Wider implications of the findings: While the findings are mostly in agreement with previous studies that severe endometriosis reduced embryos quality and pregnancy rate after ICSI, this present study also shows that pre-treatment endometriosis with Leuprorelin acetate and endometrioma excision do not improve outcomes of ICSI in the same level as women with tubal pathology.
Trial registration number: N/A.

P-226 Vitrification of oocytes and blastocysts using a fully automated cryopreservation device

A. Arav[1], Y. Natan[1], P. Levi Setti[2], P. Patrizio[3]
[1]*Fertilesafe Ltd., R&D, Ness Ziona, Israel*
[2]*Istituto Clinico Humanitas, Reproductive Medicine unit, Milan, Italy*
[3]*Yale University, Yale Fertility Center, New Haven, CT, USA*

Study question:: Vitrification has become the standard technique for oocytes and embryo cryopreservation, but it is time consuming and operator-dependent. Can the procedure be fully automated?
Summary answer:: This is the first report of a fully automated vitrification device (called Sarah) enabling the standardization and simplification of the entire process.
What is known already: Currently vitrification is the method of choice for preserving oocytes and embryos. However, the procedure is cumbersome, requires highly skilled personal and is not yet standardized. Having an automated device allowing the exposure of oocytes or embryos to the various vitrification solutions, including the final immersion into liquid nitrogen (LN), will overcome all the above mentioned disadvantages.
Study design, size, duration: Experimental research using oocytes and embryos collected from the oviducts of 6 weeks old mice (CBA x BL C57) superovulated with PMSG and hCG and vitrified using a novel fully automated device (Sarah). Upon rewarming the oocytes and embryos were assessed for viability, cleavage, blastocyst and hatching rates.

Participants/materials, setting, methods: Oocytes (n = 20) or day 2 embryos (n = 60), with 40 (study group) automatically vitrified and 20 cultured fresh (controls). Up to 6 oocytes/embryos were first loaded into 1/4cc straws end-closed by special grids (50 µm pores) and then connected to the cryo-device having a computerized rotating cylinder containing cups with increasing concentrations of vitrification/equilibration solutions. After passing through the various stations, the straws were also automatically plunged into LN slush.
Main results and the role of chance: Upon rewarming, oocyte survival was evaluated by return into the isotonic volume while viability was assessed by live/dead staining. Rewarmed d2 embryos were placed in culture and their viability was evaluated by in vitro growth assessing blastocyst and hatching rates. Results showed that 95% (19/20) of the MII oocytes regained isotonic volumes and all (100%) of the surviving were viable according to the live/dead stains. Rewarmed embryos (study group) had 95% (38/40) blastulation rate (d4) and 75% (30/40) hatching rate (d5). The fresh embryos (controls) had a similar hatching rate of 80% (16/20, p NS).
Limitations, reasons for caution: This work was done only on mice embryos and oocytes and has not yet been performed on human oocytes or embryos.
Wider implications of the findings: Currently, there is no methodology able to fully automate the vitrification process. Here we reported a method that by virtue of a fully automated, operator-independent process, including the immersion into LN, will simplify and standardize the vitrification procedures worldwide.
Trial registration number: N/A.

P-227 Time Lapse analysis of the interrelationship between direct cleavage, multinucleation and maternal age in Natural Cycle IVF and Standard IVF

S. Davies[1], C. Karamalegos[1], T. Karagianni[1], K. Ekonomou[1], C. Mendorou[1], M. Mastrominas[1]
[1]*c/o Embryogenesis, Embryology, Maroussi, Athens, Greece*

