study question: The aim of this study was to evaluate the fertilization potential and morphokinetics of MI oocytes from controlled ovarian hyperstimulation cycles of patients.
Summary answer: To compare the metaphase-II (MII) oocytes, MI-derived embryos decreased the fertilization rate. Moreover, MI oocytes were significantly slower than MII oocytes of morphokinetics.
What is known already: During human assisted reproductive technology, about 20% of oocytes fail to reach the MII stage within 38 hours after administration of hCG. The use of immature oocytes could increase the number of embryos obtained to enhance the chance of pregnancy. However, there is a low fertilization rate when ICSI is performed with immature oocytes, with the potential for abnormal embryonic development due to defective cytoplasmic maturation. Until now, reports of morphokinetics and abnormal embryo events from hyperstimulated MI oocytes are mostly limited.
Study design, size, duration: This retrospective study on 87 patients performed between January 2014 and September 2015. Sibling embryos (n = 703, MII oocytes vs n = 231, MI oocytes) from the same patient were cultured in time-lapse incubator. This study was performed in 92 cycles that had undergone ICSI treatment.
Participants/materials, setting, methods: MII and MI oocytes were obtained from controlled ovarian hyperstimulation cycles of patients. MII oocytes were performed ICSI for 4–5 h after oocyte retrieval, while MI oocytes were cultured in maturation media and then were performed ICSI after checking the maturity. All embryos were cultured after ICSI assessed in a time-lapse incubator (EmbryoScope, Unisense Fertilitech, Denmark) and annotated for pattern time of cleavage.
Main results and the role of chance: The fertilization and good quality embryo rate of MI-derived embryos were significantly lower than that of MII oocytes (63.6% vs 76.5% and 44.9% vs. 62.0%, respectively; P < 0.001). There was no difference in the rates of multinucleation at the 2-cell stage (37.2% vs. 37.4%, P = 0.957). However, the uneven blastomere size at the 2-cell stage (39.5% vs. 24.0%, P < 0.001) and direct cleavage from 1 to 3-cell (32.7% vs. 16.9%, P < 0.001) showed statistically significantly higher rates in MI oocytes compared to MII oocytes. The mean time-points for MI oocytes-derived embryos and MII oocytes respectively were; tPB2 (4.4 vs 3.0, P < 0.001), tPNf (27.7 vs 24.4, P < 0.001), t2 (29.7 vs 26.9, P < 0.001), t3 (38.6 vs 36.6, P = 0.014), t4 (41.2 vs 39.0, P = 0.002), t5 (51.6 vs 49.4, P = 0.021), t6 (54.8 vs 52.4, P = 0.013), t7 (58.5 vs 54.9, P = 0.003), t8 (61.6 vs 57.9, P = 0.013), cc2 (8.2 vs 9.6, P = 0.570), s2 (2.9 vs 2.6. P = 0.579).

Limitations, reasons for caution: The study was a retrospective study. Data set size is small numbers. It should be extended to larger populations and additional morphokinetics.
Wider implications of the findings: This is the first observation thoroughly describing the development of embryos derived from *in vitro* matured MI oocytes obtained from COH. MI-derived embryos lower the fertilization rate and significantly slower the morphokinetics than that of MII oocytes. Therefore, ovarian stimulation should be performed carefully for mature oocytes obtained at retrieval.
Trial registration number: We don't need to trial registration number.

P-170 Visualization of the metaphase II meiotic spindle and effect on the rate of multiple pronuclear formation in ART patients with positive anti-centromere antibodies

H. Ohno[1], M. Tokoro[2], N. Aoyagi[1], M. Sonohara[1], M. Tsuiki[3], E. Asano[3], M. Kojima[3], N. Fukunaga[1], Y. Asada[1]
[1]*Asada Ladies Clinic Medical Corporation, Asada Ladies Nagoya Clinic, Nagoya, Japan*
[2]*Asada Ladies Clinic Medical Corporation, Asada Institute for Reproductive Medicine, Kasugai, Japan*
[3]*Asada Ladies Clinic Medical Corporation, Asada Ladies Kachigawa Clinic, Kasugai, Japan*

Study question: Do anti-centromere antibodies (ACA) have an effect on the presence of the meiotic spindle and the rate of multiple pronuclear (MPN) formation in human embryos?
Summary answer: The present results suggest that ACA are the cause of the high rate of MPN formation due to an inhibition of mitotic spindle formation.
What is known already: ACA is an anti-nuclear antibody (ANA), and specifically recognizes the centromere. Recently, several studies have reported that the rate of MPN formation is higher in patients with ACA. We previously documented that in MI oocytes collected from ACA patients, the female chromosome were frequently dispersed in the cytoplasm. This abnormality of the female chromosome may be a cause of MPN formation. However, the association between the formation of the meiotic spindle and the high rate of MPN formation in ACA patients needs to be further investigated.
Study design, size, duration: Between May 2013 to April 2015, 160 MII oocytes from 18 treatment cycles in 8 patient cases (ACA group) found to be ACA positive following testing and 2632 MII oocyte from 362 cycles in 294 patient cases (Control group) which was not tested for ACA after oocyte retrieval from February to August 2008 were analyzed.
Participants/materials, setting, methods: The spindles of MII oocytes were examined by the the OosightTM imaging system (OIS). We compared the presence of the spindle (presence or absence) of ACA and control groups. After ICSI, the rate of MPN in ACA and control groups were recorded. MPN embryos were stained with H3K9me2 antibody to detect the female chromosome.
Main results and the role of chance: The rate of incidence of a visible spindle in ACA oocytes was significantly lower than that found in controls (38.1% versus 89.2%; $P < 0.01$). The rate of MPN formation after ICSI in ACA (visible spindle: 26.2%, no visible spindle: 60.6%) was significantly higher than that found in control embryos (visible spindle: 2.3%, no visible spindle: 7.4%) ($P < 0.01$). In MPN embryos originating from ACA cases, 100% (52/52) of the MPN embryos following ICSI had a single male PN and 2 or more female PN.
Limitations, reasons for caution: Retrospective analysis with a limited sample size due to rarity of condition.
Wider implications of the findings: The present results suggest that the female chromosome is frequently dispersed in the cytoplasm of MI oocytes collected from ACA patients. It seems highly likely that this abnormality is the direct cause of MPN formation.
Trial registration number: None.

P-171 Morphokinetic behavior of chromosomally normal and abnormal embryos in patients under 36 years old undergoing PGS for aneuploidy screening

A. Arnanz[1], I. Elkhatib[1], A. Bayram[1], A. Liñan[1], J.A. Garcia-Velasco[2], H.M. Fatemi[3]
[1]*IVI Middle East Fertility Clinic LLC, IVF Lab, Abu Dhabi, United Arab Emirates*
[2]*IVI, Clinic, Madrid, Spain*
[3]*IVI Middle East Fertility Clinic LLC, Clinic, Abu Dhabi, United Arab Emirates*

Study question: Can time-lapse monitoring of preimplantation embryo development pattern be uniformly defined in order to select noninvasively euploid embryos in patients under 36 years of age?
Summary answer: Late first cleavage, late PN fading and longer transition period between morula-early blastocyst stage were observed in aneuploid embryos as compared to euploid embryos.
What is known already: It is known that embryo aneuploidy is a major cause of IVF failure, however, PGS is not always possible due to legal, economical or sociocultural reasons. Aneuploidy has been correlated with specific morphokinetic variables used previously to develop an aneuploidy classification.

Irregular division pattern, delays in the first cell cycle and asynchrony in the disappearance of the pronuclei in abnormal embryos had previously been reported. However, some studies failed to confirm these findings. Moreover, late compaction and/or blastulation initiation and completion delay in aneuploid embryos as compare to euploid embryos has been reported.
Study design, size, duration: Embryo development was retrospectively analyzed using time lapse system EmbryoScope™ (Unisense, Danmark) in a total of 163 embryos, scheduled for aneuploidy screening with aCGH in patient of under 36 years old. These embryos were monitored in a special tri-gas incubator. The morphokinetic characteristics of each embryo were monitored until day 5.

The data were collected between August 2015–December 2015. The study was approved by ethical committee of IVI.
Participants/materials, setting, methods: Embryo biopsy was done on D3 of embryo development and chromosome screening performed through array-CGH. Development of these embryos had been monitored in a controlled environment. Images were captured in every 20 minutes from 7 different focal planes. The analyzed parameters were t2 to tSB, cc2 (t3-t2), S2(t4-t3) and S3(t8-t5). T test was used for comparison of mean timings. *P*-value < 0.05 has been considered statistically significant.
Main results and the role of chance: The mean age of our female population included in the study was 32.5 years. The indication for PGS was repeated implantation failure, described as more than 2 failed previous cycles.

Among 163 embryos analyzed, 55 had normal chromosomal content and 37 embryos were transferred in 25 cycles (mean of 1.5 embryos/cycle).

Interestingly, the results suggest that there was a statistically significant difference in tPNf ($p = 0.0432$), t2 ($p = 0.0114$), and tSB-tM ($p = 0.0044$) between abnormal and normal PGS results.

Controversially, no statically significant differences were found between euploid and aneuploid embryos for the rest of the morphokinetics parameters; tPB2, tPNF-tPB2, t3, CC2, t4, S2, t5, t6, t7, t8, t9+, tM, tSB and tM-T9.
Limitations, reasons for caution: Associations between morphokinetics and ploidy require careful interpretation due to lack of consensus for definitions, variable PGS methodologies, sample sizes and time lapse devices used. Larger studies are needed but time lapse imaging remains a promising tool to enhance clinical outcome.
Wider implications of the findings: The selection of the embryos through time-lapse technology should not be considered as a replacement for PGS. However, there is a clear benefit gained from the morphokinetics screening and selection according to these findings.

Further prospective studies are needed in order to clinically validate these results.
Trial registration number: Not applicable.

P-172 First pregnancies from human embryos vitrified-warmed using the semi-automated Gavi closed vitrification system

N. Hobson[1], J. Filipovits[1], T. Roy[2], S. Brandi[2], R. Woolcott[2], M. Bowman[1], S. McArthur[1]
[1]*Genea, Fertility, Sydney, Australia*
[2]*Genea Biomedx, Research, Sydney, Australia*

Study question: Are clinical outcomes from the transfer of human blastocysts vitrified using the semi-automated closed Gavi™ system equivalent to that of the manual open Cryotop™ system?
Summary answer: Preliminary clinical outcomes of blastocysts vitrified using the Gavi systems are comparable to the Cryotop system including embryo recovery, embryo survival and biochemical pregnancy rates.
What is known already: Vitrification of embryos is an essential component of an effective assisted conception program. When successfully executed, it

provides excellent embryo survival and pregnancy rates, with the gold-standard method arguably being the open Cryotop system. However, vitrification is a manual, high-skill and labor intensive procedure that is difficult to standardize, and results can vary greatly between embryologists and clinics. To address these issues, we developed the Gavi system, a semi-automated closed vitrification system. *In vitro* studies using mouse and human research blastocysts have shown equivalent results to the Cryotop system (Roy et al., 2014).

Study design, size, duration: This is an ongoing pilot study in which infertile pre-implantation genetic screening (PGS) patients were randomly allocated to have either their best embryo for cryopreservation vitrified using the Gavi system and their second best using the Cryotop system, or vice versa. This study, which commenced in August 2015, will assess outcomes of 50 single embryo transfers from both Gavi and Cryotop vitrified-warmed blastocysts. Results presented below are interim results from the ongoing study.

Participants/materials, setting, methods: This study was performed at the private assisted reproductive technology (ART) clinic Genea (Sydney, Australia), which has proven expertise in Cryotop vitrification (Roy et al., 2014). Participants included infertile couples undergoing assisted conception and PGS with at least one blastocyst for vitrification. Vitrification was performed using either Gavi, as described by the manufacturer, Genea Biomedx, or the open Cryotop protocol as described previously (Roy et al., 2014).

Main results and the role of chance: 180 blastocysts have been vitrified using the Gavi system and 190 vitrified using the Cryotop system. Twenty euploid embryos vitrified using the Gavi system and 15 using the Cryotop system have been warmed, all of which were recovered from the vitrification device and survived the warming process as defined by greater than 70% cells intact. A single embryo transfer policy followed and the average maternal age of Gavi vitrified-warmed embryos was 36.0 years and 35.9 years for Cryotop vitrified-warmed embryos. Of the vitrified-warmed embryos transferred 85% of Gavi system embryos were of excellent quality (ICM and TE grade excellent or good) prior to vitrification as compared with 80% of Cryotop embryos. Clinical use of Gavi vitrified-warmed embryos resulted in a 64.7% (11/17 βhCG positive, 3 pending) biochemical pregnancy rate as compared with 83.3% (10/12 βhCG positive, 3 pending) for Cryotop vitrified-warmed embryos ($p = 0.27$). Of the biochemical pregnant patients that have undergone ultrasound at 7 weeks, 100% (9/9, 2 pending) of Gavi system pregnancies had a fetal heart beat as compared with 89% (8/9, 1 pending) of Cryotop system pregnancies. The first pregnancy using a Gavi vitrified-warmed blastocyst is now at 16 weeks and progressing normally.

Limitations, reasons for caution: The main limitations of this study are (1) small sample size and (2) the absence of live birth outcomes. Clinical outcomes of Gavi-vitrified cleavage stage embryos or oocytes were not assessed.

Wider implications of the findings: The Gavi system has the potential to revolutionize embryo vitrification; standardizing the process, increasing laboratory efficiencies and improving clinical outcomes for laboratories struggling with cryopreservation. Additionally, it would show it is possible to semi-automate complicated ART procedures and open up the possibility for further improvements in efficiencies and clinical outcomes.

Trial registration number: Not registered.

P-173 Does automatic time-lapse embryo test improve embryo selection based on morphology?

S. Perez Albala[1], B. Aparicio-Ruiz[1], N. Basile[2], F. Bronet[2], J. Remohi[3], M. Meseguer[1]
[1]IVICO & IVI Teaching Program Equipo IVI, Laboratorio FIV, Valencia, Spain
[2]IVICO & IVI Teaching Program Equipo IVI, Laboratorio FIV, Madrid, Spain
[3]IVICO & IVI Teaching Program Equipo IVI, Gynecology, Valencia, Spain

Study question: Is there a correlation between the automatic classification provided on Day 3 by the Eeva (Early embryo viability assessment) system (High, Medium or Low) with implantation rates (IR)?

Summary answer: There is a direct correlation according to the automatic test embryo score, improving morphological score, being useful for the embryo selection process.

What is known already: Wong et al. (2010) developed an algorithm to classify embryos according to their probability of reaching blastocyst stage based on the combination of two parameters: P2 = t3–t2 and P3 = t4–t3 which are automatically calculated by time-lapse cell tracking. VerMilyea et al. (2014) showed that embryos with High and Medium scores had significantly higher implantation rates than those with Low scores. This test has been performed in five different clinics in the USA (Conaghan et al., 2013) showing an improvement on embryo selection when Eeva classification was used and a decrease in variability among embryologists.

Study design, size, duration: Retrospective cohort study, from October 2013 to December 2015.

Participants/materials, setting, methods: University-affiliated infertility clinic. The study includes 436 cycles in which embryos were incubated in a conventional incubator with especially designed scopes that used an automatic cell-tracking software to analyze the exact timing of first and second cleavages. The system provided a classification according to P2 and P3. From these cycles a total of 784 embryos were transferred.

Main results and the role of chance: We observed a direct relationship between morphokinetic categories and implantation potential. Results were only referred to those embryos with known implantation ($n = 521$).

When categorizing according to EEVA: 158 embryos were labelled as High, 114 as Medium and 249 as Low. Implantation rates in each of the categories were: HIGH 46.80%; MEDIUM 36.80%; LOW 27.70%. We observed this same correlation when distinguishing the day of transfer: DAY3: HIGH 38.20%; MEDIUM 31.70%: LOW 26.10%. For DAY5 transfer IR were: HIGH 66.70%; MEDIUM 50% and LOW 31%.

A multi-variable analysis was performed to quantify the chances of implantation when a high embryo is transferred and considering potential bias factors such as oocyte quality or day of transfer (Table 1). A predictive model was developed comparing predictive properties of ASEBIR morphology selection vs selection based on Eeva categories for implantation (0.622 and 0.650 respectively), indicating the moderate utility of both selection methods but showing a better predictive value of Eeva test.

		OR	CI 95%	
EEVA Categories	MEDIUM vs LOW	1.37	0.835–2.248	ns
HIGH vs LOW	2.238	1.441–3.475	>0.001	
ASEBIR (morphology) Categories	B vs C	1.062	0.529–2.133	ns
A vs C	1.45	0.791–2.657	ns	
	Donated vs Own oocytes	3.174	1.505–6.696	>0.001
	Blastocyst vs Cleavage stage	2.171	1.436–3.282	>0.001

Limitations, reasons for caution: The retrospective nature of this study may be a reason for caution; nevertheless, it is the first step previous to future prospective studies. The classification system itself has some errors due to difficulties in cell tracking generating "none result", however we only included cases where a classification was provided

Wider implications of the findings: Our study has demonstrated that embryo selection by automated time-lapse supported by the use of a two variable morphokinetic model is related with reproductive outcome. These results also show that embryo morphology together with Eeva categorization slightly increase predictive properties to select embryos with higher implantation potential.

Trial registration number: None.

P-174 Clinical outcomes after use of Embryo-Glue as a human embryo transfer (ET) medium in warming cycles

G. Fasano[1], R. Antonacci[1], J. Biramane[1], G. Mbongolo[1], M. Nguyen Thi[1], C. Vanhelleputte[1], A. Vannin[1], A. Van Langendonckt[1], A. Delbaere[1], F. Devreker[1]
[1]Hôpital Erasme, ULB, FIV Laboratoire, Brussels, Belgium

Study question: To evaluate the efficacy of Embryo-Glue as a human ET medium for warming cycles.

Summary answer: Embryo-Glue as ET medium for warmed embryos is as effective as the routine medium for infertile patients undergoing warming cycles.

What is known already: Hyaluronan (HA) is a major glycosaminoglycan present in follicular, oviduct and uterine fluid. HA concentration increases at the time of implantation. Embryo-Glue (EG) is a ready use medium that contains a high concentration of hyaluronan (0.5 mg/mL). EG has an implantation-promoting

effect in fresh IVF cycles in selected patients such as patients with poor quality embryos, repeated implantation failure and advanced maternal age.

Study design, size, duration: To validate EG usefulness in our laboratory, a prospective randomized study was carried out between June 2015 and January 2016 including a total of 253 patients undergoing 328 warming cycles. Embryo transfers were performed either in Embryo-Glue ($n = 136$) as study group or in routine ET medium as control group ($n = 192$).

Participants/materials, setting, methods: A total of 372 warmed and transferred embryos were included in the study. After warming, the embryos were cultured for 24 hours and transferred if cleaved (Embryo-Glue $n = 155$ vs ET conventional medium $n = 217$). The embryos were prospectively randomized using different lists according to the developmental stage (Day2/Day3 and Day5/Day6) between the two groups.

Main results and the role of chance: Patients' characteristics were similar for both groups in terms of maternal age, number/quality of embryos transferred, endometrial preparation and degree of difficulty of embryo transfer. Global results on the 372 transferred embryos did not showed significant differences between two groups. Pregnancy rate per transfer were (29.4% vs 23.9% $p = 0.32$) and biochemical and abortion rates were (5.1% vs 8.3% $p = 0.37$; 2.2% vs 5.2% $p = 0.32$ respectively). For Day2/Day3 embryos transfers the pregnancy rate per transfer were 22.7% ($n = 97$) vs 18.8% ($n = 143$) for EG and the control group, respectively. For Day5/Day6 embryos transfers the difference seems to in favor of EG: 46.1 ($n = 39$) vs 38.8% ($n = 49$), albeit not statistically significant.

Limitations, reasons for caution: The study was performed on unselected patients based on a prospectively randomized list. However, the two groups had similar characteristics. These are preliminary results and the small number actually included may impair the significance of the results. The comparison is still ongoing to increase the number.

Wider implications of the findings: High concentration of HA in ET medium displayed high pregnancy rate for warming cycles validating the use of EG in the laboratory. However, the difference in PR between the two groups prompts us to carry on the study in order to confirm the eventual beneficial effect of EG.

Trial registration number: None.

P-175 Mitochondrial DNA content as a measure of implantation potential in human euploid blastocysts: correlation with embryo quality and female age

N. Tarozzi[1], M. Nadalini[1], M. Di Santo[1], C. Lagalla[1], V. Distratis[1], F. Pennetta[1], E. Fragouli[2], D. Wells[2], A. Borini[3]

[1]9.baby family and fertility center, Reproductive Laboratory Unit, Bologna, Italy

[2]Reprogenetics UK, Institute of Reproductive Sciences, Oxford, United Kingdom

[3]9.baby family and fertility center, Reproductive Clinical Unit, Bologna, Italy

Study question: Is mitochondrial DNA content correlated to female age and embryo quality, or provides an independent measure of embryonic implantation potential?

Summary answer: According to our results, mitochondrial DNA content provides a useful biomarker of embryonic implantation potential, irrespective of embryo quality and female age.

What is known already: A potential association between high quantities of mitochondrial DNA (mtDNA) and the failure of human embryos to implant has been recently described. In particular, the incorporation of mtDNA copy number analysis into the routine preimplantation genetic screening (PGS) has been proposed, in order to select the euploid blastocysts with the best chances to implant.

To date it is unclear whether this new biomarker provides an independent score of embryo viability, irrespective of standard assessments, such as embryo quality, or female age: in literature, few and conflicting data appear on these issues.

Study design, size, duration: This is a retrospective observational study performed between October 2013 and January 2015. The study included the data analysis of 54 euploid blastocysts obtained from 26 patients (average age 35.5 years, range 26–42 years) following 29 PGS cycles. Single embryo transfers of 43 euploid blastocysts were performed.

The relative amount of mtDNA was assessed in relation to implantation potential, blastocysts quality and female age.

Participants/materials, setting, methods: Blastocysts quality was assessed and categorized in two groups, according to morphology and expansion (good and poor quality).

Trophectoderm biopsy was undertaken on Day 5–6 and comprehensive chromosome screening (CCS) performed through array-CGH.

Part of whole genome amplification products, necessary for CCS, was subjected to real-time PCR to quantify the mtDNA content for each of 54 euploid blastocysts. Blastocysts were categorized in two groups, according to a relative mtDNA threshold value (0.003) described in literature.

Main results and the role of chance: Twelve out of 54 euploid blastocysts showed high mtDNA levels (22.2%). The remaining 42 showed low mtDNA levels.

mtDNA content and implantation potential

Out of 43 transferred blastocysts, 11 resulted in pregnancies and successfully gave 11 healthy live births. All the pregnancies (100%) originated from blastocysts with low mtDNA levels. None of the blastocysts with high mtDNA quantities led to pregnancy.

mtDNA content and blastocysts quality

Out of 54 euploid blastocysts, 19 were classified as "poor quality blastocysts": 5 (26.3%) had high mtDNA levels and 14 (73.7%) showed low mtDNA quantities. Thirty five were classified as "good quality blastocysts": 7 (20%) had high mtDNA levels and 28 (80%) showed low mtDNA quantities. Statistical analysis revealed no correlation between embryo quality and mtDNA content inside each group.

mtDNA content and female age

The mean age of the patients with high mtDNA levels blastocysts was 35.4 years (range 30–42 years). The group of patients with low mtDNA quantities blastocysts showed a mean age of 35.7 years (range 26–42 years). No statistical significant difference, in terms of female age, was found between blastocysts with high and low mtDNA content.

Limitations, reasons for caution: Limited number of cases of the study group.

Relatively low average age of the patients (35.6 years), with no patients above 42 years of age: it would be interesting to evaluate the mtDNA content of euploid blastocysts in older patients.

Wider implications of the findings: This study provides further support for the relationship between mtDNA quantity in trophectoderm cells and embryo implantation potential and demonstrated that mtDNA content evaluation provides an independent score of embryo viability, irrespective of embryo quality and female age. Therefore, the inclusion of mtDNA analysis into routine PGS should be considered.

Trial registration number: None.

P-176 The effect of sperm selection with fertile plus on intracytoplasmic sperm injection outcome

S. Yetkinel[1], E. Bulgan Kilicdag[1], B. Haydardedeoglu[1], E. Simsek[1], T. Cok[1], P. Caglar Aytac[1], D. Alkas[1]

[1]Baskent University Adana, Division of Reproductive Endocrinology and IVF Unit, Department of Obstetrics and Gynecology, Adana, Turkey

Study question: The aim of the current study is to evaluate to effectiveness of sperm selection by using fertile plus chip on intracytoplasmic sperm injection (ICSI) cycles.