Study question: Do Natural Cycle embryos display direct cleavage, and is multinucleation or maternal age related? Are there measurable differences between Natural Cycle and Standard IVF embryos?
Summary answer: No statistical relationship between direct cleavage, multinucleation and maternal age in Natural Cycle embryos. Statistically lower parameters, with improved embryo viability, compared with stimulated cycles.
What is known already: Direct cleavage and the presence of multinucleated cells are both associated with increased aneuploidy and reduced viability in developing embryos with low blastocyst formation and implantation. The stage at which direct cleavage occurs affects the embryo viability differently. When direct cleavage occurs in the 1st cell cycle (1–3 cells), the embryo viability is reduced dramatically to almost zero. Whereas, if it occurs in the 2nd or 3rd cycles (2–5 cells & 5–9 cells) then viability is reduced but euploid embryos are found after PGS and clinical pregnancies are generated.
Study design, size, duration: This is a retrospective study including 515 embryos from Natural Cycle IVF and 525 embryos from stimulated IVF cycles. Embryos were monitored in tri-gas incubator with time lapse (Embryoscope™, UniSense, Denmark). Data from cycles carried out between Jan 2013–Dec 2015. All Embryos developed up to 8 cell stage. Annotations were performed by the same person.
Participants/materials, setting, methods: Patients undergoing Natural Cycle IVF and Standard IVF were randomly allocated to time lapse incubation immediately after standard ICSI procedure. All normally fertilised oocytes were annotated by standard procedure for timings of cleavages, the presence of micronucleation (2 cell stage), and direct cleavage (any cell dividing into 3 distinct components with nuclear structures). Statistical analysis Chi-squared contingency test performed on graphpad software and t test for means.
Main results and the role of chance: Of 515 embryos generated from natural cycle, direct cleavage was observed in 23.7% of all embryos (11.3% in 1st cleavage, 11.8% in 2nd cleavage, & 0.6% in 3rd cleavage). Multinucleation (MN) was assessed in 390 embryos at 2 cell stage (42% 0 MN, 18% MN (1 cell), 40% MN (both cells). With advancing maternal age (<38 & >38 yrs) there were no significant differences with respect to direct cleave or multinucleation, and viability score for embryos also showed no significant difference with increase in maternal age (A+B score 48.1% vs. 53.2% and Excluded 29% vs. 22% for <38 yr vs. >38 yr groups). In contrast, there were significant differences between natural and stimulated cycles. Direct cleavages were lower in natural cycles 23.7% vs. 33.2% [natural vs. stimulated (p = 0.02)], and embryo viability score elevated in natural cycles [A+B classification (51.6% vs. 41.9%) natural vs. stimulated (p = 0.002)]. The presence of MNs were statistically different in both groups, but with increased levels in natural cycles 52.0% vs. 43.0% [natural vs. stimulated (p = 0.02)].
Limitations, reasons for caution: The numbers of elective natural cycle cases are minimal, the majority have history of previous poor stimulation outcome or advanced maternal age.
Wider implications of the findings: In depth analysis of embryos derived from natural cycle IVF allows us to uncouple developmental factors inherent to the oocyte/embryo from those induced/enhanced by ovarian hyperstimulation protocols. There is consensus that higher dosage in poor responders increases oocyte quantity at the expense of quality.
Trial registration number: Not applicable.

P-228 Effect of the well-of-the-well culture system on development of human embryos – a prospective randomized study with sibling embryos

S. Inoue[1], R. Hirata[1], T. Habara[1], N. Hayashi[1]
[1]*Okayama Couple`s Clinic, Gynecology, Okayama, Japan*

Study question: To evaluate the effectiveness of the well-of-the-well (WOW) culture system (LinKID® micro25, DNP, Japan) on development of human in vitro fertilization (IVF) treatments.
Summary answer: The WOW system improved blastocyst development, especially in good-quality cleavage stage embryos.
What is known already: The WOW dish contains micro-wells in the center of the dish, allowing for the identification of individual embryos cultured together in the same microdrop. It has been reported that the WOW system improved blastocyst development of bovine embryos.
Study design, size, duration: This prospective randomized study included 1,108 embryos from 109 IVF cycles between July and December 2015. The trial's sample size was determined by the primary trial endpoint of the blastocyst formation rate. Patients were enrolled when six or more normal fertilized oocytes (2PN) were achieved
Participants/materials, setting, methods: A sibling analysis was performed. The 2PN were randomly placed in two groups and allocated to either the WOW or individual drop culture (control group) for direct comparison. In the WOW group, three or more embryos were cultured together in 50 µL of culture media. The control group embryos were placed into a 25 µl droplet individually. Furthermore, we compared blastocyst development according to cleavage quality (good/poor) on Day 3 in both culture groups.
Main results and the role of chance: Good-quality cleavage rate on Day 3 was similar in both groups (67.6% in the WOW group vs. 67.0% in the control group). However, blastocyst development showed a significant difference; there were significantly higher blastocyst formation rate and usable embryo rate (available for either fresh transfer or cryopreservation) in the WOW group than in the control group (61.2% vs. 54.3%, and 60% vs. 53%, respectively; p <.05). In addition, poor-quality cleavage stage embryos showed no difference in blastocyst development regardless of the culture system (33.7% in the WOW group vs. 33.3% in the control group). In contrast, good-quality cleavage stage embryos in the WOW culture resulted in a higher blastocyst formation rate and usable embryo rate (73.8% vs. 64.2%, and 74.6% vs. 64.8%, respectively; p < .05).
Limitations, reasons for caution: Our results did not include pregnancy or live birth rates. Further studies including this data are required to clarify the link between embryo quality and the effect of the culture system.
Wider implications of the findings: Our results suggest that the WOW system may have a beneficial effect on embryo development. The system may improve culture conditions via autocrine factors from the embryos themselves, resulting in greater blastocyst formation.
Trial registration number: Not applicable.