Summary answer: Fertilization rate, percentage of grade 1 embryo numbers and pregnancy rates were similar between sperm selection with fertile plus chip and classical gradient technique.

What is known already: Selection of sperm in *in vitro* fertilization (IVF)/intracytoplasmic sperm injection (ICSI) has a key role in the success. Fertile plus chip is chemical-free microchips that mimic natural paths of sperm, effective way of enabling selected motile sperm. Sperm selections with fertile plus provides less oxidative stress and less DNA damage.

Study design, size, duration: This retrospective analyze was constituted with the patients attended and underwent ICSI program at the Assisted Reproduction Unit of Baskent University between September 2014 and January 2016. Clinical data were obtained from patients' records. The study eligibility criteria were as follows: women younger than 40 years old and couples who had one or more IVF failure. In the 549 cycles gradient technique and in 102 cycles fertile plus chip were used for sperm selection.

Participants/materials, setting, methods: Data are expressed as means ± SD. The baseline differences between the two groups were analyzed by Student's

t test. A two sided p value < 0.05 was considered statistically significant. Data were analyzed with the use of SPSS for Windows (version 17.0; SPSS Inc., Chicago, IL). In contingency tables, the Chi-Square test was performed.
Main results and the role of chance: Baseline characteristics of the patients (the mean age of patients (33.21 ± 4.96 vs. 33.43 ± 4.43), the duration of infertility (6.03 ± 4.16 vs. 6.17 ± 3.88) were not significantly different between the groups. Metaphase II oocyte number (7.33 ± 6.74 vs. 9.15 ± 7.31), fertilization rate (70.27 ± 52.59 vs. 67.93 ± 21.91), grade 1 embryo numbers (0.69 ± 0.78 vs. 0.80 ± 0.80), transfer day (3.72 ± 1.01 vs. 3.74 ± 1.04), and transferred embryo numbers (1.67 ± 0.48 vs. 1.71 ± 0.46) were also similar in the two groups. Pregnancy rates were 38.4% in classical gradient technique group and 38.2% in the fertile plus chip group and the difference was not statistically significant.
Limitations, reasons for caution: The major limitation of our study is that the data were collected retrospectively. There are two different microfluidic design for sperm sorting. We use fertile plus for ICSI. These results cannot be said for fertile. Our another prospective randomized double blind study (ClinicalTrials.gov Identifier: NCT02488434) has been continued.
Wider implications of the findings: To our knowledge this is first clinical trial about fertile plus use for ICSI. This study didn't find any difference in terms of fertilization rate, embryo quality and pregnancy rate. But further studies may demonstrate molecular differences.
Trial registration number: This study is retrospective so we didn't obtain registration number.

P-177 Are double embryo transfers' outcome influenced by the quality of the second embryo?

M. Carvalho[1], S. Mota[1], F. Leal[1], I. Cordeiro[1], A. Aguiar[1], J. Nunes[1], C. Rodrigues[1], A.P. Soares[1], S. Sousa[1], C. Calhaz-Jorge[1]
[1]Centro Hospitalar Lisboa Norte, Hospital de Santa Maria, Obstetrics, Gynecology and Reproductive Medicine, Lisboa, Portugal

Study question: Has the quality of the second embryo in double transfers impact in the success of ART cycles?
Summary answer: Our data suggest the quality of the second embryo in double embryo transfers (DET) has no influence in the success of ART cycles.
What is known already: There is little literature concerning the impact of DET regarding different quality embryos' inter-influence. There is no consensus about the overall pregnancy rates differing or not significantly whether a poor-quality embryo is added to the transfer of one good-quality embryo. However, twining rates seem to be significantly different between the transfers of two top-quality embryos, and one top and one poor. It is known that multiple pregnancies increase their associated maternal and perinatal risks. Therefore, double embryo transfer should be thought with some concern, particularly in young patients.
Study design, size, duration: Retrospective analysis of data regarding 655 IVF or ICSI cycles, performed between October 2008 and December 2014, using agonist long protocol with DET and the transfer of at least one top quality embryo. We classified the embryos on day 2 or 3, taking into account multiple morphological criteria (cell number, degree of cytoplasmatic fragmentation, multinucleation, cell size regularity, presence of vacuoles, etc), in four categories (A, B, C, D), based on ASEBIR classification.
Participants/materials, setting, methods: The study population was <40 years old. Taking into account that at least one top quality embryo was transferred, cycles were divided into four groups. Group I (n = 296) contains two grade A embryos, Group II (n = 212) one A and one B, Group III (n = 111) one A and one C, and Group IV (n = 36) one A and one D. Clinical pregnancy, multiple pregnancy, miscarriage, live birth, preterm, duration of gestation and birth complications rates were evaluated.
Main results and the role of chance: The overall clinical pregnancy rate per transfer in our clinic during that period was 44.5%. In this study the rates were 56.1%, 55.2%, 52.3% and 41.7% for Group I, II, III and IV respectively. It was visible that there was a difference in clinical pregnancy rate per transfer between Group I and Group IV, but it was not statistically significant. There was no difference in multiple pregnancy rate among all groups (18.9% vs 13.7% vs 18.0% vs 13.9%). Miscarriage rate was lower (6.7%) in group IV when compared with the rest of the study groups (15.7%; 20.5%; 24.1%), but this was also not statistically significant. Live birth rates per transfer were 45.6% vs 41.9% vs 36.9% vs 33.3% with no statistically significant differences among the four groups. The analysis of preterm delivery rate, duration of gestation and birth complications revealed no differences in all study groups too. Women's age was similar in the four groups.
Limitations, reasons for caution: This study is limited by its retrospective nature and sample size. Also, the four study groups have a very different size. Results must, therefore, be considered with some caution.
Wider implications of the findings: Our results suggest that, in our working conditions, there has neither been an embryo-helping nor embryo-detrimental effect in double transfers. This information should be considered in the counseling of patients concerning DET vs SET.
Trial registration number: Not applicable.

P-178 Influence of sperm quality on the development to blastocyst stage and its ploidy status

R. Polese[1], F. Scarselli[1], E. Iovine[1], V. Casciani[1], A. Ruberti[1], A. Colasante[1], E. Cursio[1], G. Maria Chiara[1], G. Franco[2], C. Mencacci[1], B. Anil[3], F. Spinella[3], F. Fiorentino[3], E. Greco[1], M.G. Minasi[3]
[1]European Hospital, Reproductive Medicine, Roma, Italy
[2]Sapienza university, Department of urology, Roma, Italy
[3]Genoma, Molecular Genetics Laboratories, Roma, Italy
[3]European Hospital, Laboratory Director, Roma, Italy

Study question: Does the sperm quality correlate with the ploidy status of the derived blastocysts?
Summary answer: Blastocyst derived from poor quality sperm have the same probability to be euploid compared to ones formed from normal semen.
What is known already: Thanks to the ICSI, in severe male factor infertility it becomes possible to offer IVF treatments, although extremely impaired sperm quality may have an impact on fertilization rates. Several study analyzing the clinical outcomes obtained with embryos derived from normal sperm samples compared to severe sperm morphology abnormalities, report very conflicting data. High rate of DNA fragmentation, mitochondrial dysfunction and chromosomal aneuploidy seem to be significantly higher in the spermatozoa from oligozoospermic and/or asthenozoospermic and/or teratozoospermic (OAT) males compared with unaffected controls. However, to date few data regarding the impact of the sperm quality on embryogenesis are reported.
Study design, size, duration: This cohort retrospective study was performed from January 2014 to December 2015 on 148 Preimplantation Genetic Screening (PGS) cycles. The genetic outcome of 586 blastocysts were analyzed by mean of Whole Genome Amplification (WGA) and array-Comparative Genomic Hybridization (a-CGH). All mature oocytes retrieved were injected and cultured individually until the blastocyst stage at 37°C, 6%CO2, 5%O2. All biopsies were performed at blastocyst stage. Mean female and male ages were 34.95 ± 4.5 and 38.05 ± 5.9 years old, respectively.
Participants/materials, setting, methods: All the patients enrolled in this study submitted to the following selection criteria: maternal age ≤36 years old, only standard ICSI to be performed, normal karyotype of both parents, genetic diseases and female infertility factors were excluded. All cycles were divided in 4 groups on the basis of semen parameters performed according to WHO 2010: group 1 normal; group 2 OAT; group 3 severe OAT; group 4 NOA (Non-Obstructive Azospermia) and testis cancer patients.
Main results and the role of chance: The number of cycles enrolled were 88, 53, 20, 18 in groups 1, 2, 3, 4, respectively. The number of oocytes injected were 775, 508, 180, 184 in groups 1, 2, 3, 4, respectively. There was no difference in fertilization rate between groups 2, 3, 4: 66.1% (336/508), 66.1% (119/180), 55.5% (120/184), respectively; a statistically higher (p < 0.01) fertilization rate was found in group 1: 77.2% (598/775). The number of embryos obtained were 598, 336, 119, 120 in groups 1, 2, 3, 4, respectively. The blastocysts obtained were: 414 (69.2%), 241 (71.7%), 71 (59.7%), 62 (51.7%), respectively. The apparently lower blastocyst formation rate found in the group 4 compared to the other 3 groups does not reach a statistical significance, probably due to the low number of cycles enrolled in this group. Surprisingly, the rate of euploid/biopsied blastocysts was the same in all groups, even in number 4 in which sperms are recovered from testis: 45.5% (140/308), 53.8% (99/184), 58.6% (34/58) and 55.6% (20/36) in groups 1, 2, 3, 4, respectively. Pregnancy rates were 59.0% (46/78), 66.7% (30/45), 62.5% (10/16), 64.3% (9/14) in groups 1, 2, 3, 4, respectively (NS).
Limitations, reasons for caution: The number of cycles eligible to be included in the study is still quite low, due to the strict inclusion criteria established in order to select male factor only patients; therefore, further cycles need to be

performed to confirm these preliminary results. For that reason, the study is still ongoing.
Wider implications of the findings: Our data gives strong hope to men with an extremely low semen quality. Due to the poor fertilization rate expected, it is advisable to increase the number of oocytes to inseminate and to extend the culture until the blastocyst stage since blastocysts euploidy probability is independent from the semen used.
Trial registration number: Not applicable.

P-179 Chromosomic abnormalities involved in complex aneuploidies in human blastocysts after *in vitro* fertilization and trophoectoderm biopsy for Preimplantation Genetic Screening (PGS) cycles

A. Ruberti[1], E. Cursio[1], F. Scarselli[1], A. Colasante[1], V. Casciani[1], A.M. Lobascio[1], R. Polese[1], V. Zazzaro[1], M.T. Varricchio[1], K. Litwika[1], M.G. Minasi[1], A. Biricik[2], F. Spinella[2], F. Fiorentino[2], E. Greco[1]
[1]*European Hospital, Medicina della Riproduzione, Rome, Italy*
[2]*Genoma, Molecular Biology, Rome, Italy*

Study question: This study evaluates chromosomes involved in complex aneuploidy (CA) in human blastocysts after PGS cycles performed with trophoectoderm biopsy and array comparative genomic hybridization (aCGH).
Summary answer: Chromosomes mainly involved in CA are 16-21-22 and there is an increasing in the percentage of abnormalities of these chromosome with increasing maternal age.
What is known already: Among the main causes of infertility and failure of Assisted Reproduction Technique (ART) cycles are aneuploidies in embryonic genome. Chromosomal aberrations are simple (monosomies-M or trisomies-T) or complex (2 or more chromosomes involved). Aneuploidies rates are strictly correlated with maternal age because in women older than 40 years old about 80% of the oocytes presents aneuploidies due to meiotic non-disjunction. Some chromosomes are more prone than others to develop aneuploidies caused by non-disjunction events. These chromosomes are 16, 21, 22 due to their size and morphological structure: they are all small chromosomes and 21 and 22 have an acrocentric centromere.
Study design, size, duration: From September 2011 to September 2015, 977 PGS cycles were performed, and 3143 blastocysts were analyzed after trophoectoderm biopsy and aCGH. After genetic results, CA were analyzed to investigate the percentage of aneuploidies (monosomies and trisomies) for each chromosome and to determine different trends in the distribution of the aneuploidies among all chromosomes. CA were considered to study the percentage of aneuploidies in different chromosomes as the data were more consistent.
Participants/materials, setting, methods: Patients were divided according to maternal age in 4 groups: ≤30, 31–35, 36–40 and ≥41 years old in group A, B, C, D where 42, 209, 445 and 281 cycles were performed, respectively. All mature oocytes retrieved were injected and cultured individually until the blastocyst stage at 37°C, 6%CO2, 5%O2. After trophoectoderm biopsy, blastocyst genetic asset was anlyzed by Whole Genome Amplification (WGA) followed by aCGH.
Main results and the role of chance: Analyzed blastocysts were 180, 864, 1473, 626 in group A, B, C, D, respectively. Aneuploid embryos dramatically increase with maternal age ($p < 0.001$) and CA are higher in group-D, compared with groups A, B, C ($P < 0.001$). In group-A, 97 (53.9%) blastocysts resulted euploid, 15 (8.3%) mosaic, 3 (1.7%) no-results and 65 (36.1%) aneuploid. Among aneuploid embryos, 35 (53.8%) were CA, 20 (30.8%) M and 10 (15.4%) T. In group-B, 401 (46.5%) blastocysts resulted euploid, 70 (8.1%) mosaic, 22 (2.5%) no-results and 371 (42.9%) aneuploid. Among aneuploid embryos 201 (54.2%) were CA, 102 (27.5%) M and 68 (18.3%) T. In group-C, 536 (36.4%) blastocysts resulted euploid, 90 (6.1%) mosaic, 34 (2.3%) no-results and 813 (55.2%) aneuploid. Among aneuploid embryos, 421 (51.8%) were CA, 221 (27.2%) M and 171 (21%) T. In group-D, 90 (14.4%) blastocysts were euploid, 35 (5.6%) mosaic, 8 (1.3%) no-result and 493 (78.7%) aneuploid. Among aneuploid embryos, 361 (73.2%) were CA, 53 (10.8%) M and 79 (16%) T. Most involved chromosomes in CA were: 1 (5.7%), 16 (7%), 18 (5.7%) in group-B; 16 (7%), 21 (6.7%), 22 (7.4%) in group-C and 16 (6.8%), 21 (6.9%), 22 (7.9%) in group-D, respectively. In group-A no differences were found regarding all chromosomes.
Limitations, reasons for caution: The influence of male age in chromosomic aberration should be considered, since it is reported that in embryos from couples with men older than 50 years old the aneuploidies in some chromosomes are higher than in embryos from couples with men younger than 50 years old.
Wider implications of the findings: Genome of degenerated embryos could be analyzed to find if aneuploidies in other chromosomes than 16, 21 and 22 are really less represented or if they could influence the early stages of embryo development, leading to degeneration before reaching the blastocyst stage.
Trial registration number: Not applicable.

P-180 Endometrial injury and the quality of embryos are the most important prognostic factors for in-vitro-fertilization success after previous repeated unsuccessful attempts.

M. Reljic[1], V. Kovağ, J. Knez[1], B. Kovağğ
[1]*Univerzitetni klinicni center Maribor, Dpt. for Reproductive Medicine & Gynecological Endocrinology, Maribor, Slovenia*

Study question: Which are the most important prognostic factors for achieving a pregnancy after in-vitro-fertilization (IVF) in women with history of at least three consecutives unsuccessful IVF attempts (RIF)?
Summary answer: Endometrial injury, the quality of transferred embryos and transfer of blastocyst stage embryos are the most important factors affecting pregnancy rate in women with RIF.
What is known already: Repeated IVF treatment failure (RIF) is very frustrating to the patients and to the clinicians. It may occur due to a variety of reasons, but reduced endometrium receptivity and low embryo quality are thought to be the most important. Several approaches have been proposed to improve success rate in these women and amongst others include local endometrial injury (LEI) and blastocyst transfer. There is some evidence in the literature to support these approaches, however, in unselected group of women with RIF, LEI together with other prognostic factors affecting pregnancy rate has not yet been studied using multiple logistic regression model.
Study design, size, duration: A retrospective study including 429 IVF/ICSI cycles that was performed at the Department for reproductive medicine, University Medical Centre, Maribor. Study period was from January 2013 to December 2014.
Participants/materials, setting, methods: Women younger than 40 years with at least three previous consecutive failed IVF attempts were included. They underwent controlled ovarian stimulation and IVF/ICSI procedure. According to the doctor-patient agreement some women had hysteroscopy with local endometrial injury (LEI) in the preceding cycle. Patient's and cycle's characteristics were compared between the conception and non-conception cycles. The univariate and multivariate logistic regression model was used to identify the most important prognostic factors for clinical pregnancy.
Main results and the role of chance: Clinical pregnancy was observed in 140 (32.6%) cycles. There were no statistically significant differences between conception and non-conception cycles in women s age (33.82 ± 3.41 vs. 34.52 ± 3.07), number of previous cycles (4.30 ± 1.44 vs. 4.75 ± 2.23), causes of infertility and number of transferred embryos (1.89 ± 0.49 vs. 1.79 ± 0.65). Statistically significant different total dosage of gonadotrophins (28.82 ± 10.21 vs. 31.21 ± 11.68), number of oocytes retrieved (11.61 ± 5.19 vs. 9.93 ± 5.79), number of embryos (6.95 ± 3.78 vs. 5.34 ± 3.52), number of good quality embryos on day two (4.63 ± 3.63 vs 3.35 ± 3.12), number of blastocysts (2.76 ± 2.90 vs. 1.47 ± 2.46), number of freezing blastocysts (1.46 ± 2.13 vs. 0.80 ± 1.71), proportion of cycles with embryo freezing (49.29 vs. 32.53), proportion of cycles with transfer of at least one good quality embryo (76.43 vs.56.75), proportion of cycles with day five transfer (50.71 vs 30.43) and proportion of women with LEI (28.57 vs. 17.75) was observed in conception compared to non-conception cycles. These parameters were also found to be associated with clinical pregnancy using univariate logistic regression. In multivariate logistic regression model only transfer of at least one good quality embryo (OR: 4.32, 95% CI: 2.41–7.73), transfer on day five (OR: 3.02, 95% CI: 1.53–5.94 and LEI (OR: 1.73, 95% CI: 1.02–2.92) remained important independent prognostic factor for clinical pregnancy.
Limitations, reasons for caution: This is a single-centre retrospective analysis and despite robust methodological approach, the presence of potential bias cannot be excluded. The proportion of patients with LEI is relatively low.
Wider implications of the findings: Results of our study suggest that transfer of blastocyst stage embryos and hysteroscopy with local endometrial injury should be recommended in patients with repeated IVF failure in order to

improve the pregnancy rate. Larger prospective multicentric studies are needed to confirm these findings.

P-181 Identification of candidate epigenetic regulators that can be used to examine and monitor the epigenetic impact of assisted reproductive technologies (ART)

K. Sakurai[1], R. Gilbert[1], H.T. Ni[1]
[1]*Irvine Scientific, Research and Development, Santa Ana, USA*

Study question: Can expression of key epigenetic regulators provide predictive value to detect adverse conditions resulting from ART practices?
Summary answer: Expressions of *Dnmt3b* and *Prdm14* are sensitive to suboptimal conditions examined and can be used to monitor the epigenetic impact of ART procedures and materials.
What is known already: Growing concerns for epigenetic effects of ART procedures have been raised by the observation of an increased number of rare genetic disorders in children born after ART. Two general classes of DNA methyltransferases—de novo methyltransferases (DNMT3a and 3b) and maintenance methyltransferase (DNMT1)—were shown to have dynamic expression patterns during pre-implantation. A PR-domain-containing transcriptional regulator (PRDM14) and ESRRB were recently found to regulate DNMTs and epigenetic pathway. Incorporating evaluations of epigenetic regulator expression in an assay for screening materials and conditions could benefit risk assessment and help understand the link between epigenetic disorders and ARTs in mammals.
Study design, size, duration: Expression of known epigenetic regulators—*Dnmt1, Dnmt3a, Dnmt3b, Prdm14, Esrrb*—as candidate markers were evaluated with immunocytochemistry (ICC) from different stages of mouse embryo development (oocyte, 2-cell, 4-cell, 8-cell, morula, blastocyst, expanded/hatching blastocyst) cultured under optimal (control oil, n = 166) or suboptimal (7.5% toxic oil, n = 166) conditions for 96hrs. Experiments were repeated more than three times.
Participants/materials, setting, methods: One-cell mouse embryos (from frozen) were cultured uninterrupted up to 96 hours in Continuous Single Culture Medium-Complete (CSCM-C, Irvine Scientific) with control or suboptimal oil overlay. Embryos were fixed at T = 0, 24, 36, 48, 72, and 96 hrs for ICC, and incubated with primary antibody, then secondary fluorescent antibody to detect expression of epigenetic genes. Sox2 expression was detected as a control. Blastocyst rates (%) were evaluated at 96 hrs (n = 23 to 28).
Main results and the role of chance: The embryos cultured with suboptimal oil overlay showed a noticeable delay in development (at 72 hrs and 96 hrs compare to the control oil group) as expected. Compromised expression of DNMT3b and PRDM14 was observed in embryos cultured with suboptimal oil overlay, whereas no significant difference in expression of DNMT1, DNMT3a, and ESRRB was observed between embryos in the suboptimal oil group vs. control group. Of the five candidate genes examined, our studies revealed that DNMT3b and PRDM14 could serve as two candidate epigenetic regulators which can potentially be used to detect adverse culture conditions and further evaluate epigenetic effects.
Limitations, reasons for caution: Since embryos are inherently different from one another, each embryo may respond to the toxicity differently making observations difficult. Detection of gene expression depends largely on the performance of antibodies and reagents used in ICC.
Wider implications of the findings: Our results indicate that epigenetic regulators can be used as early biological markers to examine the impact of suboptimal conditions during pre-implantation mammalian embryo development. With the heightened sensitivity, the functional impact of materials and procedures on overall embryo development including embryo health and epigenetic defects can be adroitly evaluated.
Trial registration number: N/A.

P-182 Effective and patient-friendly endometrial preparation method for frozen-thawed embryo transfer in patients with polycystic ovary syndrome: ovulation induction with letrozole

K.H. Lee[1], I.H. Park[1], H.G. Sun[1], J.W. Kim[1], H.J. Chi[1], S.G. Kim[1], Y.Y. Kim[1], S.J. Kwak[1], J.Y. Park[1], C.S. Yoo[1]
[1]*Mamapapa & baby Hospital, OBGY, Ulsan, South Korea*

Study question: Which is better for endometrial preparation method in frozen-thawed embryo transfer (FET) cycles, hormone replacement therapy (HRT) or ovulation induction with letrozole?
Summary answer: FET after ovulation induction with letrozole showed significantly higher ongoing pregnancy rates than FET after HRT in patients with polycystic ovary syndrome (PCOS)
What is known already: Frozen-thawed embryo could be transferred in natural cycle and HRT cycle. FET in natural cycle has several advantages like avoiding medication and painful injection. However, in case of patients with PCOS, embryos are usually transferred in HRT cycle due to menstrual irregularity. Letrozole gains popularity for ovulation induction in PCOS patients. It usually promotes single follicle development and exhibits no negative effect on endometrium. Therefore, it could be used for endometrial preparation of FET.
Study design, size, duration: This retrospective cohort study included 164 women with PCOS undergoing FET between Jan 2014 and Dec 2015.
Participants/materials, setting, methods: In letrozole group, patients were administered 5 mg letrozle per day from menstrual cycle day (MCD) 3. By ultrasound examination and monitoring of serum hormone levels, exact ovulation day was assessed. Cryopreserved day 3 embryos were transferred 3 days after ovulation.

In HRT group, patients were administered 6 mg estradiol valerate from MCD 3. When endometrial thickness was above 8 mm, 50 mg intramuscular progesterone was injected. Day 3 embryos were transferred 3 days after progesterone injection.
Main results and the role of chance: In each group, age, AMH level, number of transferred embryos and percentage of top quality embryos reflected no differences. Pregnancy rate of letrozole group showed increased tendency as compared with that of HRT group [55.6%(25/45) vs. 39.5%(47/119), P = 0.094]. There was no significant difference between two groups in the spontaneous abortion rate [12.0%(3/25) vs. 29.7%(14/47), P = 0.283]. Ongoing pregnancy rate was significantly higher in letrozole group [48.9%(22/45) vs. 27.7%(33/119), P = 0.029].
Limitations, reasons for caution: This is a retrospective study. A prospective randomized study with large sample size would have minimized potential limitations.
Wider implications of the findings: FET after ovulation induction, patient-friendly endometrial preparation method without painful injection, showed significantly higher ongoing pregnancy rates than FET after HRT cycle. It suggests not only estrogen and progesterone but also another substance could affect implantation. Study about endometrium after HRT and ovulation induction could help better understanding about implantation.
Trial registration number: None.

P-183 Elective single compared to double blastocyst transfer in women aged 40–43 years of age

S. Tannus[1], T.Y.T. Ngan[1], G. Younes[1], A. Gilman[1], J. Hasson[1], W.Y. Son[1], M.H. Dahan[1]
[1]*McGill Universoity Health Center, MUHC Reproductive Center, Montreal, QC, Canada*

Study question: Does elective single blastocyst transfer (eSBT) compromise the reproductive outcome in women 40–43 years of age?
Summary answer: For older women, eSBT can be applied, with live birth rate comparable to elective double blastocyst transfer (eDBT), but with reduced chance of multiple births.
What is known already: Various studies have shown the effectiveness of elective single embryo transfer in young women in achieving comparable live birth rate, and significantly reducing the rate of multiple births. The role of elective embryo transfer in older women is still controversial with conflicting results, mainly due to scarcity of studies. According to our knowledge elective blastocyst transfer without preimplantation genetic screening (PGS) in women aged at least 40 years has not been studied before
Study design, size, duration: This was a retrospective cohort study that included all women aged 40 years and above, who underwent fresh, non-donor elective blastocyst transfer, where supernumerary blastocysts were available for vitrification, between January 2011 and June 2015. Gonadotropin-releasing hormone (GnRH) agonist downregulation or GnRH antagonist protocols were used. Embryos were cultured to the blastocyst stage and transferred on day 5, while any remaining embryos of good quality (≥3BB) were vitrified on day 5 or 6.

Participants/materials, setting, methods: 221 women were included, where one blastocyst (eSBT, $n = 146$) or 2 blastocysts (eDBT, $n = 75$) were transferred. According to our guidelines, up to 2 blastocysts can be transferred in this age group. The decision regarding the number of transferred blastocysts was dependent on the number of available embryos and opinion of the treating physician and couples. Women with 4 or more previous IVF cycles were excluded. Chi-squared tests and logistic regression controlling for confounders were used.
Main results and the role of chance: The live birth rate in the whole group was 22.62% ($n = 50$). Women with eSBT were significantly younger (40.74 ± 0.84 vs. 41.03 ± 0.82 years, $p = 0.016$) and had significantly fewer previous IVF cycles compared to women with eDBT (0.51 ± 0.8 vs. 1.07 ± 1.02 cycles, $p < 0.0001$). eSBT and eDBT had comparable; peak stimulated serum estradiol levels (7414 pmol/l vs. 8031 pmol/l, $p = 0.26$), number of Metaphase II oocytes collected (9.69 ± 4.06 vs. 10.82 ± 4.04, $p = 0.057$) and numbers of supernumerary vitrified embryos (2.29 ± 1.5 vs. 2.23 ± 1.8, $p = 0.7$), respectively. eSBT and eDBT had similar clinical pregnancy rate (32.87% vs. 42.66%, $p = 0.18$), live birth rate (19.86% vs. 28.0%, $p = 0.17$) and miscarriage rate (34.37% vs. 39.58%, $p = 0.81$,) respectively. There were 5 twin deliveries after eDBT, but there were none after eSBT (23.80% vs. 0%, $p = 0.009$).
Limitations, reasons for caution: The retrospective nature of the study and the small number of women in each group. The decision to transfer more than one embryo was tailored per patient based on clinician and patient discussion and could be a source of bias.
Wider implications of the findings: Reducing the risk of multiple pregnancies is of paramount importance in older women who are at increased risk of adverse perinatal outcomes. This study shows that eSBT achieves comparable live birth rate to eDBT, while reducing the multiple live birth rate. Larger studies are needed to approve these results.
Trial registration number: N/A.

P-184 Effect of vitrification-warming cycle at the blastocyst stage using two types of closed vitrification systems

T. Utsunomiya[1], K. Kido[2], E. Otsu[2], Y. Kai[3], H. Itoh[4], F. Kawabe[1]
[1]*St. Luke Clinic, Dept. of Ob/Gyn, Oita, Japan*
[2]*St. Luke Clinic, Labolatory, Oita, Japan*
[3]*Oita University Faculty of Medicine, Obstetrics and Gynecology, Oita, Japan*
[4]*Fukuoka University Faculty of Medicine, Obstetrics and Gynecology, Fukuoka, Japan*

Study question: To investigate which is a more valuable closed vitrification system for blastocysts Rapid-i system or control system.
Summary answer: Significantly higher pregnancy rates, along with higher survival rates post-warming, were obtained in the Rapid-i system group compared to the control system group.
What is known already: Embryo cryopreservation is an important technique in assisted reproductive technology (ART). The closed vitrification system is a safety method employed to avoid direct contact between the embryo and liquid nitrogen, and to further avoid possible cross-contamination. Recently, new devices have been developed that have had a faster cooling and warming rate. This study aims to compare embryo viability after exposure to vitrification by using two types of closed systems: the Rapid-i or the control.
Study design, size, duration: During a prospective study period between September 2013 and July 2015, 316 and 306 blastocysts that were vitrified using the Rapid-i and the control system were thawed, respectively. The survival, pregnancy and miscarriage rates were compared.
Participants/materials, setting, methods: The blastocysts were randomly vitrified on days 5/6. After warming, the blastocysts were judged to have "survived" if >40% of the features were intact. During all transfer cycles, hormone replacement treatment (HRT) was administered. A single blastocyst was transferred into the patients' uterus.
Main results and the role of chance: The embryo survival rate from the Rapid-i group was 90.2% (285/316), and 81.7% (250/306) in the control group ($P < 0.01$). The clinical pregnancy rates from embryo transfer cycles in the Rapid-i group and the control group were 39.9% (107/268) and 30.3% (71/234), respectively ($P < 0.05$). The miscarriage rates from embryo transfer cycles were 37.4% (40/107) for the Rapid-i group and 39.4% (28/71) for the control group (not significantly different). Chromosomal anomaly rates derived from the blastocysts that failed to continue to pregnancy were 66.7% (12/18) and 45.5% (5/11), respectively.
Limitations, reasons for caution: Clinical outcomes should be extended to compare live birth rates and birth defect rates between the two groups. Additional long-term follow-up research may demonstrate more evidence about the closed vitrification method's efficacy.
Wider implications of the findings: This study shows that the Rapid-i system for the vitirification of blastocyst has a higher survival and pregnancy rate than the control system. Further studies later in the fetus development are needed to confirm long-term efficacy.
Trial registration number: Not applicable.

P-185 Observation of normal cytokinesis at first mitosis 26 hours after insemination is effective in predicting embryo development

M. Marie[1], T. Nakano[1], M. Satou[1], S. Hashimoto[2], Y. Nakaoka[3], Y. Morimoto[4]
[1]*IVF Namba Clinic, Reproductive technology, Osaka, Japan*
[2]*IVF Namba Clinic, Research development, Osaka, Japan*
[3]*IVF Namba Clinic, Physician, Osaka, Japan*
[4]*HORAC Grand Front Osaka Clinic, Physician, Osaka, Japan*

Study question: Is the normal cytokinesis at 1st mitosis effective in predicting subsequent embryo development 26 hours after insemination?
Summary answer: Embryos that underwent normal cytokinesis at 1st mitosis until 26 hours after insemination had high developmental potential compared with late-cleaved or abnormally-cleaved counterparts.
What is known already: Data of time-lapse cinematography (TLC) has shown that normal cytokinesis at 1st mitosis is one of markers to predict the development to the blastocyst in human ART. In addition, the average time required for the start of 1st mitosis in embryos which developed to blastocysts was 26 hours after insemination. In this study, we examined whether we could predict the subsequent embryonic development by assessing the normal cytokinesis at 1st mitosis 26 hours after insemination using an inverted microscope, not TLC system.
Study design, size, duration: This study included 3165 embryos that underwent normal fertilization after IVF or ICSI between October 2014 and March 2015. The couples received full explanations regarding the study and gave their consent to being involved.
Participants/materials, setting, methods: We divided into two groups according to the cleavage pattern at 1st mitosis 26 hours after insemination (2 cell: Group A vs. 1 cell or abnormally-cleaved embryos: Group B). And then, embryos were cultured individually. Single embryo transfer was conducted on day 3. One morphologically-good embryo was selected for transfer. We investigated the rates of good quality embryo (GQE) on day 3, of blastulation, of good quality blastocyst (GQB) on day 5, and of implantation.
Main results and the role of chance: The normal cytokinesis at 1st mitosis was observed in 779 embryos until 26 hours after insemination (24.6%). The rate of GQE in Group A was significantly higher than that in Group B ($P < 0.0001$, 90.8 vs 62.0%). The rates of blastulation and GQB in Group A (70.7 and 40.4%) were also significantly higher ($P < 0.0001$) than those in Group B (37.8% and 22.4%). After single embryo transfer on day3, the implantation rate in Group A was significantly higher than in Group B ($P < 0.01$, 40.9% vs 17.9%).
Limitations, reasons for caution: This study includes all cases obtained informed consents in the period without considering the patients' characteristics. So, we would like to assess effects of maternal age and stimulation protocol in the future.
Wider implications of the findings: The observation of 1st mitosis 26 hours after insemination with a conventional microscope would be helpful to predict embryo development without using a high-priced TLC system.
Trial registration number: None.

P-186 Introduction of Follicular Fluid Activation ICSI (FFA-ICSI): retrospective investigation of a culture result and a clinical outcomes

Y. Tanaka[1], H. Tajima[1], H. Takahashi[1], Y. Watanabe[1], A. Jinno[1], H. Inai[1], S. Akimoto[1], H. Asada[1]
[1]*Shin-Yurigaoka General Hospital, Obstetrics and Gynecology, Kawasaki, Japan*

Study question: We performed a retrospective analysis of results derived from a culture result and clinical studies of Follicular Fluid Activation intracytoplasmic sperm injection (FFA-ICSI) and conventional ISCI (N-ICSI).

Summary answer: Compared to N-ICSI, FFA-ICSI showed better results in total fertility rate, normal fertilization rate, blastulation rate, top grade blastocyst rate and pregnancy rate.
What is known already: It was previously reported that addition of follicular fluid had stimulated activation of sperm and contributed to the process of capacitation.
Study design, size, duration: We divided mature eggs retrieved from each patient into two groups, the FFA-ICSI group and the N-ICSI group, and analyzed obtained results in five different categories. 73 cases of ICSI performed in our hospital between January, 2013 and September, 2014 were subjected to this analysis.
Participants/materials, setting, methods: Among the cases where ICSI was applied in our hospital, patients from which we could collect eggs from multiple ova were subjected to this analysis. Cases where female patients had anti-sperm antibodies and endometriosis were excluded from this analysis. Follicular fluid was added in washed sperm 90 minutes prior to ICSI, and ova of each patient were divided into the FFA-ICSI group and the N-ICSI group. We then enforced ICSI.
Main results and the role of chance: The results for the FFA-ICSI group and N-ICSI group, shown in percentage and actual numbers in parenthesis, are as follows: total fertility rate {90.9% (239/263) vs. 86.1% (192/223)}, normal fertilization rate {83.6% (220/263) vs. 76.2% (170/223)}, blastulation rate {64.7% (141/218) vs. 53.4% (93/174)}, top grade blastocyst rate {45.4% (99/218) vs. 37.4% (65/174)}, clinical pregnancy rate{45.0% (86/191) vs. 43.8% (42/96)}. In this analysis, a significant difference was observed in one of the categories. FFA-ICSI showed a better outcome than N-ICSI in other categories. There is a possibility that the Follicular Fluid technique has improved the outcome of ICSI, and contributed to the increase of pregnancy rate.
Limitations, reasons for caution: With regard to pregnancy rates, we transferred embryos with the highest grades. Therefore, there is a possibility that the deviation was observed because of the differences between embryos derived from FFA-ICSI or N-ICSI.
Wider implications of the findings: Increasing number of available embryos by blastulation rate is better, there is a possibility to contribute to the increase pregnancy rate.
Trial registration number: Not applicable.

P-187 Successful blastocyst biopsy and Preimplantation Genetic Screening after embryo cryopreservation and extended culture: analysis on 213 frozen-thawed supernumerary embryos, previously cryopreserved without biopsy

E. Greco[1], M.G. Minasi[1], A. Ruberti[1], V. Casciani[1], F. Scarselli[1], A. Colasante[1], E. Cursio[1], M. Lobascio[1], A. Greco[1], P. Greco[1], A. Caragia[1], M.T. Varricchio[1], A. Biricik[2], F. Spinella[2], F. Fiorentino[2]
[1]*European Hospital, Infertility, Rome, Italy*
[2]*GENOMA, Molecular Genetics Laboratory, Rome, Italy*

Study question: To evaluate the efficacy of performing extended culture until blastocyst stage, trophectoderm biopsy, whole genome amplification and preimplantation genetic screening (PGS) on previously cryopreserved embryos.
Summary answer: Performing PGS at blastocyst stage on cleavage embryos previously cryopreserved without biopsy and subsequent genetic analysis, allows to achieve excellent clinical and biological outcomes.
What is known already: In the last 10 years, the enhancement of cleavage stage embryo's and blastocyst's vitrification procedures, led to very good survival rate and clinical outcomes. Simultaneously, the improvement in blastocyst biopsy combined with the analysis of all the 24 chromosomes in PGS cycles, allowed to achieve pregnancy rates per transfer higher than 60%. Combining these two methodologies could offer concrete possibility of delivery a healthy baby to all couples who still have their supernumerary embryos cryopreserved in the past years.
Study design, size, duration: This retrospective study was performed from January 2011 to December 2015. Fifty-one couples required to be informed about the genetic constitution of their own supernumerary embryos, previously cryopreserved without any genetic screening. All embryos were vitrified at cleavage stage. All survived embryos were cultured until blastocyst stage at 37°C, 6%CO^2, 5%O^2, in order to perform trophectoderm biopsy. All biopsies were analyzed by mean of whole genome amplification (WGA) and array-comparative genomic hybridization (aCGH).
Participants/materials, setting, methods: The mean female age was 36.3 ± 4.23. Only euploid blastocysts were transferred. Depending on when the blastocysts were obtained, some transfers were performed the day after the biopsy, as soon as receiving the genetic results (group-A), while the other blastocysts were once again individually cryopreserved, in order to perform the transfer in a subsequent cycle (group-B). In group-A, 5 double and 24 single embryo transfers were performed. In group-B, 15 single embryo transfers were performed.
Main results and the role of chance: A total of 217 cleavage stage embryos were warmed and 213 (98.2%) of them survived. After the extended culture, 146 (68.5%) or them reached the blastocyst stage, 97 (66.4%) on day-5, 43 (29.5%) on day-6 and 6 (4.1%) on day-7 of culture. After the genetic analysis, 62 (42.5%) of them resulted euploid, 8 (5.5%) mosaic, 71 (48.6%) aneuploid and 5 (3.4%) without genetic result. Forty-nine euplodid blastocysts were transferred in 44 transfers, leading to cumulative clinical pregnancy (CPR) and implantation (IR) rates of 61.4% (N = 27) and 55.1% (N = 27), respectively. In group-A, 34 blastocysts were transferred in 29 transfers, leading to CPR of 55.1% (N = 16) and IR of 47.1% (N = 16); 14 healthy babies born, 1 pregnancy is still ongoing and 1 miscarried. In group-B, 15 blastocysts were transferred in 15 single embryo transfer transfers, leading to CPR and IR of 73.3% (N = 11); 3 healthy babies born, 4 pregnancies are still ongoing and 4 miscarried. There are no statistically significant differences in clinical outcomes between group-A and group-B. Statistical analyses were performed using the Fisher's exact test at the level of $P < 0.05$.
Limitations, reasons for caution: Performing double vitrification, some blastocyst could be lost due to the cryopreservation procedures. Performing the transfer on the day after the biopsy after receiving the genetic result, the endometrial receptivity could be altered.
Wider implications of the findings: Embryos cryopreserved before the advancement of the PGS procedures, can now be tested before proceeding with their embryo transfer, in order to improve the clinical outcomes obtaining a safe pregnancy. Performing the biopsy at blastocyst stage do not interfere with embryo's development, probably because only few extra-embryonic cells are removed.
Trial registration number: Not applicable.

P-188 Expression of Glucose Metabolism Genes in Human Embryos Cultured in a Sequential Media System by Single-cell RNA-seq

Q. Zeng[1], J. Ma[2], L. Lu[2], X. Zhang[2], L. Cai[1], R. Chian[1], J. Liu[1], Z. Xue[2]
[1]*First Affiliated Hospital, Nanjing Medical University, The Center of Reproductive Medicine, Nanjing Jiangsu, China*
[2]*Tongji University, Translational Center for Stem Cell Research, Tongji Hospital, Department of Regenerative Medicine, Shanghai, China*

Study question: Using single-cell RNA-seq and Weighted Gene Co-expression Network Analysis (WGCNA) to explicit expression of glucose metabolism genes in human pre-implantation embryos cultured in the sequential media.
Summary answer: Glucolysis genes are gradually increase and highly upregulated in morula and blastocysts compared to cleavage-stage embryos, and tricarboxylic-acid-cycle genes are fluctuant through all developmental stages.
What is known already: Different stage embryos require different glucose metabolism. Zygotic genome activation (ZGA) is a gradual process or a stringently controlled program, and glucose metabolism is regulated by ZGA with specially appointed features in different stages of pre-implantationembryos.
Study design, size, duration: Human pre-implantation embryos were obtained from patients who underwent IVF treatment and written informed consent was obtained. Total of 39 oocytes and embryos were used in this study: 6 oocytes, 6 pronuclei, 4 zygotes, 5 2-cellstage embryos, 4-cellstage embryos, 5 8-cellstage embryos, 4 morula and 4 blastocysts. After digestion, 78 cells or blastmeres were used for construction of single-cell RNA-library.
Participants/materials, setting, methods: Human pre-implantation embryos were cultured in the sequential media (SAGE, USA) including cleavage- and blastocyst-media. Embryosat different stages were treated with Tyrode's acidic solution to remove zona pellucida, and then be separated by 0.25% Typsin digestion to acquire single cells that were used to construct RNA library for RNA-seq data using Quartz-seq and SMART-seq methods. After raw reads being mapped to the human genome, all datasets were independently constructed and analysis using the WGCNA.

Main results and the role of chance: The expressions of glucolysis genes (relationship to anaerobic respiration) are speedily increasing in morula and reach the highest in blastocysts, e.g., glucosetransporters (SLC2A1, SLC2A3 and SLC2A8) were not expressed before 8-cell stage until morula. Moreover, three key genes of glucose catabolism (hexokinase, phosphofructokinase and pyruvate kinase) could not be detected in 2-, 4- and 8-cell stage embryos but in morula and blastocysts. However, expressions of tricarboxylic acid cycle genes (relationship to aerobic respiration) were fluctuant, e.g., pyruvate dehydrogenase (PDHB/DLD) and citrate synthase (CS), key enzymes of tricarboxylic acid cycle, were slightly high-expressed in 2-cell stage and morula but were lowly expressed in 8-cell stage embryos.
Limitations, reasons for caution: In this study, every stage of human pre-implantation embryos was not cultured in gradient concentration glucose media to detect effects of concentrations on glucose metabolism in the embryos.
Wider implications of the findings: The results provide a valuable information to improve the composition of culture medium for human pre-implantation embryos. Also this study provides new insight into sequential activation of metabolism-specific genetic programs and gene regulatory mechanisms underlying progressive development of early human embryos.
Trial registration number: None.

P-189 Diameter of immature oocytes collected in IVM cycles and its association with nuclear maturation timing

D. Gunasheela[1], J. Menon[1], J. Amitha[2], H. Nirmala[2], G. Uttur[2], G. Deepanjali[2], W.Y. Son[3]
[1]*Gunasheela Surgical & Maternity Hospital, Infertility, Bangalore, India*
[2]*Gunasheela Surgical & Maternity Hospital, Embryology, Bangalore, India*
[3]*McGill University, Embryology, Montreal, Canada*

Study question: Study questions: What is the *in vitro* maturation timing of human Germinal Vesicle (GV)-stage oocytes collected from IVM cycles? Is oocyte diameter at GV-stage associated with meiotic competence?
Summary answer: Summary answer: The GV-period is shorter than Germinal Vesicle Breakdown (GVBD)-stage *in vitro*. Oocyte diameter at GV-stages is an indicator of oocyte maturation capacity
What is known already: IVM has been less successful than standard IVF in terms of embryo development and clinical outcomes. The nuclear oocyte maturation timing process of immature GV-stage oocytes during *in vitro* culture hasn't been known. Previous studies have linked oocyte size to the maturation status but no direct correlation has been made. It is currently unclear whether the diameter is different between IVM oocytes and *in vivo* matured oocytes derived either from same cohort in IVM cycles or from conventional IVF cycles.
Study design, size, duration: The maturation timing process from GV-stage oocytes obtained was recorded following culture by adopting the EmbryoScope time-lapse system (TLS) equipment. Seventy-five MII- and 193 GV-stage oocytes were possible to analyze under TLS. The average size of oocytes were compared in oocytes matured *in vitro* ($n = 93$), arrested at GV-stage ($n = 100$) and matured *in vivo* of same cohort ($n = 75$) using the ellipse function of the TLS.
Participants/materials, setting, methods: The oocytes were obtained from PCOS patients undergoing FSH/hCG-primed IVM cycles. Most of the cumulus cells (CC) were removed 3 hours after oocyte retrieval in order to see the oocyte maturation. GV-stage oocytes were cultured for 28 hours in the TLS prior to ICSI. The diameters of the GV-stage oocytes and maturation timing were recorded. All oocytes matured or arrested after 28 hours of culture were included in this study.
Main results and the role of chance: The average time from GV- to GVBD-stage was 6.3 hours (±2.3, range: 3.5–12.3 hours) after retrieval and GBVD- to MII-stage was 15. 5 hours (±1.5, range: 10.7–18.6 hours) during culture *in vitro*. Analysis of oocytes at the GV-stage revealed that oocytes matured *in vitro* ($n = 93$) had significantly larger diameters (μm) at GV-stage than those that failed to resume meiosis after IVM ($n = 100$) (110.7 ± 4.8 versus 106.7 ± 4.6 μm; $P < 0.0001$). Interestingly, no GV-stage oocyte with average diameter < 102 μm matured *in vitro* after 28 hours of culture ($n = 14$). The diameter did not change from GV- to GVBD-stage, but decreased after the first polar body extrusion (109.1 ± 4.9 μm). The average diameter at the MII-stage matured *in vitro* were similar with cohort of *in vivo* matured oocytes in IVM cycles (108.8 ± 3.3 μm) and oocytes matured *in vivo* obtained from conventional IVF cycles (108.6 ± 3.6 μm).
Limitations, reasons for caution: Most of CC at GV-stages were removed, which may act differently than oocytes with intact CC. Maturation timing may be different between different sources of immature oocytes. Studies are required to clarify the maturation timing of immature oocytes depending on CC presence, culture media and different sources of immature oocytes.
Wider implications of the findings: This is the first observation describing thoroughly the *in vitro* maturation process of GV-stage oocytes derived from IVM cycles using TLM. This study clearly demonstrated a direct correlation between the diameter at GV-stage and oocyte maturation capacity *in vitro*. This study may provide essential information for improving human IVM program.
Trial registration number: Not applicable.

P-190 Follicle size and synchronicity of follicular development influence morphokinetic variables in embryos

S. Kahraman[1], C. Pirkevi Çetinkaya[1], M. Çetinkaya[1], M. Montag[2]
[1]*Istanbul Memorial Hospital, Assisted Reproductive Technologies and Reproductive Genetics Center, Istanbul, Turkey*
[2]*ilabcomm GmbH, Eisenachstr. 34, 53757 Sankt Augustin, Germany*

Study question: Are morphokinetic parameters of embryo development influenced by follicular size (large and small) in synchronous and asynchronous follicle development during stimulation?
Summary answer: Embryos from small follicles in asynchronous cycles develop significantly faster starting from 5-cell stage up to expanded blastocyst stage.
What is known already: Several studies have investigated the effect of culture media, culture conditions, patients' etiology, smoking habit, BMI and stimulation types on embryo morphokinetics. These parameters were reflected to different extents in subtle changes in morphokinetic variables. However, whether similar changes occur in implanting embryos or if these follow a more universal pattern, is currently unknown. Since the implementation of time-lapse systems, clinic-specific morphokinetic models have been proposed. In search of a general applicability of morphokinetic models, potential confounding factors that can be objectively assessed need to be investigated. This holds true for synchronicity of follicular development and size.
Study design, size, duration: This retrospective cohort study was conducted in a private IVF clinic between July 2014 and September 2015. Strict inclusion criteria (<2 previous treatment cycles, age ≤ 39 years, ≥8 oocytes retrieved) and exclusion criteria (PGD or PGS indication, > 24 COCs during pickup) were applied. Morphokinetic analyses were performed only for fertilized oocytes achieving the blastocyst stage ($n = 1217$) derived from 187 infertile patients.
Participants/materials, setting, methods: Synchronous cycles were defined as follicles of all sizes being present, whereas asynchronous cycles were those clearly separated into a small and a large cohort. Small follicles were defined as <17 mm on OPU day. Culture was performed in EmbryoScope at 6%CO2 and 5%O2 using a single-step culture medium (Global) with change on day3. Morphokinetic variables for all cleavage events up to the expanded blastocyst stage were annotated. Embryo selection was done according to morphology.
Main results and the role of chance: Embryos developing from small follicles in asynchronous cycles were found to achieve all cleavage times earlier than those developing from large follicles in asynchronous cycles but also than small and large follicles developing in synchronous cycles. At the end of the culture, the time to reach the expanded blastocyst stage (tEB) was 3 hours earlier in small follicles of asynchronous cycles when compared to the other three categories.

Next we looked at the timings of embryos with known implantation data (KID). For implanting blastocysts (KID positive) the mean time for tEB was 110 h for those developed from small and large follicles in synchronous cycles and from small follicles in asynchronous cycles, whereas implanting blastocysts from large asynchronous follicles showed a different mean tEB time (tEB 113 = h).
Limitations, reasons for caution: Inclusion and exclusion criteria favored a group of good prognosis patients. Results were obtained in a defined IVF setting and cannot necessarily be translated in another laboratory.
Wider implications of the findings: Constructing optimized morphokinetic algorithms for a specific center needs to take into account further variables such as follicular size and synchronicity. This is of uttermost importance if the final goal is to use models for identifying embryos for an elective single embryo transfer.
Trial registration number: Not applicable.

P-191 Proliferation of two sources of trophectoderm cells from the same cohort in human blastocysts. A time lapse imaging report

O. Perez[1], S.J. Chantilis[2], K. Lee[2], M. Thomas[2], R. Gada[2], L. Lawrence[2]
[1]*Dallas Fertility Center, IVF laboratory, Dallas, USA*
[2]*Dallas-Fort Worth Fertility Associates, IVF Clinic, Dallas, USA*

Study question: Is it possible to transplant and proliferate trophectoderm cells in blastocysts from the same cohort with low number of trophectoderm cells?
Summary answer: A successful transplant and proliferation of trophectoderm cells were achieved in blastocysts with low number of trophectoderm cells.
What is known already: Approximately 80% of human blastocysts are discarded because they do not reach the optimal quality to provide a chance of a clinical pregnancy and/or a birth outcome. Blastocyst quality is expressed in terms of the number of trophectoderm cells as well as the inner cell mass during this stage of embryo development. To be successful, a few embryos must be of good quality in the trophectoderm area. Trophectoderm morphology has been considered a highly independent predictor of both clinical pregnancy and birth outcome. Blastocysts with a higher number of trophectoderm cells correlate significantly with a higher implantation rate.
Study design, size, duration: Embryos that were non-viable that would subsequently be discarded were selected for this study based on the quality of the outer cells. Specimens were derived from unused cells obtained from *in vitro* fertilization patients who had consented to have these discarded cells used for research purposes. Embryos were monitored using a time lapse imaging system (EmbryoScope™, Vitrolife).
Participants/materials, setting, methods: Approximately 8–10 trophectoderm cells were injected into two blastocysts from the same cohort with a low number of trophectoderm cells. An assisted 30 μm hole in the zona pellucida was needed to inject the trophectoderm cells. Blastocysts were placed in the embryoScope and cultured with G2 plus media (Vitrolife) for 20 hours. Images were acquired every 20 minutes from 7 different focal planes. Cellular activity was monitored every 20 minutes.
Main results and the role of chance: A successful transplant and proliferation of trophectoderm cells were achieved in two blastocysts with low number of trophectoderm cells. Cellular activity started within the first 20 minutes with an increment and proliferation of trophectoderm cells from 113 μm on diameter and an area of 11031 μm^2. Blastocysts started hatching approximately 40 minutes after cell transplantation with and increment of 35% of blastocyst perimeter and 40% of blastocyst area (172 μm and 18309 μm^2, respectively). Cell growth continued until a blastocyst hatched stage. Hatched blastocysts were removed from the EmbryoScope and placed in a 15 microliter drop for a final video evaluation.
Limitations, reasons for caution: These results are the preliminary findings of a research project involving the transplant and proliferation of trophectoderm cells in human blastocysts. More subjects are needed to understand the attachment and proliferation of trophectoderm cells from two different sources.
Wider implications of the findings: The intended result is the rescue of more embryos that may be considered viable for a fresh transfer and/or cryopreservation with a higher rate of clinical pregnancy and/or birth. If successful, this novel technique may result in a 10–15% increase in the potential for pregnancy.
Trial registration number: USA Institutional Review Board (IRB) # 201505154 Protocol #: SAIRB-15-0062.

P-192 Impact of exposure time of fresh and frozen-thawed blastocysts to Hyaluronic acid containing transfer medium

S. Cooke[1], V. Hua[1], C. Venetis[1]
[1]*IVFAustralia, Science Department, Greenwich, NSW, Australia*

Study question: Is the EmbryoGlue exposure time prior to transfer in fresh and frozen-thawed (FET) single blastocyst transfers (SBT) associated with the probability of clinical pregnancy?
Summary answer: No correlation between EmbryoGlue exposure time and clinical pregnancy rates was detected for both fresh and frozen-thawed SBT.
What is known already: A recent Cochrane systematic review (Bontekoe et al., 2014) has shown that the use of Hyaluronic Acid (HA) in embryo transfer media is associated with higher live birth and clinical pregnancy rates in in-vitro fertilization cycles when compared to the use of low or minimal HA. The recommended exposure time for embryos to EmbryoGlue prior to transfer has traditionally been short (10–30 min). However, it is still unknown whether a longer duration of embryo exposure to HA before transfer is associated with the probability of pregnancy.
Study design, size, duration: This is a retrospective cohort analysis of 931 consecutive cases of fresh ($n = 489$) and frozen-thawed ($n = 442$) SBT that took place over a period of ten weeks.
Participants/materials, setting, methods: Patient age ranged from 21.2 to 52.1 years (mean: 36.5 years and SD: 4.7) with EmbryoGlue exposure times ranging from 7 to 720 min (mean:115 min, SD:82.9). Four groups were constructed (Group 1: ≤60 min, Group 2: 61–120 min, Group 3: 121–180 min, Group 3: >180 min). The correlation between exposure time prior to transfer with clinical pregnancy rate was evaluated using logistic regression analysis, while controlling for the confounding effect of female age.
Main results and the role of chance: In fresh SBT, longer exposure to EmbryoGlue did not result in significantly different clinical pregnancy rates as compared to ≤60 min (Group 2 vs. Group 1 odds ratio (OR): 0.61, 95% CI: 0.36–1.03; Group 3 vs. Group 1 OR: 0.65, 95% CI: 0.36–1.18; Group 4 vs. Group 1 OR:0.75, 95% CI: 0.41–1.36). Similarly, in frozen-thawed SBT, longer exposure to EmbryoGlue also did not result in significantly different clinical pregnancy rates as compared to ≤60 min (Group 2 vs. Group 1 OR: 1.02, 95% CI: 0.62–1.66; Group 3 vs. Group 1 OR: 1.67, 95% CI: 0.91–3.05; Group 4 vs. Group 1 OR:1.22, 95% CI: 0.67–2.22).
Limitations, reasons for caution: This is a retrospective analysis and although adjustment for major confounding has been performed, the presence of residual bias cannot be excluded.
Wider implications of the findings: These results do not support either a positive or negative effect of prolonged EmbryoGlue exposure on clinical pregnancy rates after Fresh or Frozen-thawed transfer. Embryologists can organize their embryo transfers without being concerned about the duration of embryo exposure to EmbryoGlue.
Trial registration number: Nil.

P-193 Comparative assessment of human blastocyst resiliency to vitrification solution toxicity and osmotic stress associated with re-vitrification (rVTF)

M.C. Schiewe[1], L. Gamboa[1], V. Smetona[2], K. Baskevitch[3], J. Borba[1]
[1]*Ovagen Fertility, ART Laboratory, Newport Beach, CA, USA*
[2]*UCLA, Undergradate, Los Angeles, CA, USA*
[3]*UC Berkeley, Undergraduate, Berkeley, CA, USA*

Study question: What is the cryotolerance of human blastocysts to repeated re-vitrification (rVTF) and varying exposures to different VTF solutions as sources of osmotic injury and cytotoxicity?
Summary answer: Human blastocysts are more resilient to extended vitrification solutions exposures and to the potential osmotic stress of repeated rVTF (≤6 times) than previously assumed.
What is known already: Vitrification has proven to be a highly efficient mode of embryo cryopreservation. Vitrified embryo survivability is dependent on: 1) exposure to concentrated cryoprotective solutions that form a glasseous solid upon rapid cooling; and 2) high warming rates followed by cellular elution to an isotonic, equilibrated condition. We have previously shown that human embryos are highly adaptive to osmotic shifts during elution and that the rVTF of aneuploidy blastocysts can serve as a useful model. Current dogma suggests that high molar concentrated vitrification solutions (>5.5 M) exposures must be brief to avoid cellular toxicity and that embryos are susceptible to osmotic stress.
Study design, size, duration: 360 research consented, discard blastocysts were randomly assigned to: Expt.1) 2 × 3 factorial design: repeated rVTF (1, 3 or 5 times) with or without elution/equilibration; or Expt.2) 6 × 3 factorial design: comparing 6 exposure intervals post-warming (1, 3, 5, 10, 15, 20 min/20 blastocysts/group) in a commercial EG/DMSO (15/15% solution; LifeGlobal), EG/PPG (16/16% solution; Vitrolife) or our control Glycerol/EG (≥7.9 M; Innovative Cryo Enterprises) vitrification solutions. Differences in % survival and %24 hr development were statistically compared by Chi-square analysis.
Participants/materials, setting, methods: Biopsied blastocysts (AA to BB quality) were vitrified using microSecure vitrification (μS-VTF), an aseptic closed system. Upon determination of their aneuploidy status, embryos were discarded or assigned a research treatment and discarded within 24 hr. Standard μS-VTF rapid warming was performed on all embryos, with non-elution treatment blastocysts (Expt.1) simply being wiped dry and reinserted/sealed

into straws and plunged back into LN_2 1-min post-warming. Embryo survival assessments were performed at 0 and 24 hr (i.e., continued expansion) post-treatment.

Main results and the role of chance: Human blastocysts proved to be highly cryotolerate to extended VTF solution exposure (with or w/o VTF), dilutions/elutions and repeated rVTF (up to 5 times), with no differences in post-warming or developmental survival (95–100% expansion) being observed in Expt.1. However, in Expt.2, 24 hr development was significantly reduced with ≤5 min exposure in the EG/DMSO group (83.3%), compared to EG/PPG (93.3%) or Glycerol/EG (96.7%). Interestingly, the developmental integrity of Glycerol/EG treated blastocysts reduced (75%; $p < 0.05$) by 10 min and was significantly lower at 15/20 min (30–35%) than either EG/DMSO (55–70%) or EG/PPG (55–60%). In Expt.1, the high survival rate of non-eluted rVTF-treated blastocysts was facilitated by repeated rapid warming. Conversely, the elution group endured repeated osmotic stress characterized by cellular shrinkage and re-expansion in sucrose and vitrification solutions. The plasticity and cryotolerance of blastocyst to vitrification treatment was dramatically demonstrated on our control group (µS-VTF in Glycerol/EG), which proved to be very safe up to 5 min. Note, that the Glycerol/EG group has an appreciably higher solute concentration than the other solutions, insuring more metastability in its vitrified "glassy" state without the ultra-rapid cooling of an open-system. However, the latter solution was more toxic with prolonged cryoprotectant exposures >10 min.

Limitations, reasons for caution: The genotoxicity of all treatment solutions remains unknown, especially in the extended exposure groups (>5 min). Certainly 2 min exposures and 2X rVTF are regarded as safe, having previously yielded proven live births. Additional investigation is needed to determine how EG/DMSO –treated blastocysts will respond to repeated rVTF.

Wider implications of the findings: Human blastocysts are highly resilient to rVTF, with or without repeated elutions, and extended exposures to non-DMSO containing VTF solutions. The safety and efficacy of VTF was clearly shown to be highly tolerable by the functional cell membrane integrity sustained after repeated metastable rVTF.

Trial registration number: None.

P-194 Day 2 to 4 embryo transfers, with timing of syngamy as an additional selection criterion, produces similar clinical outcomes as day 5 transfers

P.L. Tan[1], A.S.N. Lee[1], M.N. Lim[1], C.F. To[1], E.M.J. Ong[1], R.S.R. Wong[1], S.L. Yu[1]
[1]*Singapore General Hospital, Centre for Assisted Reproduction CARE, Singapore*

Study question: Does further selection of embryos based on the timing of syngamy for day 2 to 4 transfers achieve clinical outcomes comparable to day 5 transfers?

Summary answer: Incorporating timing of syngamy with development and morphology for embryo selection allows day 2 to 4 transfers to achieve clinical outcomes of day 5 transfers.

What is known already: Culturing embryos to day 5 for transfer serves as a selection for embryos that have a higher chance of implantation. Day 5 transfers are proven to give better clinical outcomes than day 2 to 4 transfers. The absence of pronuclei in an embryo 26 hours after intracytoplasmic sperm injection or sperm insemination indicates that it has reached its syngamy stage. This implies that it is a more developmental competent embryo.

Study design, size, duration: This retrospective study includes 264 patients who underwent IVF cycles between August 2013 and December 2015 and had 2 embryos for embryo transfer. The patients were categorized into two groups. Group A consisted of patients with both embryos that had reached syngamy (at 26 hours after injection or insemination) for transfer, either on day 2, 3 or 4. Group B consisted of patients with day 5 embryos for transfer, regardless of their timing of syngamy.

Participants/materials, setting, methods: Selection of embryos for transfer was based on embryo development and morphology on the day of embryo transfer in both groups. All the patients were aged between 27 and 45 years old. Group A had 126 patients (average age: 35.18) and Group B had 138 patients (average age: 35.84). The outcomes compared were clinical pregnancy, implantation and live birth rates.

Main results and the role of chance: Analysis of the results through chi-square test proved that there were insignificant differences between the two groups in terms of clinical pregnancy, implantation and live birth rates. In Group A, the clinical pregnancy rate was 44.4% which is not significantly different from the 42.0% of Group B (p-value = 0.69). Implantation rates were 29.4% and 31.5% for Group A and B respectively and the difference was negligible (p-value = 0.59). This is also the same for live birth rate (p-value = 0.43), where Group A has the rate of 77.2% with 15 ongoing pregnancies while Group B has 70.7% with 19 ongoing pregnancies. These results suggest that embryos selected for embryo transfer from day 2 to 4, based on timing of syngamy together with embryo development and morphology, possessed the implantation potential of embryos selected for Day 5 transfers.

Limitations, reasons for caution: Only fresh IVF cycles were included in this study. The addition of frozen embryo transfer data may affect the cumulative pregnancy rate of the two groups.

Wider implications of the findings: By considering timing of syngamy, day 2 to 4 transfers can achieve comparable clinical outcomes to day 5 transfers. This provides a possible option when resources to perform blastocyst culture are limited. It will encourage single embryo transfer practice and reduce potential risks associated with multiple pregnancies and extended culture.

Trial registration number: NA.

P-195 Aberrant cell division in early-stage human embryos observed by time-lapse monitoring and its negative impacts on subsequent embryonic development

M. Tsuneto[1], K. Yumoto[1], Y. Matoba[1], S. Miyazaki[1], J. Yamauchi[1], M. Sugishima[1], C. Mizoguchi[1], A. Tanaka[1], N. Okada[1], M. Nakaoka[1], K. Iwata[1], Y. Iba[1], Y. Mio[1]
[1]*Mio Fertility Clinic, Reproductive Centre, Yonago, Japan*

Study question: Does aberrant cell division at an early stage of human embryonic development have negative impacts on further embryonic development?

Summary answer: Aberrant division was associated with retardation of embryonic development and an increased incidence of multinucleated blastomeres (MNB) resulting in poor-quality embryos.

What is known already: In recent years, incubators equipped with time-lapse monitoring systems have enabled assessment of the dynamic morphology of human embryonic development. Using such monitoring, we often observe embryos showing aberrant cell division in which a single zygote divides into more than three blastomere-like cells in the first cleavage and a single blastomere into three or more blastomere-like cells in the second cleavage. It seems to be an abnormal behavior of embryos; however, the developmental potential and negative impacts on embryonic quality of embryos showing aberrant cell division have not been elucidated.

Study design, size, duration: From August 2012 to December 2014, intracytoplasmic sperm injection (ICSI) was performed on 2,274 oocytes, which were then cultured for three days in incubators with time-lapse monitoring. We analyzed the occurrence of aberrant division in whole normally fertilized zygotes (n = 1,818), comparing embryos from younger patients (31 to 33-year-olds; n = 372) with an advanced-aged group (41 to 43-year-olds; n = 249). We transferred aberrantly divided embryos reaching fair quality if the only alternative.

Participants/materials, setting, methods: We performed ICSI on matured oocytes 4 hours post-oocyte retrieval. Digital images were acquired at 15-minute intervals for two days with the EmbryoScope®. We evaluated cell-cleavage patterns based on time-lapse images of the first and the second cleavage of blastomeres. We classified a cell division yielding more than three blastomere-like cells (diameter >30µm) from one blastomere as an aberrant division. We also analyzed the time course of embryonic development and clinical outcomes for transferred embryos.

Main results and the role of chance: Of 1,818 zygotes, 246 (13.5%) showed aberrant division, and the occurrence rate was not significantly different between young and advanced-aged groups {12.4% (46/372) vs. 10.8% (27/249)}. The rate of MNB was significantly higher in aberrantly divided embryos (aberrant group) than normally divided embryos (normal group) (63.8% vs. 21.2%, $P < 0.01$). Among embryos in the aberrant group, 63.8% (157/246) and 36.2% (89/246) of embryos showed aberrant division in the first cleavage (aberrant^{1st}) and in the second cleavage (aberrant^{2nd}), respectively. Of 246 embryos, 13 embryos (5.3%) showed aberrant division in both first and second cleavages (aberrant$^{1st/2nd}$).

Time required from ICSI procedure to syngamy in the aberrant group was significantly longer than in the normal group (aberrant^{1st}; 24.5 ± 4.4, aberrant^{2nd}; 24.6 ± 3.1, aberrant$^{1st/2nd}$; 26.8 ± 6.6, and normal group; 23.0 ± 3.6 hours).

Additionally, time required from syngamy to the first cleavage in aberrant[1st] embryos (aberrant[1st] vs. normal; 4.7 ± 3.6 vs. 2.8 ± 1.4 hours, $P < 0.01$) and the first cleavage to the second cleavage in aberrant[2nd] embryos (aberrant[2nd] vs. normal; 13.0 ± 3.6 vs. 11.3 ± 1.7 hours, $P < 0.01$) was significantly longer than in the normal group.

In cases of transferring aberrantly divided embryos, the pregnancy rate was 27% (4/15); three gave healthy babies, and pregnancy is ongoing in the remainder.

Limitations, reasons for caution: It was impossible to determine all nuclei of blastomere-like cells because of focusing difficulties. Aberrant division could be further classified based on whether one blastomere divides into three blastomeres or into two blastomeres and a large fragment. Molecular biological approaches are thus necessary for detecting all nuclei.

Wider implications of the findings: Our study suggested that aberrant cell division was associated with the formation of MNB and a delay in developmental events until the second cleavage. We hypothesized that aberrant cell division could be related to dysregulation of the spindle, controlling the distribution of cytoplasm and chromosomes.

Trial registration number: None.

P-196 An embryo score established with a Time Lapse incubation system to early predict the chance to obtain a blastocyst

M. Benchaib[1,2,3], C. Edel[1], E. Labrune[1,2,3], J. Lornage[1,3,4], S. Giscard d'Estaing[1,3,4]

[1]Hôpital Femme Mere Enfant, Biology of Reproduction, Bron, France
[2]Université Lyon 1, Faculté de Medecine Lyon Est, Lyon, France
[3]Inserm U1208, SBRI, Bron, France
[4]Université Lyon I, Faculté de Medecine Lyon Sud, Oullins, France

Study question: The objective of this to study is to establish a score based on Day 3 stage morphokinetic parameters obtained with an Embryoscop© **to predict** the chance to obtain a blastocyst.

Summary answer: With few morphokinetics parameters it is possible to obtain a simple score allowing predicting the chance to obtain blastocyst.

What is known already: Blastocyst transfer allows increasing the pregnancy rate. By this way an elective single embryo transfer (eSET) could be proceed in order to minimize the multiple pregnancies. By choosing the embryo at day 3 it could be possible to increase the turnover of embryos and the number of couple benefit the time lapse procedure.

Study design, size, duration: The score was established with a retrospective register cohort study included 564 embryos. The ART procedures were performed from May 2013 to April 2015. In order to avoid oocytes alteration, the exclusions female factors were anti-mullerienne hormon (AMH) less than 0.4 ng/mL; a BMI higher than 35; and less than 5 retrieved oocytes. For men, were excluded ART process with sperm obtained surgically or with frozen. sperm.

Participants/materials, setting, methods: 108 ART cycles were performed. All patients had extended culture to blastocyst using Embryoscop©. The first step was to select the more predictive parameters to predict the blastocyst obtaining. The second step was to establish the score with the constraint of the Embryoscop© software. The Chaid procedure was used to find a cut off value to each selected morphokinetiks parameters. The weight for each class was the coefficient obtained with a Multiple Composante Analysis.

Main results and the role of chance: Among twelve morphokinetics parameters, fours were selected: fading of pronuclei (PNf), t2, S2 and S3. The score range is from 0 to 18. When the score is below to 5, the chance to obtain a blastocyst is equal to 71.6% (78/109), this chance is equal to 83.3% (170/204) when the score is between 5 and 11, and equal to 94.0% (110/117) when the score is higher than 11 ($p < 0.001$). No relationship was found between this score and the female age. A relationship was found between the quality of the blastocyst and the score, the risk to obtain a blastocyst grade C is equal to 35.9% (28/78) when then the score is below to 5 and equal to 20.9% (23/110) when the score is greater than 11 ($p < 0.05$). A relationship was found between the score and the blastocyst stage chronology. When the score is below to 5, a blastocyst at day 5 was obtained in 69.7% (76/109) of cases and in 82.1% (96/117) when the score is higher than 11 ($p < 0.05$). As a eSET was performed for 56 cycles, no relationship has been established between score and pregnancy rate because the size was not sufficient.

Limitations, reasons for caution: A retrospective study was performed to establish the score. This score has to be validated with a prospective study. The study between the score and the pregnancy rate could be studied when eSET is performed.

Wider implications of the findings: With this score, the choice of the transferred embryo could be performed at day 3. A prospective study has to be performed to validate this result. This score should be included in a wide score which included male and female parameters in order to have a global ART procedure score.

Trial registration number: None.

P-197 clinical outcome of frozen embryo transfer versus fresh embryo transfer of 3129 cycles

J. liu[1], H. guoning[1]

[1]Chongqing Maternity and Children Health Care Hospital, institute of reproductive and genetic, Chongqing, China

Study question: Does freeze all embryos and subsequent frozen embryo transfer (FET) results in better outcomes compared with fresh transfer?

Summary answer: Freezing all embryos and differing transfer to a subsequent endometrial preparation cycle does not improve cycle outcome when compared to fresh embryo transfer.

What is known already: Several studies suggest that endometrial receptivity could be diminished during controlled ovarian stimulation (COS). Some authors have suggested the solution by freezing all embryo and transferring the embryo in a delayed cycle.

Study design, size, duration: It is a retrospective observational cohort study. We include 3129 cycles aged <35 undergoing their first or second IVF/ICSI cycle between January 1st 2013 and December 31st, 2013, in which day 3 embryo transfer was performed.

Participants/materials, setting, methods: The study was performed in the Chongqing reproductive and genetic institute, China. Included 3129 cycles of which 2397 (76.6%) were fresh embryo transfer and 732 (23.4%) were FET. The outcomes of interest were ongoing pregnancy rate, clinical pregnancy rate, implantation rate and take home baby rate.

Main results and the role of chance: No differences were observed between both groups in terms of mean ages and embryo transfer number. The raw analysis showed that clinical pregnancy rate (67.7 vs.68.4%, $p = 1.25$),implantation rate (51.0 vs.48.1%, $p = 3.73$), ongoing pregnancy (62.0 vs.59.6%, $p = 1.40$) and take home baby (59.9 vs. 58.2%, $p = 0.68$) rates for fresh vs. freeze all cycles respectively were similar.

Limitations, reasons for caution: The main limitation is that this is a retrospective study. Furthermore, the cycles number of frozen embryo transfer was small.

Wider implications of the findings: These findings suggest that freeze all embryo could get similar clinical outcomes if patients were not suitable for fresh embryo transfer. But these findings do not support freeze-all strategy in all patients, since the treatment cost and the time to pregnancy is shorter when fresh embryos are transferred.

Trial registration number: NA.

P-198 The correlation between the time interval ICSI performance and hCG administration

J. Dong[1], L. Cai[1], Q. Zeng[1], R.C. Chian[1]

[1]First Affiliated Hospital, Nanjing Medical University, Reproductive Medicine Center, Nanjing Jiangsu, China

Study question: To assess the correlation between the time interval of hCG administration and ICSI performance for clinical pregnancy outcome intracytoplasmic sperm injection outcome.

Summary answer: There was a strong correlation in the time of ICSI performance following hCG injection for the subsequent clinical pregnancy outcomes.

What is known already: It is well known that oocytes retain their ability to become fertilized much longer than their capacity to develop into viable embryos. Incubation of oocytes for 2–6 h prior to IVF improves fertilization and pregnancy rates. However, the optimal ICSI timing following egg retrieval is still unclear and the existing results are not fully conclusive.

Study design, size, duration: Data were collected from ICSI cycles with day-3 embryo transfers recorded in the Clinical Reproductive Medicine Management System (CCRM) database of our IVF center between January 2010 to August 2015.

Participants/materials, setting, methods: A total of 5,215 ICSI cycles in which oocyte retrieval was performed 36 or more than 36 h after hCG administration were analyzed. According to the length of time interval between ICSI performance and hCG administration, there were six groups, such as: 36–37 h (including 37 h), 37–38 h (including 38 h), 38–39 h (including 39 h), 39–40 h (including 40 h), 40–41 h (including 41 h), >41 h.
Main results and the role of chance: When ICSI was performed in 36–37 hours after hCG administration, the rate of MII oocytes was lower compared to other Groups ($P < 0.05$). The normal fertilization rate had a trend of increasing with time prolonging, and it was significantly lower when ICSI was performed between 36–39 h after hCG administration than performed 39 h or more ($P < 0.05$). The high-score embryo rate had a decreased trend with time prolonging, and it was significantly higher when ICSI was performed between 38–39 h after hCG administration than performed 41 h or more ($P < 0.05$). There was no differences of implantation rate, clinical pregnancy rate and ongoing clinical pregnancy rate among six groups.
Limitations, reasons for caution: The timing of ICSI after hCG administration affected in ICSI outcome, but how to balance the relationship between normal fertilization rate and clinical pregnancy rate needs to be confirmed.
Wider implications of the findings: The timing selection might be important not only for ICSI but also for other timed assisted reproduction techniques.
Trial registration number: –

P-199 IMSI (Intracytoplasmic Morphologically Selected-sperm Injection) versus conventional IVF (*In Vitro* Fertilization): a randomized prospective study about the management of the idiopathic infertility

M.A. Llabador-de Royer[1], A. Chargui[1], M.M. Hurtado-nedelec[2], A. Benammar[1], X. Ferraretto[1], C. Gauche-cazalis[3], S. Gricourt[3], S. Epelboin[3], C. Patrat[1]
[1]*Bichat-Claude Bernard Hospital AP-HP, Reproductive Biology Department, PARIS, France*
[2]*Bichat-Claude Bernard Hospital AP-HP, Hematology and Immunology Department, PARIS, France*
[3]*Bichat-Claude Bernard Hospital AP-HP, Reproductive Medicine Department, PARIS, France*

Study question: Comparison IMSI *versus* IVF in the management of unexplained infertility of the couple after at least 2 failures of IUI (IntraUterine Insemination) or 1 miscarriage.
Summary answer: Better results in terms of embryo quality and clinical pregnancy and live-birth rates were observed after IMSI.
What is known already: It has been widely reported in randomized studies that IMSI performed after implantation failure(s) after ICSI improved implantation, clinical pregnancy, miscarriage and live-birth rates (Bartoov et al., 2003; Berkovitz et al., 2007; Antinori et al., 2008; Gonzalez-Ortega et al., 2010; Klement et al., 2013), and also the embryo quality (Bartoov et al., 2003; Wilding et al., 2011). It seems also that IMSI is better than ICSI in terms of clinical pregnancy rate and live-birth rate in attempts with sperm high DNA (DeoxyriboNucleic Acid) fragmentation rate (Hammoud et al., 2013).
Study design, size, duration: Prospective cohort study at Bichat-Claude Bernard Hospital (AP-HP, Paris) including 35 couples with unexplained primary or secondary infertility and without pregnancy after at least 2 IUI or 1 miscarriage, between January 2010 and June 2015.
Participants/materials, setting, methods: All couples gave their informed consent. Only couples with normal semen parameters (OMS 2010) and no female anomalies were included. For each man 2 semen analyses, MSOME (Motile Sperm Organelle Morphology Examination), DNA fragmentation and DNA decondensation were performed. After the oocyte retrieval, the cohort (≥ 8 cumulus-oocyte complex) was shared equally between conventional IVF and IMSI. Embryo transfer was performed at day 2/3 or 5. Variables included embryo quality, implantation, clinical pregnancy and live-birth rates.
Main results and the role of chance: The MSOME performed in all patients was positive (proportion of type 0 and/or type 1 sperm > 8%) in 22 patients (62.9%). By comparing biological parameters, we observed higher embryo cleavage rate and embryo quality rate (top embryo defined with 4 cells at day 2 or 8 cells at day 3, with regular blastomers, < 10% fragments and without multinucleation) after IMSI than after IVF (respectively 36.3% *versus* 16.5%, $p = 0.014$; 12.7% *versus* 4.3%, $p = 0.046$). The number of blastocyst obtained trended to be higher in IMSI (16.7% *versus* 0.0%, $p = 0.081$). No difference was found for fertilization rate and embryo cleavage rate between day 2 and 3. Higher implantation rate was evidenced after IMSI (31.03% *versus* 13.63%, $p = 0.068$). No difference was found for clinical pregnancy rate per transfer. Live-birth rate per transfer was significantly higher after IMSI than after IVF (50.0% *versus* 0.0%, $p = 0.019$).
Limitations, reasons for caution: Small size of study: we need more patients to strengthen our first results. Long time of study-period to include patients.
Wider implications of the findings: Despite the small size of the study, it is suggested that IMSI could improve ART (Assisted Reproductive Technology) parameters in unexplained infertility and failure of IUI.
Trial registration number: Not applied.

P-200 Are smooth endoplasmic reticulum aggregates associated with detrimental outcome?

M. Carvalho[1], F. Leal[1], I. Cordeiro[1], S. Mota[1], A. Aguiar[1], J. Nunes[1], C. Rodrigues[1], A.P. Soares[1], S. Sousa[1], C. Calhaz-Jorge[1]
[1]*Reproductive Medicine Unit, Department of Obstetrics, Gynaecology and Reproductive Medicine, Hospital de Santa Maria, Lisbon, Portugal*

Study question: Does smooth endoplasmic reticulum (SER) aggregation negatively impact the overall outcome of ART cycles?
Summary answer: Our findings suggest no evidence that the presence of SER aggregates in the oocyte cytoplasm is associated with a compromised embryological, clinical or neonatal outcome.
What is known already: The presence of SER clusters is considered one of the most severe dysmorphisms, identifiable in metaphase II oocytes, caused by an unknown underlying mechanism. The transfer of embryos originated in these cells has been correlated with an increased risk of abnormal outcome. However, reports of smaller clusters, undetected under light microscopy, found exclusively in presumably SER-negative oocytes but siblings of SER-positive gametes, suggest a compromised cohort of oocytes and possibly an underestimated number of SER-positive transferred embryos. Still, the use of affected gametes and embryos is generally discouraged and should be carried out with caution until its implications are understood.
Study design, size, duration: Retrospective analysis of data regarding 724 ICSI cycles performed between January 2009 and December 2014. Women underwent controlled ovarian hyperstimulation using recombinant FSH or highly purified hMG in either an agonist or antagonist protocol and hCG was administered for the final maturation of the oocytes. Demographic and clinical characteristics of the female population, as well as laboratorial, clinical and neonatal parameters were analyzed.
Participants/materials, setting, methods: Cycles were assorted into two groups, according to the presence or absence of smooth endoplasmic reticulum aggregates in metaphase II oocytes of a population of women 40 years. Group I includes cycles without visible SER clusters and Group II comprises cycles with one or more oocytes with an identifiable SER aggregate. Embryos originated from affected oocytes were selected for transfer exclusively if no other embryos of superior or equivalent quality were available.
Main results and the role of chance: 2815 metaphase II oocytes were checked for the presence of SER aggregates and 128 were affected (4.5%). SER-negative oocytes were found in 642 ICSI cycles and 82 presented at least one cell with SER aggregates (11.3%). Maternal age did not correlate with the presence of SER clusters and the number of retrieved oocytes (8.2 vs. 8.6) and fertilisation rate (65.3% vs. 64.0%) was comparable in both groups. The formation of SER aggregates did not correlate with the stimulation regimen, duration of stimulation, total dose of gonadotrophins, clinical pregnancy rate per embryo transfer (44.9% vs. 39.5%) or miscarriage rate (19.2% vs. 15.6%). The analysis of obstetrical and neonatal data revealed no differences when comparing duration of gestation, birth weight and number of malformations per live birth (5/270 vs. 1/33) in SER-negative and positive cycles. 32 healthy babies were born from the SER-positive group, including 2 pairs of twins originated from a mixed transfer of one SER-positive and one SER-negative embryo.
Limitations, reasons for caution: The frequency, size and location of the cluster in the oocyte was not taken into consideration, and the existence of a threshold for the correlation of these characteristics and a negative outcome cannot be excluded. Also, preferential transfers of embryos originated in SER negative oocytes might be representative of bias.
Wider implications of the findings: Considering that smaller SER clusters may be undetected under light microscopy, the possibility of a higher number of

transfers with affected embryos must be considered. It is fundamental that laboratories record and publish detailed information concerning SER aggregates to better understand its origin and clarify the issues concerning clinical outcome.
Trial registration number: Not applicable.

P-201 Embryological results of couples undergoing ICSI-ET treatments with males currying the single nucleotide polymorphism rs175080 of the MLH3 gene

G. Anifandis[1], O. Markandona[1], K. Dafopoulos[1], C. Messini[1], A. Tsezou[2], P. Georgoulias[3], A. Daponte[1], I. Messinis[1]
[1]University of Thessaly, School of Health Sciences, Faculty of Medicine, Department of Obstetrics and Gynaecology, Larisa, Greece
[2]University of Thessaly, School of Health Sciences, Faculty of Medicine, Department of Molecular Genetics and Cytogenetics, Larisa, Greece
[3]University of Thessaly, School of Health Sciences, Faculty of Medicine, Department of Nuclear Medicine, Larisa, Greece

Study question: Are there any relationships between the MLH3 gene single nucleotide polymorphism rs175080 of males and the embryological results of couples undergoing ICSI-ET treatments?
Summary answer: The deteriorating effect of the mutant genotype AA on sperm characteristics does not seem to impact on embryo development after fertilization in vitro.
What is known already: The human MLH3 (hMLH3) gene, identified the year 2000, leads to the production of the MutL homolog protein. hMLH3 gene has been suggested to play a role in the DNA mismatch repair mechanism, while it has been also proposed to play a distinct role in the meiotic recombination mechanism. It may be also associated with abnormal spermatogenesis, since a negative impact of the MLH3 rs175080 polymorphism on sperm parameters has been recently found in men. This may affect male fertility, as it has been suggested from the presence of the MLH3 C2531T polymorphism in infertile men.
Study design, size, duration: Our study population comprised of 132 men of couples that were subjected to 132 consecutive ICSI-ET treatment cycles over a 3-year period (2010 to 2012) were included. The 132 men were divided into three groups according to their genotype: the wild type GG ($n = 28$), the heterozygotic type GA ($n = 72$) and the mutant type AA ($n = 32$), while 117 couples finally reached the stage of ET. Fertilization or cleavage failure occurred in 15 of them.
Participants/materials, setting, methods: Participants were men of infertile couples undergoing ICSI-ET treatment. Genomic DNA was extracted from peripheral blood samples from all men followed by conventional quantitative real time PCR for genotyping. Primary endpoint was evaluation of embryological results, while secondary endpoint was pregnancy outcome.
Main results and the role of chance: Significantly lower sperm concentration and progressive motility were observed in the AA group as compared to the other two groups (Concentration: 14.57 + 4.9 mil/ml in AA, 38.3 + 5.4 mil/ml in GA and 41.03 + 6.8 mil/ml in GG, $p < 0.05$, mean + SEM). However, significantly better embryological results (Mean Score of Embryo Quality – MSEQ) were found in the AA (8.12 + 0.5) and the GA group (7.36 + 0.4) as compared to the GG group (5.82 + 0.7), ($p < 0.05$). Clinical pregnancy rate was significantly higher in the AA genotype group (43.8%) and the GA group (30.6%) than in the GG group (14.3%), ($p < 0.05$). Live birth rate was not different.
Limitations, reasons for caution: This polymorphism was studied for the first time. Nevertheless, the number of cases may not allow us to draw solid conclusions. In addition, the possibility that the heterozygotic state of the embryo may be responsible for its competent development cannot be excluded.
Wider implications of the findings: The findings could help in a better understanding of the pathophysiology in human spermatogenesis. In clinical terms, they may provide the means for a better evaluation of the infertile men. Since these are preliminary data, a large prospective randomized trial is needed to study the impact on live birth rate.
Trial registration number: N/A.

P-202 Differences in embryo development after IVM and conventional ICSI assessed by time lapse imaging

S. Roesner[1], B. Toth[1], J. Dietrich[1], J. Weigert[1], M. Montag[1], T. Strowitzki[1]
[1]Universitäts-Frauenklinik, Gyn. Endokrinologie und Reproduktionsmed, Heidelberg, Germany

Study question: Is there a difference in the morphokinetics of embryos originating from in vitro matured oocytes as compared to mature oocytes assessed by time lapse Imaging?
Summary answer: Although growth dynamics of embryos after IVM differ from embryos after conventional ICSI, pregnancy rates and live birth rates are similar.
What is known already: In vitro maturation is an established technique in particular in patients with PCOS. However, data on the impact of IVM on embryo development and fetal outcome are rare. Time lapse imaging might be a suitable method to evaluate embryo development after IVM compared to embryos after conventional IVF/ICSI.
Study design, size, duration: Prospective case-control study. Between January 2012 and November 2014 $n = 30$ IVM cycles in $n = 23$ patients with PCOS (G1) were matched to 30 conventional ICSI patients without PCOS (G2) and $n = 19$ patients with PCOS (G3).
Participants/materials, setting, methods: IVM patients were matched according to age and number of oocytes with conventional ICSI patients with and without PCOS. Morphokinetic markers in embryo development like time until pronuclei visibility (tPNa) and fading of pronuclei (tPNf) as well as time to 2- cell (t2) and blastocyst-stage (tB) were analysed in all groups. In addition, cell-cycle lengths, clinical pregnancy and live birth rates were recorded.
Main results and the role of chance: The groups did not differ according to age, BMI and smoking habits. A significant difference was found in AMH levels which were higher in G1 and G3 compared with G2 ($p = 0.000$). In total, $n = 292$ embryos were analysed [$n = 105$ IVM (G1), $n = 115$ conventional ICSI without PCOS (G2) and $n = 72$ with PCOS (G3)]. Embryonal development in G1 was significantly accelerated with regard to tPNa ($p = 0.001$) compared to G2 but slowed down in reaching t6 ($p = 0.032$) and following stages compared to G3. When we focused on the development of only good quality embryos G1-embryos were faster in reaching the first stages compared with G2-embryos (e.g., tPNf, $p = 0.013$). Time till reaching tB was also longer in G1-embryos than in G3-embryos ($p = 0.003$). No significant differences were present with regard to pregnancy and live birth rates between the three groups.
Limitations, reasons for caution: The study population was small, therefore further studies are needed to confirm our results.
Wider implications of the findings: Time lapse imaging may be a useful tool to identify good quality embryos after IVM to enhance pregnancy rates and live birth rates.
Trial registration number: not applicable.

P-203 Euploid rate sensitivity to laboratory culture environment: a blind, prospective, randomised, sibling study

C. Hickman[1], D. Wells[2], D. Gwinnett[1], T. Wilkinson[1], S. Christiansen[1], O. Oliana[1], B. Abramov[1], A. Carby[1], S. Lavery[3]
[1]The Fertility Partnership, Boston Place Clinic, London, UK
[2]Reprogenetics UK, Oxford, UK
[3]The Fertility Partnership, IVF Hammersmith, London, UK

Study question: To determine whether culturing embryos in two different single step culture media affects the proportion of chromosomally normal embryos.
Summary answer: Following Pre-implantation Genetic Screening (PGS) at the blastocyst stage, change in culture environment was associated with a doubling of the proportion of euploid embryos.
What is known already: Comprehensive chromosomal screening at the blastocyst stage has been proposed as an embryo selection tool and is increasingly widely used for this purpose. Several publications confirm that modern PGS methods accurately distinguish aneuploid embryos from those that are chromosomally abnormal. Female age is the most potent factor influencing embryo aneuploidy rates. Some research has suggested that stimulation protocols might also have the potential to influence embryo ploidy, although this remains controversial. However, the effect of laboratory culture conditions on aneuploidy risk, if any, remains to be established.
Study design, size, duration: A prospective sibling study in a private IVF clinic comparing two single-step culture media with different composition and protein supplementation. Following insemination, 2620 mature oocytes from 363 patients were equally and randomly split between both treatments. Embryologists responsible for grading embryos and deciding on suitability for transfer, cryopreservation or biopsy were blinded to treatment. 333 embryos were

selected for transfer, and genetic information following biopsy was available for 295 blastocysts.

Participants/materials, setting, methods: Medium 1 (KSOM supplemented with complex protein) was compared with Medium 2 (Sage supplemented with Human Serum Albumin, HSA) with regards to traditional Key Performance Indicators (KPIs). Embryos were cultured to the day of transfer/biopsy/cryopreservation in the EmbryoscopeTM. Morphokinetic data were collected similarly to Ciray et al. (2015). Blastocyst biopsies were analysed using Next Generation Sequencing (NGS). Embryos were graded daily (ACE or Gardner grading schemes). Bimodal data were analysed using Chi-square test. Data presented as treatment 1 vs. 2.

Main results and the role of chance: Fertilisation (72% vs. 70%), 3 pronucleate rate (5% vs. 5%), cleavage (99% vs. 99%), blastulation (73% vs. 76%), selection for transfer per MII (12% vs. 13%) and implantation rate (patients under 38 years: 38% vs. 47%; patients under 35 years: 47% vs. 58%) did not significantly differ between treatment. Biochemical loss rate was greater 3.5 fold greater with treatment 1 (23.6% vs. 6.7%, $p < 0.025$), whilst the proportion of chromosomally normal embryos was almost two-fold greater with treatment 2 (16%, $N = 141$ vs. 29%, $N = 154$, $p < 0.025$). The following morphokinetic parameters did not differ between treatments: tPB2, tPNa, tPNf, t2, t3, t4, t5, t6, t7, t8, time of start of compaction (tc), tM, VP, ECC1, ECC2, ECC3, S3, dc, dB, cc2a, cc2b, cc3b, cc3c, tB-tSB, KIDScore median. The following parameters were affected by treatment (tSB: 103 vs. 101 hpi; tB: 110 vs. 108 hpi; teB: 118 vs. 116 hpi; thB: 119 vs. 114 hpi; s2: 1.8 vs. 2.6 h; cc3a: 12 vs. 11 h; tsB-tPNf: 79 vs. 77 h; $p < 0.001$), suggesting that embryos cultured in medium 2 reached the blastocyst stage faster.

Limitations, reasons for caution: The cause of observed differences in blastulation time, biochemical loss and euploidy rate between the two media may not necessarily be directly due to media composition, since, in order to culture both treatments in the same incubator, pH values differed (7.27 vs. 7.14 with incubators set to 7 ± 0.3% carbon dioxide).

Wider implications of the findings: Increased aneuploidy is known to cause reduced implantation, elevated pregnancy loss rate and delayed development, all characteristics of treatment 1. This study suggests that ploidy rates and morphokinetic parameters are sensitive to environmental change, and, therefore, should be monitored as part of the quality control programme in the IVF laboratory.

Trial registration number: Not Applicable.

P-204 Fractal analysis and related forms of complexity of embryo development. Is there a new tool for human embryo selection?

B. Doroftei[1,2], C. Buzea[3], G. Simionescu[2,4], S. Cumpata[5], M. Agop[6], R. Maftei[2,4]

[1]*University of Medicine and Pharmacy Iasi, Teaching Hospital Obgyn"Cuza Voda", Iasi, Romania*

[2]*Origyn Fertility Center, Human Reproduction, Iasi, Romania*

[3]*National Institute of Research and Development for Technical Physics – D. Mangeron, Physics, Iasi, Romania*

[4]*Teaching Hospital Obgyn "Cuza Voda", Obstetrics – Gynecology, Iasi, Romania*

[5]*Origyn Fertility Center, Embryology, Iasi, Romania*

[6]*Gheorghe Asachi Technical University of Iasi, Physics, Iasi, Romania*

Study question: Fractal analysis of the microscopic image of embryos, using different forms of complexity, can predict the embryos with highest implantation potential?

Summary answer: We reveal a decrease of fractal dimension from 72 h to 110 h morphokinetics for embryos associated to pregnancy and a constant value for those who not.

What is known already: Fractal analysis has found applications in the detection of coding regions in DNA and measurement of the space-filling properties of tumors, blood vessels and neurons. Fractal concepts have incorporated into models of biological processes, including epithelial cell growth, blood vessel growth and viral infections. There find various uses of fractal geometry in pathology: molecular biology, tumor development, vascular pathology. Three aspects of texture are considered by fractal geometry: fractal dimension, lacunarity and succolarity. The importance of morphokinetics fractal embryo analyse in IVF process reflected in literature is limited. Previous reported data show accuracy prediction of pregnancy between 67.4% and 74%.

Study design, size, duration: The reproductive outcome using fractal dimension analyse provided by EmbryoViewer – Fertilitech, Denmark was analyse by programs ImageJ (IJ) 1.28 and Adobe Photoshop CS4. Fractal dimension was calculated with FracLac for ImageJ using box counting method, and with Fractalyse using grid, mass-radius, correlation and pixel dilation methods. Lacunarity was calculated with FracLac for ImageJ program. Succolarity was calculated using a program we built, on MS VC 2010 Express Edition.

Participants/materials, setting, methods: 168 couples (mean age 36.2 years) was included in the study. Ovarian stimulation was performed with gonadotropins: 87% short antagonist protocol and 13% long agonist protocol, and we did ICSI for 72% and IVF for 28%. We obtained a number of 1092 embryos monitored by time-lapse imaging (EmbryoScope). We include patients where obtain between 3 and 20 oocyte. Transfer was done with single blastocyst to patients who have progesterone level at trigger day below 1.5 ng/dl.

Main results and the role of chance: Fractal dimension was measured by four different methods: mass-radius, box-counting, correlation and pixel dilation. Fractal dimension decrease from 72 to 110 h evolving time (the difference exceeding the standard error) for embryos led to pregnancy and remain constant (linear) for those who did not. For both measured samples, which headed for pregnancy or not, the fractal dimension at 72 h was 1.933 ± 0.002 and 1.932 ± 0.001 respectively, and at 110 h was 1.928 ± 0.002 and 1.930 ± 0.002, respectively. Fractal analysis of the microscopic image of embryo in a culture dish revealed a decrease of lacunarity from 72 to 110 h evolving time, for both embryos which after implant led to pregnancy or not and the lacunarity slope from 72 to 110 h evolving time, decreased only for embryos which led to pregnancy and was constant for those who did not. For both measured samples, which headed for pregnancy or not, the lacunarity at 72 h was 0.197 ± 0.002 and 0.190 ± 0.002 respectively, and at 110 h was 0.142 ± 0.002 and 0.147 ± 0.002, respectively. For both measured samples, which headed for pregnancy or not, the lacunarity slope at 72 h was 0.0725 ± 0.0004 and 0.0675 ± 0.0005 respectively, and at 110 h was 0.0674 ± 0.0003 and 0.0685 ± 0.0003, respectively.

Limitations, reasons for caution: More number of embryo images should use to improve accuracy of prediction model. In this study of embryo morphokinetics we use only images at 72 and 110 h.

Wider implications of the findings: Our results show that fractal model could predict pregnancy in 75%. Using a support vector machine related to supervised learning methods in conjunction with learning based intelligent software could improve pregnancy prediction. In a personalised approach proposed model predicts pregnancy correctly in 83% cases. More study are needed for validation.

Trial registration number: N/A.

P-205 Assessment of the impact of asynchronous syngamy by time-lapse imaging on early human embryo development, implantation and live birth rates

S. Sayed[1], S. Eikeland[1], C.M. Howles[2], A. Schwennicke[1], J.W. Hausken[1]

[1]*Klinikk Hausken, IVF, Haugesund, Norway*

[2]*Aries Consulting, Founder and Senior Vice President Scientific Affairs, Geneva, Switzerland*

Study question: Does an asynchronous syngamy (AS) phenotype serve as a primary selection biomarker in predicting embryo development and live birth in human embryos?

Summary answer: AS is associated with higher probability of developing nucleation and cleavage errors. Implantation and live births were not affected in the absence of accompanying errors.

What is known already: With the advent of time-lapse imaging as a non-invasive selection tool for human embryo assessment, the search for additional selection/de-selection parameters, which indicate viability and outcome, has increased. Syngamy as observed by breakdown of pronuclei indicates the union of two sets of chromosomes. This disappearance or pro-nuclei (PN) fading occurs a few hours prior to first cytokinesis. However, an AS phenotype as observed by asynchronicity in the disappearance of pronuclei, indicates a lag in the PN fading pattern and thereby may allow early identification of human embryos with lower development potential.

Study design, size, duration: To assess embryo development and top quality embryos (TQE) based on Istanbul Consensus workshop; 2011, 3141 zygotes cultured in the EmbryoScope ™ between April 2014 and December 2015 were retrospectively analyzed. These were incubated for a minimum of 42 hours to assess their impact on development of nucleation and cleavage errors.

To assess implantation and live birth potential, 2002 transferred embryos cultured between 2011 and 2014 with complete traceability (known implantation data-KID) were included.

Participants/materials, setting, methods: PN fading was annotated for normally fertilized zygotes irrespective of insemination method and user-defined annotation was adopted to denote synchronous and AS phenotypes. The simultaneous disappearance of both the PN was annotated as synchronous syngamy (SS) and was observed by smooth dispersion of nuclear envelopes. However in AS phenotypes, the PNs disappeared one at a time indicating a lag in the fading process. Subsequent annotations of embryo quality were according to the clinic's standard protocol.

Main results and the role of chance: Overall incidence of AS was 15.6% (491/3141) amongst all the embryos analyzed. Of the 3141 zygotes included for embryo development and TQE assessment, AS phenotypes exhibited a higher probability of developing nucleation errors and cleavage anomalies (trichotomous cleavages and rapid cleavages) than those that displayed SS phenotypes (44.8% vs. 38.9%) ($p = 0.02$). Of 3141 zygotes, 28% developed to be scored as TQE. AS zygote phenotypes had a lower probability of developing to TQE, than their synchronous counterparts (22.2% vs. 28.9%) ($p = 0.002$). 2002 transferred embryos cultured under similar culture conditions with regards to media used as well as reduced O2 concentrations, between 2011 and 2014 were included in the outcome study. When AS phenotypes were selected for transfer and their exact traceability known, there was no statistical significance between AS phenotypes and SS phenotypes with respect to KID, (18.4% vs. 20.7%) ($p = 0.45$). Live birth rates were also not statistically significant between AS and SS phenotypes (15.4% vs. 16.5%) ($p = 0.73$). The implantation potential and live birth rates of AS phenotypes with accompanying errors are however underrepresented in the cohort of embryos selected for fresh transfer.

Limitations, reasons for caution: Most of the embryos analyzed were cultured up to day 3 of embryo development and hence any impact on development to blastocyst stage is not known. Confounding factors such as maternal age, etiology of infertility or seminal parameters were not considered. There may be possible selection bias for transferred embryos.

Wider implications of the findings: Observation of AS as early as day 1 of embryo development could serve as novel primary selection biomarker. This along with de-selection biomarkers such as nucleation error and cleavage anomalies observed on subsequent days of development may facilitate identification of viable embryos. Optimizing selection criteria will augment IVF success rates.

Trial registration number: None.

P-206 Time-lapse analysis does not further predict implantation potential of euploid blastocysts in women with advanced maternal age (AMA)

S. Mumusoglu[1], I. Yarali[2], M. Polat[3], G. Bozdag[1], H. Yarali[1]
[1]*Hacettepe University, Faculty of Medicine, Reproductive Endocrinology and Infertility, Ankara, Turkey*
[2]*Anatolia IVF Center, Embryology, Ankara, Turkey*
[3]*Anatolia IVF Center, Reproductive Endocrinology and Infertility, Ankara, Turkey*

Study question: Do morphokinetic parameters differ among those euploid blastocysts that will result in clinical pregnancy or not following single embryo transfer in AMA patients?

Summary answer: Euploid blastocysts that result in clinical pregnancy or failed conception have comparable morphokinetic parameters.

What is known already: Several, if not all, studies have reported beneficial effect of various morphokinetic parameters to predict enhanced implantation potential of embryos. However, the ploidy status has not been evaluated in the majority of such studies. In one trial, among patients with ≥2 euploid blastocysts, selection according to the best time-lapse parameters was associated with significantly higher implantation rate when compared to selection with best morphology. However, whether enhanced implantation rate is due to embryo selection or undisturbed culture condition cannot be discriminated. There is no study looking for time-lapse parameters among implanted and not implanted euploid blastocysts cultured in undisturbed condition.

Study design, size, duration: Pre-implantation genetic testing by array-CGH (24-chromosomes) as a routine policy for women with AMA (≥36 yr old), regardless of ovarian reserve, was implemented in April 2015 and included in the current retrospective cohort study. Patients with single gene disorders and translocations were excluded. Of the initial 97 consecutive AMA patients starting controlled ovarian stimulation, 33 had single, euploid blastocyst transfers during April 2015–December 2015.

Participants/materials, setting, methods: All embryos were individually cultured in a time-lapse incubator (Embryoscope, Vitrolife, Denmark) from intracytoplasmic sperm injection up to the blastocyst development. Following trophoectoderm biopsy on Day 5/6, blastocysts were vitrified. A single senior embryologist annotated full morphokinetic information from second polar body appearance up to blastocyst hatching. Single euploid embryo transfer was performed in a frozen replacement cycle in all patients. Clinical pregnancy was defined as visualization of gestational sac with fetal heart beat.

Main results and the role of chance: Of the 33 single, euploid transfers, 23 (69.7%) resulted in clinical pregnancy. Twenty-five time-lapse parameters were analyzed. The mean values of the analyzed 25 parameters were comparable among those blastocysts that implanted or not. Among those 25 parameters, the mean t2 was 26.4 ± 2.5 and 28.4 ± 5.2, in the implanted and non-implanted euploid blastocyst groups, respectively ($p > 0.05$). The respective figures for t3 (38.0 ± 3.2 and 38.2 ± 9.1; $p > 0.05$), t5 (49.1 ± 8.3 and 48.2 ± 12.0; $p > 0.05$), t8 (55.2 ± 8.5 and 57.2 ± 8.2; $p > 0.05$), cc2 (11.1 ± 2.0 and 10.6 ± 3.8; $p > 0.05$), tM (91.9 ± 9.2 and 94.2 ± 14.3; $p > 0.05$), tSB (100.4 ± 7.8 and 105.2 ± 15.2; $p > 0.05$), tB (108.0 ± 7.6 and 114.0 ± 17.3; $p > 0.05$), tEB (112.4 ± 6.6 and 116.5 ± 12.2; $p > 0.05$) and tHB (114.0 ± 7.3 and 118.2 ± 2.8; $p > 0.05$).

Limitations, reasons for caution: Type-II error due to limited sample size cannot be excluded. Lack of automated system for annotation and lack of live birth data are limitations of the current study.

Wider implications of the findings: Time-lapse assessment does not discriminate whether euploid blastocysts will or will not implant following single embryo transfer in a frozen replacement cycle in AMA patients. Further studies are warranted to delineate the euploid blastocyst with the highest implantation potential in such patients.

Trial registration number: None.

P-207 Does morphokinetic assessment predict blastocyst ploidy status?

I. Yarali[1], S. Mumusoglu[2], M. Polat[3], G. Bozdag[2], H. Yarali[2]
[1]*Anatolia IVF Center, IVF Lab, Ankara, Turkey*
[2]*Hacettepe University, Faculty of Medicine, Reproductive Endocrinology and Infertility, Ankara, Turkey*
[3]*Anatolia IVF Center, Reproductive Endocrinology and Infertility, Ankara, Turkey*

Study question: Do time-lapse parameters differ among euploid and aneuploid blastocysts as assessed by trophoectoderm biopsy?

Summary answer: Time to blastulation (tB), time to expended blastocyst (tEB) and time to hatching blastocyst (tHB) are significantly delayed among aneuploid embryos compared to euploid embryos.

What is known already: There are seven studies evaluating the association of time-lapse parameters with ploidy status of embryos with contradicting conclusions. Of these seven studies, cleavage stage-biopsy was performed in three and trophoectoderm biopsy in the remaining four. There is also heterogeneity of the included patient population among the available seven studies. Therefore, there is still no consensus whether time-lapse assessment can be predictive for the ploidy status of embryos as assessed by trophoectoderm biopsy.

Study design, size, duration: In this retrospective cohort study, pre-implantation genetic testing by array-CGH (24-chromosomes) was employed in women with advanced maternal age (≥38 yr old), recurrent implantation failure and recurrent miscarriage. Patients with single gene disorders and translocations were also included. During April 2015 to January 2016, of the consecutive 180 patients enrolled, 107 (59.4%) developed at least 1 blastocyst to be biopsied and 67 (62.7%) had at least one euploid blastocyst. In total, 327 blastocysts were biopsied.

Participants/materials, setting, methods: All embryos were individually cultured in a time-lapse incubator (Embryoscope, Vitrolife, Denmark) from intracytoplasmic sperm injection up to the blastocyst development. Following trophoectoderm biopsy on Day 5/6, blastocysts were vitrified. A single senior embryologist annotated full morphokinetic information from pronuclear formation up to blastocyst hatching. In total, 25 time-lapse parameters were analyzed.

Main results and the role of chance: Of the analyzed 25 time-lapse parameters, 3 were found to be significantly different among euploid and aneuploid blastocysts. Median time to blastulation (tB) [102.58 (range 89.50–125.62)

vs. 108.46 (range 89.06–129.56), $p = 0.01$], time to expanded blastocyst (tEB) [108.31 (range 95.40–129.18) vs. 112.95 (range 102.40–140.06), $p < 0.001$] and time to hatching blastocyst (tHB) [111.65 (range 97.25–139.18) vs. 117.02 (range 103.15–142.32), $p < 0.001$] were significantly delayed among aneuploid embryos compared to euploid ones. In the univariate regression analysis, relative risk for aneuploidy increased with delaying tB (RR = 1.03 95.0% CI 1.00–1.05, $p = 0.027$), tEB (RR = 1.04 95.0% CI 1.01–1.07, $p = 0.003$), tHB (RR = 1.06 95.0% CI 1.02–1.10, $p = 0.002$). However, multivariate logistic regression was not performed due to high level of positive correlation between these 3 time-parameters. When receiver operating curve (ROC) analysis was performed to delineate the optimum cut-off point to predict euploidy, tHB had the best AUC (AUC = 0.77, CI 95%: 0.68–0.87). The optimum cut-off value for tHB was 113.88 (sensitivity 71.7%, specificity 75.7%, Positive predictive value 82.7% and Negative Predictive Value 62.2%).

Limitations, reasons for caution: Embryos from each patient were assumed to be independent observations in the current study, which carries the risk of overestimating potential correlations. However, embryos from one patient may elicit clustering, which means that a large part of the variation observed between embryos can be explained by differences by patients.

Wider implications of the findings: Median time to blastulation, time to expanded blastocyst and time to hatching blastocyst may have limited ability for prediction of aneuploidy.

Trial registration number: None.

P-208 Clinical validation of Eeva test when the embryos are cultured in embryoscope instead of standard incubator

M. De Las Heras[1], E. Martinez[1], J.I. Arambarri[2], M. Garcia[3], G. Barrenetxea[2]
[1]*Reproduccion Bilbao, IVF Laboratory, Bilbao, Spain*
[2]*Reproduccion Bilbao, Obstetrics and Gynecology, Bilbao, Spain*
[3]*Reproduccion Bilbao, Nursing, Bilbao, Spain*

Study question: To asses how the *Eeva* Test™ algorithm works when embryos are cultured in a benchtop incubator, such EmbryScope™, instead of a standard incubator.

Summary answer: The parameters used by the Eeva™ test to predict embryo viability are a useful tool when implemented as a model in the Embryoscope™.

What is known already: Time-lapse allows for monitoring embryo development, combining morphology with timing of cleavage embryos. In EmbryoScope™, the image acquisition unit is an integral part of the culture chamber, facilitating the monitoring of embryos while they remain inside a controlled, stable culture environment.

Eeva Test™ categorizes embryos on day 3 into "High" or "Low" likelihood of usable blastocyst formation groups using a dark-field, time-lapse imaging and cell-tracking software algorithms. It fits into a standard incubator and although embryos are maintained in a continuous and uninterrupted imaging process from D1 through D3, the conditions are not so stable as in a benchtop incubator.

Study design, size, duration: A retrospective observational cohort study was performed at a University associated private Assisted Reproduction Center between February and November 2015. A total of 103 embryos cultured in Embrysocope™ from 49 patients undergoing an IVF cycle were included in the study. PGD cycles were excluded. Eighteen double embryo transfer and 67 single embryo transfer were performed. Double embryo transfers were included in the study only when transferred embryos had the same Eeva score.

Participants/materials, setting, methods: All the embryos were cultured in the Embryoscope™ and scored as "High" or "Low" with the option "Compare and select" of the EmbryoViewer software using a model based on the Eeva™ Test. The model took into account the timings for P2 (the time between the first and second cytokinesis) and P3 (the time between the second and the third cytokinesis) that are the parameters used for developing Eeva prediction and cell-tracking software.

Main results and the role of chance: The mean number of transferred embryos was 1.21. Eighty out of the 103 embryos transferred were scored as high ($9.33 \geq P2 \geq 11.45$ h and $0 \geq P3 \geq 1.73$ h) whereas 23 were scored as low (P2, P3 or both, out of the Eeva High window). Overall implantation rate was 37.86%: 42.42% and 35.09% for those scored as high and low respectively ($t = 1.044$; $p = 0.298$). The clinical pregnancy rate in those high scored embryo transfers was 48.49% whilst a percentage of 35.09% was the achieved clinical pregnancy rate among the low scored embryo transfers (Pearson`s Chi square = 3.204; $p = 0.073$). Finally we found both clinically and statistically significant differences in ongoing pregnancy rates between high and low scored embryo transfers (42.42% and 21.05% respectively; Pearson`s Chi square = 8.612; $p = 0.003$). There were no significant differences in age between the patients that got pregnant and those who did not. Our embryo implantation and pregnancy rate data correlate to those published in the literature when the Eeva™ Test is used to score embryos in a standard incubator. Moreover, our data confirm a positive and significant association between the high scored embryo transfers and a higher ongoing pregnancy rates.

Limitations, reasons for caution: Limitation is due to the subjectivity when choosing the exact time of cell division in the Embryoscope. P2 and P3 are narrow windows that the Eeva software detects automatically and objectively, because of that, the embryologist should be consistent with himself and we the rest of embryologist in the lab.

Wider implications of the findings: The advantages of undisturbed embryo culture in a stable device such as the EmbryoScope™ time-lapse incubator in association with the use of the model of *Eeva* Test™ could represent an important improvement in IVF, reducing early pregnancy loss and increasing ongoing pregnancy and implantation rate.

Trial registration number: No clinical trial.

P-209 Effect of antioxidants addition on the redox sate in vitrified/warmed human oocytes: preliminary results

M.D.M. Nohales Corcoles[1], G. Sevillano[2], L. Alegre[2], A. Coello[2], D. Castelló[2], P. Campos[2], G. Di Emidio[3], C. Tatone[3], A. Cobo[2], R. Dumollard[4], M.J. De los Santos[2]
[1]*IVI-Valencia, Valencia, Spain*
[2]*IVI-Valencia, Embryology, Valencia, Spain*
[3]*University of L´Aquila, Department of Health, L´Aquila, Italy*
[4]*Centre National de la Recherche CNRS Sorbonne Universités, Laboratoire de Biologie du Développement, Paris, France*

Study question: Does the Crocin, a natural carotenoid antioxidant from saffron, decreases the oxidative stress in vitrified human oocytes?

Summary answer: Our data show that the intracellular oxidation state can be decreased by adding the antioxidant Crocin in the vitrification/warming media.

What is known already: It is well known that vitrification can cause subtle damage in oocytes. One of the most important aspects to consider is the alteration of the normal mitochondrial function that could be responsible of the increase of oxidative stress in the cryopreserved female gametes. Previous studies from our group demonstrated that oocyte vitrification produces an increase of the oxidative stress in young women (<27 years old) when compared with fresh oocytes. Ooplasmic redox state was evaluated in vivo by measuring FAD++/NAD(P)H autofluorescence ratio, which is a marker of the intracellular redox condition.

Study design, size, duration: Case control study including a total of 78 oocytes (control group = 34, treatment group = 44,) from young oocyte donors (average age 25.57 ± 4.45) recruited from December 2014 to October 2015. Oocytes were vitrified and warmed with the antioxidant Crocin and without antioxidant (control group).

Participants/materials, setting, methods: After signed informed consent, 25 patients undergoing controlled ovarian stimulation donated their discarded oocytes to research. Thirty four oocytes were vitrified and warmed without antioxidant (control group) and forty four oocytes were vitrified and warmed with 400 µg/mL of the Crocin (treatment group). Intracellular redox state was assessed by measuring NAD(P)H and FAD++ autofluorescence ratio by confocal microscopy. Statistical analysis was performed using Student's *t*-test for means comparison. *p*-values 0.05 were considered statistically significant.

Main results and the role of chance: We found that both oocyte groups, control and treatment, showed similar vitrification survival rates (88.09% vs. 85.45% respectively, *p*-value >0.05). Confocal microscopy revealed that the FAD++/NAD(P)H ratio was higher in conventional vitrified oocytes than in oocytes vitrified/warmed with the antioxidant (0.76 ± 0.23 vs. 0.60 ± 0.16; *p*-value < 0.05). This result shows a decrease in the oxidation state in donor oocytes when adding 400 µg/mL of the antioxidant Crocin in the vitrification/warming media.

Limitations, reasons for caution: Additional studies with a larger number of oocytes are required to confirm these preliminary results.

Wider implications of the findings: Our results suggest the oxidative stress of human oocytes is decreased following the addition of the antioxidant Crocin in the vitrification/warming media, which eventually may improve the embryo

development. Our findings emphasize the relevance of continuing research with antioxidant molecules, in order to obtain better outcomes after oocyte vitrification procedures.
Trial registration number: NA.

P-210 High gonadotropin dosage does not affect euploidy and pregnancy rates in PGT cycles

O. Barash[1], S. Willman[2], K. Ivani[1], L. Weckstein[2], M. Hinckley[2]
[1]*Reproductive Science Center of the San Francisco Bay Area, IVF Lab, San Ramon, CA, USA*
[2]*Reproductive Science Center of the San Francisco Bay Area, MD, San Ramon, CA, USA*

Study question: Does high gonadotropin dosage affect euploidy and pregnancy rates in PGT cycles? The purpose of this study was to compare euploidy and pregnancy rates after administration of different dosages of gonadotropins in PGT cycles.
Summary answer: High gonadotropin dosage does NOT affect euploidy and pregnancy rates in PGT cycles.
What is known already: The proportion of euploid embryos in PGT (Preimplantation genetic testing) cycles decreases significantly with advancing maternal age. Recruitment of an adequate number of follicles is crucial in PGT cycles and it can be regulated by administration of proper gonadotropin doses.
Study design, size, duration: 406 cycles of IVF treatment with PGT between January 2013 and November 2015 were included in the study (average number of embryos for ET – 1.17). In 132 IVF cycles (109 patients, average age – 35.37 ± 2.21) less than 3000 IU were administered, in 196 IVF cycles (153 patients, average age – 37.79 ± 3.01) from 3000 to 5000 IU were administered and in 78 IVF cycles (59 patients, average age – 39.67 ± 4.19) over 5000 IU were administered.
Participants/materials, setting, methods: A retrospective study of SNP PGT outcome data was conducted to identify differences in euploidy and clinical pregnancy rates. Patients were divided into three gonadotropin dosage groups (<3000 IU, 3000–5000 IU, >5000 IU per IVF cycle) and in four age groups (<35, 35–37, 38–40, ≥41 year old).
Main results and the role of chance: Euploidy rates in the young patient group (<35 year old) were similar regardless of gonadotropin dosage used during controlled ovarian stimulation: 59.66% in the group of patients with low gonadotropin dose (<3000 IU), 62.79% in the group of patients with medium dose (3000–5000 IU), and 66.67% with high gonadotropin dose (>5000 IU). The difference in euploidy rates between the three gonadotropin dosage groups was not statistically significant: $p = 0.5$, $\chi^2 = 0.454$. In the group of patients 35–37 years old euploidy rates ranged from 53.1% to 60.01% ($p = 0.253$, $\chi^2 = 1.31$), in the group of patients 38–40 year old euploidy rates ranged from 43.28% to 51.11% ($p = 0.283$, $\chi^2 = 1.153$) and in the group of patients over 40 year old euploidy rates ranged from 28.57% to 32.26% ($p = 0.623$, $\chi^2 = 0.238$). Ongoing pregnancy rates were statistically not different within all age groups (ranging from 55.22% to 60.79%) ($p = 0.422$, $\chi^2 = 0.645$).
Limitations, reasons for caution: Retrospective study and heterogeneity of patients included.
Wider implications of the findings: Analysis of the data proved that euploidy and ongoing pregnancy rates are not affected by high gonadotropin dosage in PGT cycles. To maximize efficiency and cost-effectiveness in PGT cycles the number of follicles recruited in each cycle should be limited only by medical safety concerns and patient well-being.
Trial registration number: None.

P-211 Inter-observer agreement between embryologists during selection of a single blastocyst for transfer: a multicenter study

S. Kilani[1], C. Venetis[2], S. Cooke[1], W. Ledger[2], A. Storr[1]
[1]*IVFAustralia, Embryology, Sydney, NSW, Australia*
[2]*University of New South Wales, School of Women and Children's Health, Sydney, NSW, Australia*

Study question: What is the inter-observer variability between embryologists when selecting a blastocyst for transfer on day 5?
Summary answer: A good level of agreement was found between embryologists in all assessments evaluated.
What is known already: One of the major factors for pregnancy achievement after IVF is embryo quality. The process of determining embryo quality, though, is highly subjective because it involves the interpretation and application of certain morphological criteria by individual embryologists. Some variation in embryo scoring is therefore expected among different assessors and may compromise the accuracy of morphology-based embryo selection. Previous research on the morphological assessment of early-stage embryos has shown varying levels of inter-observer agreement. However, single blastocyst transfer is now becoming increasingly popular and there is no published data that assesses inter-observer agreement when selecting an embryo for day 5 transfer.
Study design, size, duration: This was a prospective study performed using ten embryologists working at five different clinics within IVFAustralia in New South Wales between July 2013 and November 2015. These embryologists were selected based on their yearly QAP (Quality Assurance Program) results for blastocyst grading and were asked to choose an embryo for transfer in 100 cases using 2D images obtained from an EmbryoViewer.
Participants/materials, setting, methods: Cases with ≥2 Day 5 embryos were included in this study. A questionnaire was developed with a web survey designer. For each case, day 5 images (one for every embryo) were shown and embryologists were asked to make a decision for transfer for each case. Subsequently, day 3 and day 5 images of the same embryos were shown and embryologists' were asked to decide again. Inter-observer agreement was assessed using the kappa coefficient.
Main results and the role of chance: Inter-observer agreement among embryologists when selecting an embryo for transfer on day 5 was good (kappa = 0.734, 95% CI 0.665–0.791). This agreement was similar in the subgroup analyses performed according to professional experience (≤ 10 years vs. >10 years: kappa = 0.745, 95% CI 0.660–0.811 vs. 0.735, 95% CI 0.677–0.806), research experience (no vs. any research experience: kappa = 0.716, 95% CI 0.629–0.776 vs. 0.748, 95% CI 0.696–0.814) and exposure to embryo grading (≤ 2 days vs. ≥3 days per week: kappa = 0.743, 95% CI 0.677–0.819 vs. 0.736, 95% CI 0.676–0.794). Similarly, the agreement between embryologists was good when there was more than one top quality embryo (kappa = 0.745, 95% CI 0.667–0.871) or when there were only poor quality embryos available for transfer (kappa 0.718, 95% CI 0.648–0.775).

The agreement between embryologists, when day 3 images were added, was still good, but slightly decreased (kappa = 0.676, 95% CI 0.617–0.724), which was also seen throughout in every subgroup analyses. This was also observed when there was more than one top quality embryo (kappa = 0.674, 95% CI 0.574–0.802) or when there were only poor quality embryos available for transfer (kappa = 0.637, 95% CI 0.420–0.841).
Limitations, reasons for caution: All embryologists had already fulfilled their training and were working under one organisation with similar policies. The inter-observer agreement might not be as high between embryologists with different levels of training or between embryologists working in clinics with different policies.
Wider implications of the findings: Although the agreement between embryologists was deemed good for most of the outcomes of this study, it could certainly be further improved leading potentially to more consistent pregnancy rates. Future studies need to be directed towards methods or technologies that can help achieve this.
Trial registration number: N/A.

P-212 Elective vs. non-elective fresh Single Blastocyst Transfer (SBT) in women aged 35–40 years

J. Hasson[1], S. Behbehani[1], T. Shavit[1], S. Tannus[1], J. Chung[1], W.Y. Son[1], W. Buckett[1]
[1]*McGill University Health Center, Reproductive Center, Montreal, QC, Canada*

Study question: Does the availability of blastocysts for vitrification correlate with higher pregnancy rate compared to cycles without vitrified blastocysts in fresh single blastocyst transfer (SBT) in women aged 35–40.
Summary answer: In women aged 35–40 years, fresh elective SBT (eSBT) achieves higher pregnancy rate compared to fresh SBT cycles without supernumerary vitrified blastocysts (obligatory SBT)
What is known already: Availability of supernumerary embryos for cryopreservation is known to be associated with higher implantation rates in cleavage-stage embryo transfers. It has also been shown that in young, good

prognosis patients, eSBT correlates with better implantation rate compared to obligatory SBT. Data on eSBT in women aged 35 years and over are scarce. As this group of patients is more prone to adverse perinatal outcome in case of multiple pregnancy, finding prognostic markers for clinical pregnancy which can promote the practice of single embryo transfer are of paramount importance.

Study design, size, duration: A retrospective cohort study performed at a single academic reproductive center between January 2012 and June 2015. All cycles with a fresh autologous SBT of good quality embryos (defined as Gardner's grade ≥3bb) were included in the analysis. Exclusion criteria were cycles with SBT of fair and poor quality blastocysts, multiple embryos transferred, cycles using donor oocytes, frozen-thaw embryo transfers and cleavage-stage embryo transfers.

Participants/materials, setting, methods: There were 692 fresh, autologous, SBT cycles of good quality blastocysts in women aged 35–40 years available for analysis. All embryos were cultured to the blastocyst stage and transferred on day 5. According to provincial guidelines single embryo transfer is mandatory in this age group, so excess blastocysts of adequate quality were vitrified on day 5 or 6. Comparison between study groups was performed by *t*-test and Chi-square tests where applicable.

Main results and the role of chance: In 555 fresh SBT cycles, supernumerary blastocysts were available for vitrification (80.2%). In these cycles elective SBT was performed and the rest of the blastocysts were vitrified. An average of 2.8 ± 1.8 supernumerary blastocysts were vitrified. In 137 fresh SBT cycles no blastocysts were available for vitrification (obligatory SBT). Mean age of patients was similar in both groups (36.7 ± 1.3 vs. 36.8 ± 1.3 years, $p = 0.51$). Number of MII oocytes was significantly higher in the elective SBT group compared to the obligatory SBT group (9.6 ± 4.6 vs. 6.97 ± 4.4, $p < 0.01$) although fertilization rates were similar (81.3% in the eSBT vs. 78% in the obligatory SBT, $p = 0.38$). Clinical pregnancy rate per transfer (defined as intra-uterine fetal heart rate by vaginal ultrasound at 6 weeks) was significantly higher in the eSBT group compared to the obligatory SBT group (46.1% vs. 35%, $p = 0.01$).

Limitations, reasons for caution: Fair to poor quality blastocysts were excluded from the study in order to control for transferred embryo quality and avoiding a bias against the obligatory SBT group. This may suggest the results may not apply to poor prognosis patients. Also, the retrospective nature of the study limits conclusions.

Wider implications of the findings: Similar to younger patients, eSBT achieves higher pregnancy rates in women aged 35–40 years. This may imply that supernumerary blastocysts may serve as positive prognostic markers and promote SBT in this age group. This practice may reduce multiple pregnancy risk in these patients who are candidates for multiple embryo transfer.

Trial registration number: none.

P-213 The availability of time-lapse (TL) analysis proves the relationship between morphokinetics and outcomes in IVM with PCOS

H.J. Yoon[1], H.J. Kim[1], Y.J. Lee[1], S.H. Yoon[1], Y.K. Shin[1], W.D. Lee[1], J.H. Lim[1]
[1]*Maria Fertility Hospital, Fertility Laboratory, Seoul, South Korea*

Study question: Is it effective using kinetic information based morphokinetic evaluation for embryo selection in IVM with polycystic ovaries syndrome (PCOS)?

Summary answer: With the exclusion of abnormal events in development simultaneously, kinetic information could offer new additional technique in embryo selection for transfer in IVM with PCOS.

What is known already: TL analysis by morphokinetic monitoring of embryonic development is safe and reliable embryo selection method. Lots of studies suggest that selection of embryos with detailed observation using TL system could improve pregnancy rates in IVF. But, there are few studies examining whether the possibility of benefit from TL in IVM and the effect on clinical outcomes of IVM is still under debate.

Study design, size, duration: This retrospective study was conducted from August 2013 to August 2015. It included 148 infertile patients. Embryos were incubated in TL incubator (EmbryoScope™) and morphokinetics of 820 embryos from oocytes matured in vivo or in vitro was analyzed.

Participants/materials, setting, methods: The average age was 32.0 ± 1.6 and 32.7 ± 3.0 and the total number of embryos after ICSI was 412 and 408 for in IVF and IVM, respectively. We compared clinical outcomes and timepoints of each morphokinetic events and abnormal events between IVF and IVM.

Main results and the role of chance: There were no significant differences in the age and the number of retrieved oocytes between two groups. Although fertilization and good quality embryo rates were lower in IVM (54.0% vs. 67.5% and 18.4% vs. 52.2%, $p < 0.0001$, respectively), implantation rate (22.5% vs. 28.9%) was not differ.

All the morphokinetic parameters were analyzed. Compared to IVF embryos, extrusion of second polar body was slower (3.7 h vs. 3.1 h, $p = 0.024$) and existence of pronuclear was shorter (14.0 h vs. 14.3 h, $p = 0.025$) in IVM. No significant differences were observed between the time-point of pronuclear fading and t5.

In IVM embryos, the rates of direct cleavage (<5 h) and the incidence of multi nucleated blastomere and embryo arrest were higher significantly (32.6% vs. 22.8%, $p = 0.002$, 46.3% vs. 34.9%, $p < 0.001$, 8.8% vs. 4.4%, $p = 0.01$, respectively).

Limitations, reasons for caution: This retrospective study may not represent all embryos because this includes small number of oocytes. Small data size is a limiting factor to make reliable statistical analysis and sample size needs to be enlarged.

Wider implications of the findings: Embryo selection for transfer by morphokinetic analysis and detection of abnormal development may provide an opportunity for improving the success rate in IVM cycle. In addition our study could confirm previously studies about embryos generated from IVM have more increased rate of abnormal development by TL system.

Trial registration number: NA.

P-214 Predictive model to determine the optimal number of fresh versus vitrified oocytes to obtain similar implantation and live birth rates in a donor oocyte program

M. Calonge[1], D. Morbeck[2], F. Gonzalez-Valdez[3], J. Remohi[4], A. Pellicer[4], M. Meseguer[5], C. Troncoso[6]
[1]*IVI Santiago de Chile, IVF Laboratory, Santiago RM, Chile*
[2]*Mayo Clinic, IVF Laboratory, Rochester, NY, USA*
[3]*Pontificia Universidad Catolica de Chile, Engineering, Santiago, Chile*
[4]*IVI Valencia, Gynecology, Valencia, Spain*
[5]*IVI Valencia, IVF Laboratory, Valencia, Spain*
[6]*IVI Santiago de Chile, Gynecology, Santiago RM, Chile*

Study question: Which donor and recipient factors are relevant to predict implantation and live birth rate in an egg donor program with fresh versus vitrified oocytes?

Summary answer: The predictive model included seven factors: gamete source (fresh vs. frozen/vitrified), sperm concentration, donor´s fertility, donor's estradiol (E2) at trigger, donor and recipient body mass index (BMI).

What is known already: Currently there are predictive models that analyze clinical and embryo parameters to predict clinical outcomes after IVF, e.g., risk of multiple pregnancies. However, there are no reports of models to determine the optimal number of oocytes needed for egg donation with fresh and vitrified oocytes. Survival rates in oocytes vitrified are not 100%. Addition, vitrified oocytes yield blastocyst formation that are less than cycles using fresh donor oocytes. Thus, the number of vitrified oocytes needed in an oocyte donation cycle is likely higher than a fresh donor cycle.

Study design, size, duration: We performed a retrospective observational study with oocyte recipients presenting for treatment at IVI Santiago de Chile during the years 2012–2014. The study includes 645 cycles of oocyte donation, 462 fresh and 183 vitrified oocyte cycles from which a total number of 9583 oocytes were included.

Participants/materials, setting, methods: Econometric modeling was applied to build a model capable of providing an estimate for the appropriate number of fresh or vitrified oocytes needed in a recipient cycle. The dependent variables studied were all discrete. When possible, we used multinomial logit models and otherwise we used generalized lineal models representing a binomial process with a logit link function. Variable significance was analyzed through a *t*-test.

Main results and the role of chance: With the data analysis, seven parameters were determined important for development of the algorithm: donor and recipient BMI, gamete origin (fresh or frozen/vitrified), sperm concentration, E2 at trigger and fertility of donor (previous pregnancy from donation). According to our data, more vitrified oocytes are needed to achieve similar rates of implantation and live birth compared to fresh oocytes. Using the algorithm we may calculate the additional number needed on vitrified oocytes cycles. That number

it depends on the clinical characteristics and parameters of the cycle of donors and patients considered in the model.

The impact of oocyte vitrification is illustrated by the following example: while keeping other parameters constant, four fresh versus five vitrified oocytes are required to obtain an implantation rate of 61.45% with a confidence of 70%. This algorithm allows a user to enter data for the likelihood of implantation and live birth based on number of oocytes.

Limitations, reasons for caution: Not all factors that impact success of IVF were included. In addition, the correlations identified may vary in different populations or countries.

Wider implications of the findings: A predictive model capable of estimating the probability of implantation and live birth would be extremely helpful to improve outcomes and assist clinicians deciding how many oocytes are needed in a oocyte donation programs, according to the odds to get an blastocyst and live birth for each mature oocyte.

Trial registration number: not trial study.

P-215 Antinuclear antibody of discrete speckled immunofluorescence staining pattern is associated with polypronuclear fertilization

A. Ohtani[1], O. Aya[1], M. Hiroshi[1], M. Satoshi[1], F. Aisaku[1], M. Yoshiharu[2]
[1]*IVF Osaka Clinic, Department of Obstetrics and Gynecology, Osaka, Japan*
[2]*HORAC Grand Front Osaka Clinic, Department of Obstetrics and Gynecology, Osaka, Japan*

Study question: The present study was conducted to investigate the influence of immunofluorescence staining pattern and titer of antinuclear antibody (ANA) on maturation and fertilization of human oocyte.

Summary answer: Maturation rates were similar between ANA-negative and positive irrespective of immunofluorescence staining pattern. Polypronuclear fertilization increased significantly in ANA of discrete speckled pattern.

What is known already: ANA is an autoantibody against nuclear components of eukaryotic cells such as DNA, centromere and histone. Immunofluorescence staining pattern of ANA is commonly applied to identify corresponding antigens. Discrete speckled staining pattern indicates that its corresponding antigen is centromere. The relationship of anti-centromere antibody (ACA) with abnormal oocytes maturation, compromised embryo developmental competence and poor prognosis post pregnancy in human IVF has been reported.

Study design, size, duration: Total of 1646 cycles of IVF (355 cases with ANA determined) from January 2012 to December 2013 were retrospectively investigated.

Participants/materials, setting, methods: Patients with positive ANA were divided into 4 groups according to their patterns (A: homogeneous, B: speckled, C: nucleolar, D: discrete speckled) and ANA negative patients were used as control. The rates of oocytes maturation and polypronuclear fertilization either by IVF or ICSI were compared among its patterns and control. Patients with discrete speckled pattern were further divided into 5 groups based on their titer. Correlation between high polypronuclear fertilization rate (>25%) and antibody titer was also analyzed.

Main results and the role of chance: The rates of maturation, polypronuclear fertilization in IVF and polypronuclear fertilization in ICSI of control were 75.9% (3772/4870), 9.0% (72/798) and 4.6% (137/2974), respectively. Rates of group A were 80.3% (965/1201), 11.7% (33/282) and 4.0% (27/683), respectively. Rates of group B were 82.6% (2037/2465), 11.7% (58/495) and 4.3% (66/1542), respectively. Rates of group C were 94.6% (210/232), 7.4% (8/108) and 4.9% (5/102), respectively. Rates of group D were 84.2% (85/101), 50.0% (27/54) and 51.6% (16/31), respectively. Maturation rates were similar between ANA-negative and positive regardless of staining pattern. The ANA-positive patients with discrete speckled pattern showed significantly higher incidence of polypronuclear fertilization both in IVF and ICSI than control ($p < 0.01$; x2-test). Percentages of the patients with high polypronuclear fertilization rates in the group of antibody titer 1:80, 1:160, 1:320, 1:640 and 1:1280 were 100.0% (2/2), 100.0% (3/3), 0.0% (0/1), 0.0% (0/1) and 90.9% (10/11), respectively. No correlation was confirmed between high polypronuclear fertilization rate and intensity of antibody titer.

Limitations, reasons for caution: Discrete speckled staining pattern indicates its corresponding antigen is centromere. However, evaluation of staining pattern is not well established.

Wider implications of the findings: Polypronuclear fertilization increased in the patients with discrete speckled pattern of ANA. This result suggests that ACA might cause polypronuclear fertilization and further research is required to clarify the mechanism. Embryos for transfer should be carefully selected for the patients with positive ANA, especially with discrete speckled staining pattern.

Trial registration number: None.

P-216 Fatty Acid-Binding Protein 4 in endometrial epithelium is involved in embryonic implantation

M. Dong[1], W. Peng[2]
[1]*Women's Hospital, Zhejiang University School of Medicine, Reproductive Genetics, Hangzhou, China*
[2]*Women's Hospital, Zhejiang University School of Medicine, Central Lab, Hangzhou, China*

Study question: What are the roles of fatty acid-binding protein 4 of endometrial epithelial cell in the establishment and maintenance of pregnancy and early pregnancy loss?

Summary answer: FABP4 regulates embryo implantation via altering uterine receptivity, and decreased expression of FABP4 in endometrium may be linked with pregnancy loss.

What is known already: The establishment and maintenance of pregnancy occurs through the interaction between maternal uterine endometrium and embryo (mainly the trophoblasts). In the research before, we found FABP4 is an important regulator for the proliferation, migration and invasion of endometrial epithelial cells.

Study design, size, duration: Cell experiment, animal experiment and molecular biology experiment.

Participants/materials, setting, methods: The expression of FABP4 and uterine receptive factor was determined by western blotting. FABP4 siRNA and FABP4 inhibitor were used to silence FABP4 and the function of FABP4 respectively. ICR mice and trophoblast spheroids mimicking embryos were set up to evaluate the effect of FABP4 silence or inhibition on embryo implantation in vivo.

Main results and the role of chance: The expression of FABP4 mRNA was significantly decreased in the deciduas of women with early pregnancy loss compared with that of women with normal pregnancy ($p = 0.04$). FABP4 siRNA significantly reduced the number of embryos implanted ($p < 0.001$) and FABP4 expression in ICR mice. FABP4 inhibition also significantly decreased the number of embryos implanted ($p < 0.001$). Either silence or inhibition of FABP4 in endometrial epithelial cell abolished the expression of uterine receptive factors induced by the combination of estrogen and progesterone, and reduced the number of trophoblast spheroids adhered onto endometrial cell.

Limitations, reasons for caution: The limitations of this study include relative small size of women with pregnancy loss was recruited and embryonic aneuploidy was not excluded in women with EPL.

Wider implications of the findings: FABP4 regulates embryo implantation via altering uterine receptivity, and decreased expression of FABP4 in endometrium may be linked with pregnancy loss, indicating FABP4 has biological role in the establishment and maintenance of pregnancy and subsequently is involved in pathogenesis of pregnancy loss.

Trial registration number: Natural Scientific Foundation of China (81170572).

P-217 Asymmetric division in the first cleavage of human fertilized oocytes observed by high-resolution time-lapse cinematography and its negative impacts on further developmental potential

K. Iwata[1], M. Sugishima[1], K. Yumoto[1], M. Nakaoka[1], M. Tsuneto[1], Y. Iba[1], Y. Mio[1]
[1]*Mio Fertility Clinic, Reproductive Centre, Yonago, Japan*

Study question: Does asymmetric division occurring in the first cleavage of human fertilized oocytes adversely affect their further developmental potential?

Summary answer: Asymmetric division in the first cleavage leads to poor developmental potential, suggesting the first cleavage pattern might be a useful parameter predicting further embryonic development.

What is known already: Predicting embryo viability reliably and safely is crucial to the successful application of assisted reproductive technology (ART). To this end, we have found various novel phenomena correlated with embryo quality and have clarified the velocity of human embryonic development by high-resolution time-lapse cinematography (hR-TLC). However, there is still

no reliable benchmark to assess future embryo quality. According to the Istanbul consensus (2011), both the time course and morphology of human embryonic development are important for assessing subsequent embryo quality; however, this study did not consider the impact of morphokinesis events such as cell-volume asymmetry between blastomeres.
Study design, size, duration: Since 2003, we have used donated oocytes ($n = 230$) for hR-TLC observation. Of those, 157 were fertilized normally and 86 developed to the 2-cell stage. We calculated the maximal cross-sectional area at the 2-cell stage just after the first division, and thus categorized the 2-cell embryos into two groups (symmetric; area difference ≤ 800 μm^2, asymmetric; area difference >800 μm^2). We then compared further embryonic development using hR-TLC between symmetric and asymmetric embryos.
Participants/materials, setting, methods: Of 157 fertilized oocytes, 63 were fertilized by conventional in vitro fertilization (c-IVF) and 94 by intracytoplasmic sperm injection (ICSI). The hR-TLC observation was commenced 1 hour post-insemination by c-IVF, and immediately after ICSI procedures. Images were acquired for 50 ms (exposure time) at 2-minute intervals for approximately 40 h. Once the hR-TLC imaging was complete, good-quality embryos developed to the 4-cell stage were subsequently cryopreserved for future clinical use.
Main results and the role of chance: Of the 157 fertilized oocytes, 86 (IVF; $n = 34$, ICSI; $n = 52$) cleaved into two cells at the first cleavage, and of those 2-cell embryos, 69.8% (IVF; $n = 25$, ICSI; $n = 35$) cleaved symmetrically, and the remaining (IVF; $n = 9$, ICSI; $n = 17$) cleaved asymmetrically. The rate of multinucleated blastomeres in the asymmetric group (50.0%; 13/26) was significantly higher than that in the symmetric group (23.3%; 14/60; $p < 0.05$). The rate of good quality embryos after the second cleavage was also significantly higher in the symmetric group at 63.3% (38/60) than in the asymmetric group at 15.4% (4/26); $p < 0.01$). Embryos cleaved in an asymmetric manner at the first cleavage thus showed a higher rate of multi-nucleation and poor development, while there was no significant difference in the patient profiles or time course of each embryonic morphological event between the symmetric and asymmetric groups.
Limitations, reasons for caution: Our findings suggested that asymmetric division might be involved in aberrant spindle position or cytoskeletal abnormalities during human embryonic development. However, further studies including molecular biological analyses are needed to clarify the mechanisms leading to this phenomenon.
Wider implications of the findings: We showed that embryonic development was significantly better in 2-cell embryos with a smaller cross-sectional area difference between cells (≤ 800 μm^2) than in those with >800 μm^2 difference between cells, suggesting cytoskeletal dysfunction. This parameter would be useful for detailed assessments of human embryos by the Istanbul Consensus.
Trial registration number: None.

P-218 Cytokine GM-CSF in day 3 spent culture drops decides the fate of embryonic development to blastocyst stage & quality of blastocyst

N. Chimote[1], N. Nath[2], N. Chimote[3], A. Chimote[4], B. Chimote[1]
[1]Vaunshdhara Clinic & Assisted Conception Centre, Embryology & Reproductive Endocrinology, Nagpur, India
[2]Vaunshdhara Clinic & Assisted Conception Centre, Biochemistry, Nagpur, India
[3]Vaunshdhara Clinic & Assisted Conception Centre, Embryology, Nagpur, India
[4]Vaunshdhara Clinic & Assisted Conception Centre, Gynecology, Nagpur, India

Study question: Quantitative estimation of GM-CSF in day 3 spent culture media drops to investigate whether early human embryos cultured in-vitro synthesize their own GM-CSF and utilize it for their development into blastocyst.
Summary answer: Utilization of GM-CSF produced endogenously by early human embryo influences blastocyst formation rate and quality in terms of ICM development and number of TE cells.
What is known already: GM–CSF expressed in the female reproductive tract, is produced by epithelial cells of structures such as the ovaries, fallopian tubes, endometrium and pre-implantation embryos. In humans and mice, GM-CSF receptor has been detected in embryos from the fertilized oocyte until the blastocyst stage. GM-CSF, due to its anti-apoptotic and mitogenic effects, is known for its importance in the development of blastocysts and in normal fetal and placental development. Several studies have concentrated on embryonic development in culture media supplemented with GM-CSF. But none has focused on influence of endogenously synthesized GM-CSF by embryo on embryo development.
Study design, size, duration: Prospective study without randomization done at our IVF centre from May 2015 to October 2015. In every IVF cycle, each fertilized zygote was cultured individually in cleavage media drop till day 3. Neither the media contained GM-CSF nor was the culture drop externally supplemented with GM-CSF. After shifting all embryos ($n = 203$) into blastocyst medium, GM-CSF in each of the day 3 spent drops was measured by ELISA. Quality of Day 3 embryos and day 5 blastocysts was morphometrically evaluated.
Participants/materials, setting, methods: According to the 25 and 75 percentile values of GM-CSF in spent culture drops, three groups Low (<3.75 pg/ml; $n = 50$), Medium (3.75–9.78 pg/ml; $n = 97$) and High (>9.78 pg/ml; $n = 56$) were formed. All day 3 embryos and day 5 blastocysts were evaluated morphometrically and graded as Top/Good/Poor quality as per Gardner's criteria. Blastocyst formation rate and quality of blastocysts formed were the main outcome measures. Statistical analysis was done using Graph-pad Prism V software.
Main results and the role of chance: Age of patient remained comparable in all three groups with no statistically significant difference (One way ANOVA $p = 0.3128$). However, D3 embryo quality was significantly better in low compared to medium & high GM-CSF content groups ($p = 0.0398$). Blastocyst formation rate was extremely significantly high in low GM-CSF as compared to medium/high GM-CSF groups ($p = 0.0008$). Blastocyst quality also showed significant differences between the three groups. Blastocoelic cavity was much superior and larger ($p = < 0.0001$); organization and compactness of inner cell mass (ICM) was greater ($p = 0.0015$); and the number of trophectodermal (TE) cells was significantly higher ($p = 0.0004$) in the low GM-CSF group than in the medium/high GM-CSF groups. Interestingly, no significant difference in these parameters was seen when intercompared between just the medium and high GM-CSF groups. The correlation of content of GM-CSF in all spent drops with blastocyst formation and its quality was inversely proportional with a robust correlation coefficient (Spearman $r = – 0.2188$; $p = 0.0017$). Hence, this unique study successfully implicates GM-CSF level in day 3 leftover culture medium drop (after transferring embryos to blastocyst culture medium) in formation of higher number and better quality of blastocysts.
Limitations, reasons for caution: To our knowledge this is the only study that explores the possibility of endogenous GM-CSF production by embryo for its development. Hence larger multicentre studies are needed to endorse these findings. It is also imperative to establish why and how poor quality embryos extrude un-utilized GM-CSF in the culture media.
Wider implications of the findings: Concept of GM-CSF supplementation to culture media for better embryonic development is gaining ground in recent times. We believe, it would be appropriate to follow natural pathway and add GM-CSF only to select embryos that have high GM-CSF content in day 3 culture drops rather than empirically adding to all embryos.
Trial registration number: Not Applicable.

P-219 Determination of morphological variables during embryo culture that explain the human blastocyst development through model selection algorithms

I. Cardoso[1], P. López[1], E. Cervantes[2], L. Osorio[3], F. Valdéz[4]
[1]Instituto Mexicano de Alta Tecnología Reproductiva (Inmater), Laboratorio de Fertilización In Vitro, de México, Mexico
[2]Instituto Mexicano de Alta Tecnología Reproductiva (Inmater), Dirección Médica, de México, Mexico
[3]Universidad Nacional Autónoma de México, Facultad de Ciencias, de México, Mexico
[4]Medical Science Liaison, Fertility, Medical Affairs, Merck, Mexico

Study question: Which human morphological variables during embryo culture explain the successful development of a day 5 embryo based on model selection algorithms?
Summary answer: Model analysis showed that Fertilization method, third day symmetry, number of cells and fragments at fourth day, are variables that can explain the successful development.
What is known already: After fertilization, morphological evaluation criteria are used daily during embryonic development, mainly based on Veeck and recently, morphokinetics apparently improves this evaluation. Embryo selection parameters such as the fertilization method, pro-nucleous morphology, polar

bodies morphology, cleavage time, blastomere organization, presence or absence of citoplasmatic fragments, are among the most important criteria. These embryo features related to morphology can indirectly explain the appropriate function of the intracellular machinery responsible of implantation process. This is relevant because it has been suggested that aberrant development in the early stages can impact negatively in later stages of embryo development.
Study design, size, duration: A retrospective analytical study, assessed with computational statistical analysis using R programming software. Database included observations from 2013–2014. All records were performed by the same embryologist and per duplicate. Statistical analysis was performed to obtain multiple interactions between 18 embryo morphological variables in 679 entries.
Participants/materials, setting, methods: Collected database of embryo morphological assessment generated in ART using standardized protocol based on Veeck criteria. Sample consists of embryos transferred on day 3 and 5, frozen in day 3 and 5 or blocked in days 3, 4, 5. Observations were recorded during five days. Patients ranged from 26–45 years. Variables for this study were fertilization, Z score, cells from Days 2–5; fragments amount and disposition through 2–5 days. Symmetry and organization at days 2–5.
Main results and the role of chance: A series of mathematical models were proposed, whose structure was determined using a formula generator which considered all possible combinations of the predictor variables. Logistic regression models were adjusted and parameter values were estimated. A hypothesis test of all parameters for each logistic regression was performed and the models with significant adjustment were chosen. Finally, a comparison of the models performance using the AIC (Akaike Information Criterion, which is a maximum likelihood criterion used in the selection of statistical models, which penalizes models with more parameters). Therefore the model with the lowest AIC was chosen. It was generated formulas for each of the variables and their possible combinations using the model selection algorithm and we found that the best combination of variables were (Fertilization method, third day symmetry, fourth day developmental stage, and fourth day fragmentation with a value of AIC = 362.49.
Limitations, reasons for caution: Morphological criteria has limitations to predict embryo clinical outcomes, because depend on the embryologist criteria. The variables included in this study were numerical and categorical; however, other variables could be included to improve the power of the analysis and the predictive value such as metabolic or genetic markers information.
Wider implications of the findings: The results of this advanced data analysis could help to determine which of the evaluated variables and combinations have the potential to explain the success based on embryo morphological observations. This can be used to build an equation that could predict success or failure for an embryo at the laboratory.
Trial registration number: N/A.

P-220 Morphodynamic observations at the 2-cell stage can be correlated to the occurence of direct cleavage from 2 to 5 cells

B. Balaban[1], ğ. Keles[1], A. Isiklar[1], F. Yakar[1], M. Tasdemir[1], B. Urman[1]
[1]Amerikan Hastanesi – American Hospital, Assisted Reproduction Unit, Istanbul, Turkey

Study question: Can fragmentation, multinucleation and symmetry at the 2-cell stage potentially be used to predict direct cleavage from 2 to 5 cells?
Summary answer: Multinucleation and asymmetry are higher at the 2-cell stage for embryos that undergo direct cleavage from 2 to 5 cells in less than 5 h.
What is known already: Evidence based data demonstrate that embryos directly cleaving from one to three cells have lower implantation rate than embryos with a normal cleavage pattern and thus detecting direct cleavage (DC) is important. DC of embryos from 2 to 5 cells is a less known phenomenon but also associated with less optimal outcome. Little is known about the morphological appearance of fragmentation, symmetry and multinucleation in these embryos and if these parameters may be used to predict DC 2to5 eventually even without the need of time-lapse equipment.
Study design, size, duration: This is a retrospective cohort study using data from all cycles that were incubated in a closed time-lapse system between July 2013 to October 2015. 1615 embryos were annotated for morphokinetic (2PN, tPNf, t2, t3, t4, t5, t8, tM, tSB, tB) and for morphological variables at the 2- and 4-cell stage (fragmentation, multinucleation, symmetry). The morphological variables, were examined at the middle of the 2-cell stage.
Participants/materials, setting, methods: For detecting direct cleaving embryos from two to five cells the formula t5–t3 was applied using 5 h as a cut-off value for subgroups that either showed direct cleavage (group one < 5 h) or not (group two 5 h). Embryos with direct cleavage 1 to 3 (t3–t2 < 5 h) were excluded from this analysis.
Main results and the role of chance: Embryos in group 1 with direct cleavage 2 to 5 showed later values for t2 (28.6 ± 4.0) and t3 (41.1±5.5) compared to group 2 (27.7±5.2; 39.5±5.9, respectively). Values for t8 did not differ between both groups. Fragmentation at the 2-cell stage was assessed at 31.2 h± 5.5 for group one and 31.6 h±6.7 for group two, multinucleation at 33.4 h±5.6 for group one, 33.5h ± 6.2 for group two and symmetry at 31.5 h±5.3 for group one, and 32.5 h± 8.3 for group two. These values represent the middle of the cell cycle of the 2-cell stage for respective groups. Degree of fragmentation did not differ between both groups. The incidence of multinucleation in 2- cell embryos was significantly higher (45.2%: 80/177) for group one compared to group two (30.3%: 436/1438) ($p < 0.0001$). Percentage of asymmetric embryos was also significantly higher in group one (72.5%: 161/222) compared to group two (53.6%: 849/1584) ($p < 0.0001$).
Limitations, reasons for caution: The timing of direct cleavage from two to five cell and the cut off values suggested should be controlled and adjusted for potential confounding parameters like patient's characteristics as well as changeable clinical and laboratory procedures.
Wider implications of the findings: Although the higher incidence of MN and asymmetry at the 2-cell stage may predict direct cleavage from 2- to5-cells, proper assessment can only be done in the middle of the cell cycle which predicts the use of time-lapse imaging. Implantation assessment of embryos in study groups is required.
Trial registration number: None.

P-221 Background signals and potential measurement errors in miRNA microarray analysis of IVF culture media

K. Kirkegaard[1], H.J. Ingerslev[2], B.S. Sorensen[1]
[1]Aarhus University Hospital, Department of Clinical Biochemistry, Aarhus N, Denmark
[2]Aarhus University Hospital, Department of Obstetrics and Gynaecology and Department of Clinical Medicine, Aarhus N, Denmark

Study question: What is the background signal when analyzing unconditioned culture medium with miRNA microarrays?
Summary answer: All of the 84 evaluated miRNAs were randomly detected in the samples with Ct values >30, most likely representing false positive calls.
What is known already: miRNAs are small single-stranded non-coding RNA molecules, serving as gene regulators at the post-transcriptional levels. miRNAs secreted into culture media from human IVF embryos have been suggested to correlate with implantation. However, the majority of miRNAs measured have been weakly expressed with Ct values above 30, which introduces suspicion of potential errors with false positive calls. Furthermore, previous studies using a limited number of samples have reported that miRNAs are present in unconditioned control medium in levels comparable to presumed secreted miRNAs from the embryos. A thorough evaluation of background signals is crucial before concluding on clinical significance.
Study design, size, duration: miRNA expression was evaluated in unconditioned culture media (media in which no embryos have been cultured). Three commercial media were evaluated: Sydney IVF Blastocyst medium, G2 protein-free (Vitrolife) and GTL (Vitrolife). Two different batches were evaluated from Sydney IVF Blastocyst medium and one batch from each of the other two. Four samples of 200 µl were analyzed from each batch (16 samples in total). RNAase free water was used as negative control.
Participants/materials, setting, methods: All procedures were performed according to the manufacturer's (Qiagen) protocol. *C. elegans* miR-39 was added as an internal spike-in control along with MS2 carrier RNA to optimize purification. miRNA was isolated using miRNeasy Serum/Plasma kit. cDNA was generated using the miScript II RT kit followed by 12 rounds of pre-amplification using miScript preAMP. 84 specific miRNAs expressed during cellular and organism development were quantified using the Human Cell Differentiation & Development miScript miRNA PCR Array.
Main results and the role of chance: The Ct values of the positive PCR control and the RT control were both within the recommended range (19±2 and C_T^{miRTC}-C_T^{PPC} < 2, respectively). There was no difference between the Ct values

(11–12) of the added spike-in miRNA, the positive PCR control and the RT control between the samples, which indicates low inter-assay variability. All of the 84 miRNA were randomly detected in one or more of the samples. With a few exceptions the Ct-values were above 30, which is the limit the manufacturer sets for negative calls. Similarly, the 6 normalizers suggested by the manufacturer (SNORD61/68/72/95/96A and RNU6B) were all detected in one or more media samples with Ct values comparable to the Ct values for the 84 specific miRNAs. For two of the samples the Ct value of one of the suggested normalizers (SNORD68) was 28.
Limitations, reasons for caution: For two of the media types, only samples from one batch was analysed. The Ct values may reflect the presence of contamination introduced during the workflow. As the 84 miRNAs detected were randomly distributed between the samples, we do not consider this explanation plausible. Only one platform (Qiagen) was tested.
Wider implications of the findings: This methodology study demonstrates that Ct values >30 obtained with the procedure employed most likely represent background signals or false positive calls, and should be interpreted with great caution. Using miRNAs expressed at extremely low levels as normalizers may introduce significant bias or result in false positive detection of miRNAs.
Trial registration number: NA.

P-222 Effect of ICSI with Calcium ionophore on embryo fertilization, multinucleation, direct cleavage and morphokinetics

J. Aguilar Prieto[1], E. Muñoz[2], M. Ojeda[1], E. Taboas[1], M. Perez[1], M. Meseguer[3]
[1]*IVI Vigo, FIV, Vigo, Spain*
[2]*IVI VIGO, Gyneacology, VIGO, Spain*
[3]*IVI Valencia, FIV, Valencia, Spain*

Study question: Does Calcium Ionophore (Ica) affect ICSI outcomes?
Summary answer: The use of ICa does not affect the fertilization, embryo multinucleation, pregnancy and implantation rates, direct cleavage proportion or the embryo morphokinetics, expect tPB2.
What is known already: Artificial oocyte activation (AOA) with ICa has shown successful ICSI outcomes in patients with previous fertilization failure. However, information regarding the impact of ICa on embryo development is scarce.
Study design, size, duration: Retrospective cohort study of 65 couples with severe male factor (sperm Samples under 1 mill/ml) were studied. 271 oocytes from 36 couples who underwent ICSI with Ica (Ca2+ group) were compared to 232 microinjected oocytes from 29 couples (control group), with severe male factor (SMF), between January 2011 and December 2015 in IVI VIGO Clinic.
Participants/materials, setting, methods: AOA was performed by injecting the oocytes with spermatozoa in a buffered media with Ica. Later, they were incubated for twenty minutes with culture media and ICa in a 37°C, 6%CO2 atmosphere. Embryo culture was carried out in a time lapse monitored incubator. Fertilization, embryo multinucleation at 2 and 4 cells, pregnancy, implantation rates and direct cleavage events and embryo morphokinetics, were analysed. χ^2, *t*-Student and Mann–Whitney tests were employed when applicable.
Main results and the role of chance: Fertilization rate was similar between Ica and control group, 54.2% vs. 58.1% ($p = 0.06$). No differences among groups were found for abnormal fertilization (1.3 or 4 pronucleai) rate. No differences in embryo multinucleation rate at 2 and 4 cells between Ica and control group were found; $p = 0.8$ and $p = 0.09$ respectively, and the proportion of direct cleavage events was not different ($p = 0.447$) either. Pregnancy rate was similar in the Ica group, 55.55% vs. 60.8%, as well as the implantation rate, although without statistically significant differences. Embryo morphokinetics tPB2, tPNa, tPNf, t2 to t8, cc2, and s2 were analyzed among groups and there were statistically significant differences on tPB2. We suppose that Ica may affect the calcium signals patterns that trigger embryo fertilization, and it could be reflected at the time at which the second polar body is extruded (tPB2)
Limitations, reasons for caution: The Ica embryos analyzed were obtained from patients with SMF with previous complete fertilization failure, and compared to embryos from SMF patients. The conclusions reached may not be applicable for patients with other ethyologies. Sample size is still limited and more cycles are needed to draw firm conclusions.
Wider implications of the findings: Our findings offer new data about the embryos behaviour under AOA with Ica, reflect the safety of its application.
Trial registration number: none.

P-223 Compaction dynamics of the morula stage embryo defined by time-lapse monitoring predicts blastocyst formation rates and quality

İ. Keles[1], B. Balaban[1], A. Isiklar[1], F. Yakar[1], M. Tasdemir[1], B. Ata[1], B. Urman[1]
[1]*Amerikan Hastanesi – American Hospital, Infertility Unit IVF Centre, Istanbul, Turkey*

Study question: Can compaction characteristics of day 4 morula stage embryo visualized by time-lapse systems be an objective marker to define blastocyst formation and quality?
Summary answer: Fully compacted embryos on day 4 have a significantly higher rate of blastocyst formation and good quality blastocysts compared to partially compacted day 4 embryos.
What is known already: Despite the fact that day 3 cleavage stage embryo morphology, cell number and kinetic characteristics had been correlated with blastocyst formation rate and quality, few studies examined the effect of day 4 morula stage embryo morphology on same parameters. Since compaction of mammalian embryos represents the first morphological event reflecting differentiation of the inner cell mass and trophoectoderm, the characteristics of compaction on day 4 could play an important role on the quality and viability of the resultant blastocyst.
Study design, size, duration: 113 patients with a mean age of 34.1 and without severe endometriosis or severe male factor were analysed retrospectively from February 2014 to December 2015. A total of 566 blastocysts obtained were monitored for 5 days in a time-lapse incubator. Change in morula morphology were continuously visualized from the time at which blastomere fused and compaction was completed until the time of the beginning of blastulation.
Participants/materials, setting, methods: A total of 100 blastocysts were of top quality with the score ≥4AA based on Gardner grading scheme. The characteristics of compaction were divided into two groups. First group of blastocysyts originated from fully compacted morulae whereas the second group developed from partially compacted morulae. The outcome parameters were blastocyst formation rates and number of ≥4AA blastocysts.
Main results and the role of chance: Blastocyst formation rate from fully compacted morulae in the first group was 97.0% (197/203) whereas it was 91.7% (369/402) from partially compacted morulae in the second group ($p < 0.01$). The incidence of ≥4AA blastocysts was 49.2% (100/203) for the first group and 7.4% (30/402) for the second group which was found to be highly significant ($p < 0.001$). Mean timing for the blastomere fusion and compaction visualized by time-lapse was 89.1 ± 0.58 h in the first group, and 92.6 ± 0.45 in the second group, whereas the start of blastulation in the first study group was 99.0 ± 0.54, and 102 ± 0.46 h. For the second group. The timing difference for the blastomere fusion and compaction as well as the blastulation start was significantly delayed in the second study group compared to the first one ($p < 0.0001$).
Limitations, reasons for caution: Patient related factors were not investigated in subgroup analysis as potential confounding parameters for blastocyst formation and quality despite compaction morphology. Despite the fact that same culture media was used during the entire study, it needs to be noticed that different culture media may influence the time of compaction.
Wider implications of the findings: Our findings underline the importance of day 4 morula stage embryo compaction characteristics on blastocyst formation rates as well as blastocyst quality. The implantation potential of such blastocysts should be further investigated to analyse whether the viability potential of these embryos are different in the study groups.
Trial registration number: None.

P-224 Correlation between oocyte yield, blastocyst formation and euploidy: longitudinal cohort study in advanced maternal age population

L.F. Rienzi[1], A. Capalbo[2], A. Farcomeni[3], S. Colamaria[1], A. Vaiarelli[1], F. Sapienza[1], L. Buffo[4], R. Venturella[5], F. Ubaldi[1]

Study question: Is metaphase II oocyte (MII) yield in an IVF/ICSI cycle correlated to blastocyst and euploid blastocyst (eblastocyst) formation rates per inseminated MII?
Summary answer: Ovarian response to stimulation is unrelated to oocyte quality in terms of blastocyst formation and chromosomal status in advanced maternal age (AMA) population.
What is known already: The ovarian response and thus the number of MII available for insemination is a function of the woman's ovarian reserve and type of ovarian stimulation protocol used. Low or excessive ovarian response, have previously been suggested to have a detrimental effect on oocyte quality. The aim of this study was to analyse the possible correlation between the size of oocyte cohorts retrieved (oocyte yield), oocyte development competence and chromosomal status in a single stimulation protocol group of AMA patients. Aneuploidy testing (PGD-A) was performed at blastocyst stage with comprehensive chromosomal analysis. Primary outcome measures were: Blastocyst/MII and eblastocyst/MII rates.
Study design, size, duration: Longitudinal cohort study preformed between April 2013 and December 2015. Only IVF/ICSI cycles with PGD-A were included. Severe male factor infertility was excluded. All patients underwent the same protocol for ovarian stimulation using FSH and LH in combination with GnRH antagonist starting on day 2 of the cycle. The dose was adjusted according to patients and cycle characteristics with the aim to maximize the number of oocytes to be retrieved.
Participants/materials, setting, methods: 847 patients undergoing 1046 cycles were included. Data are presented as mean+SD and percentages with 95%CI for continuous and categorical variables, respectively. Mean female age was 39.3+2.0 years (range 35–42). Overall, 7285 MII oocytes were obtained and inseminated by ICSI (6.9+4.5, range 1–25). Effects were estimated with multivariable analysis using mixed logistic regression models with a subject-specific intercept to take into account unobserved heterogeneity due to repeated measurements in the same woman.
Main results and the role of chance: 2532 blastocysts were obtained and analysed. Overall, 34.8% (range 26–100%, 95CI: 33.7–35.9) and 15.8% (range 20–100%, 95CI: 15.0–16.7) inseminated MII oocytes developed to blastocyst and to eblastocyst, respectively. Day of development to blastocyst stage/MII was 14.3% (95CI: 13.5–15.2), 17.7% (95CI: 16.8–18.6) and 2.7% (95CI: 2.4–3.1) for day 5, 6 and 7, respectively. Blastocyst/MII rate was not related to oocyte yield (OR: 0.990, 95%CI: 0.98–1.00, $p = 0.144$). Similarly, eblastocyst/MII rate was not associated to oocyte yield (OR: 0.995, 95%CI: 0.85–1.0, $p = 0.55$). The statistical analysis was adjusted for confounders including patient and cycle's characteristics. Only female was significantly related to outcomes. Blastocyst and eblastocyst/MII rates decreased significantly with increasing female age (OR: 0.930, 95%CI: 0.912–0.948, $p < 0.001$ and OR: 0.828, 95%CI: 0.809–0.980, $p < 0.001$, respectively). A relative decrease of 7.0% and 17.2% in the probability to reach blastocyst/MII and eblastocyst/MII respectively was observed for each additional year of age.
Limitations, reasons for caution: This study has been performed in a selected population of AMA patients treated with a single protocol for ovarian stimulation aimed at maximizing the oocyte yield. Results cannot be applicable to different population and protocols.
Wider implications of the findings: We show that ovarian reserve, measured as the response to a specific stimulation protocol, doesn't compromise oocyte competence. Poor ovarian response is thus only associated to a decline in oocyte quantity but not in quality.
Trial registration number: none.

P-225 The impact of severe endometriosis on embryo quality and pregnancy rate after intracytoplasmic sperm injection (ICSI)

J. Sudiman[1,2], N. Tondohusodo[1,2], A. Suardika[1,2], I.P. Adnyana[1,2]
[1]*Obstetrics and Gynaecology Department, Faculty of Medicine, Udayana University, Denpasar, Bali, Indonesia*
[2]*Bali Royal Hospital, IVF clinic, Denpasar, Bali, Indonesia*

Study question: Study question: Do the presence of severe endometriosis (grade III–IV) leads to reduce embryo quality and pregnancy rate after ICSI?
Summary answer: Summary answer: Severe endometriosis decreases fertilisation and top quality embryos which imply with significantly decreasing in clinical pregnancy.
What is known already: No consensus concerning the impact of severe endometriosis on oocyte and embryo quality as well as pregnancy rate from women who underwent in vitro *fertilization* (IVF)/ICSI. Some studies have suggested that endometriosis reduced quality of oocytes and embryos and impaired uterine receptivity thus reduced pregnancy rate. In contrast, several studies have presented that endometriosis patients who underwent IVF/ICSI had comparable outcomes compared to those with tubal factors infertility.
Study design, size, duration: A case control study of patients ≤ 35 years old undergoing ICSI at BROS hospital between September 2010 and August 2015. 65 patients in control group were diagnosed with tubal factors infertility whilst 23 patients were diagnosed with severe endometriosis diagnosed by laparascopy according to American Fertility Society (AFS) classification (treatment group). Patients with other factors besides tubal factors infertility and severe endometriosis were excluded. Only patients with first cycle were included.
Participants/materials, setting, methods: Before undergone hormonal stimulation, treatment group was treated with Leuprorelin acetate and endometrioma cysts (diameter ≥3 cm) were taken out. All patients were administrated with rFSH (short protocol). Ovarian stimulation parameters were observed based on dose of rFSH, days of stimulation, number of follicles, oocytes and maturation. Variables in assessment of embryos included fertilisation, cleavage, and number of top quality embryos on day 3. Maximum 3 embryos were transferred. Clinical pregnancy was confirmed by heartbeat.
Main results and the role of chance: There were no significant differences in basal serum LH, FSH or estradiol and number of follicles between women with severe endometriosis and women with tubal factors infertility. Women with severe endometriosis required more days of ovarian stimulation compared to women with tubal factors infertility (8.2 ± 0.9 versus 7.6 ± 1.1, $p < 0.05$, respectively). There was a trend towards an increasing of dosage of stimulation ($p = 0.07$) but decreasing in number of oocytes ($p = 0.06$) and mature oocytes ($p = 0.06$) in treatment group compared to control group. Fertilisation rate and number of top quality embryos were significantly higher in control group compared to treatment group (5.3 ± 0.4 versus 3.8 ± 0.3, 3.1 ± 0.3 versus 2.2 ± 0.3, $p < 0.05$, respectively). These implied with significantly decreasing in clinical pregnancy of women with severe endometriosis (29.2%) compared to women with tubal factors infertility (55.4%, OR 3.0, 95% CI, 1.11 to 8.16). There is a higher pregnancy with two gestational sacs/pregnancy rate (14.3% versus 30.6%) and triple gestational sacs (0% versus 11.1%, respectively) in women with tubal factors infertility compared to those with severe endometriosis.
Limitations, reasons for caution: The excision of endometrioma cysts with diameter ≥3 cm before starting hormonal stimulation may reduce ovarian reserve in women with severe endometriosis.