P-229 Embryo Quality Assessment in in Vitro Fertilization (IVF) using metabolite footprints secreted to human embryo culture media by ATR-FTIR spectroscopy and multivariate analysis

S. Garip[1], S.T. Ceyhan[2], C. Korkmaz[2], A. Muge[3], E. Guney[3], E. Bal[2], F. Severcan[3]
[1]*Faculty of Medicine, Istanbul Kemerburgaz University, Medical Biochemistry, Istanbul, Turkey*
[2]*GATA School of Medicine, Obstet & Gynecol, Ankara, Turkey*
[3]*Middle East Technical University, Biological Sciences, Ankara, Turkey*

Study question: Can embryo quality be determined noninvasively using FTIR spectroscopy to analyze human embryo culture media in IVF treatment?
Summary answer: The embryos which provided pregnancy were diagnosed by FTIR spectroscopy with multivariate analysis with 100% sensitivity and specificity.
What is known already: The success level of IVF method is low with cumulative delivery rates of 47–51% per cycle. The greatest limitation of IVF method is not to know the quality of the embryo and thus unavailability to designate which embryo would result in pregnancy after transfer. Morphological assessment is the primary method used to determine embryo quality with the disadvantage of having a modest predictive value during IVF cycles. Therefore there is an urgent need for reliable methods to choose the most viable embryo for transfer and as a result of decreasing multiple gestations, as well as increasing overall pregnancy rates.
Study design, size, duration: In this prospective, double-blind study, embryo quality was determined by analysing spent culture media after fertilization by ATR-FTIR spectroscopy and hierarchical cluster analysis (HCA). For each patient, transferred embryos were selected according to morphological assessment and ATR-FTIR studies were carried out collaterally without knowing the morphological grading of each embryo. Therefore, this study also provides an accurate comparison of morphological assessment and ATR-FTIR results of the same embryos via culture media.
Participants/materials, setting, methods: 30 patients (24–36 years old) with unexplained infertility were included in the study. A total of 634 spent embryo culture medium samples were collected individually on days 3 and 5 for ATR-FTIR studies. A control medium sample incubated under the same conditions without an embryo was also collected as unspent controls. ATR-FTIR studies were carried out blinded to the morphological grading of the embryos, which embryo was transferred and which patient was clinically pregnant.
Main results and the role of chance: Among 30 patients, 10 patients got pregnant. Nine pregnancies gave birth after the IVF treatment, while one pregnancy was miscarriage. There was no success in transfer of morphologically selected embryo in the remaining 20 patients. In ATR-FTIR studies, the best results for the discrimination of spent culture medium samples of good quality embryos (embryos which provided pregnancy) were obtained with the cluster analysis performed on the vector-normalized spectra in the 4000–400 cm^{-1} wavenumber range. The embryos which provided pregnancy in 10 patients were diagnosed by clustering near the unspent culture medium (control) in the HCA dendrogram. Thus, best qualified embryos of these patients were diagnosed with 100% sensitivity and specificity (10/10) by FTIR spectroscopy. In 15 out of 20 patients with IVF failure, different embryos were diagnosed as best qualified in FTIR studies and morphological assessment. In the remaining 5 patients, although transferred embryos selected by morphological assessment were clustered as good-qualified embryos in FTIR studies, they could not provide pregnancy.
Limitations, reasons for caution: None.
Wider implications of the findings: Using FTIR spectroscopy to define embryo quality in IVF cycle may increase the success rates of pregnancy in IVF cycle by enabling the selection of the best qualified embryo. It may also contribute to prevention of multiple pregnancies by decreasing the transferred embryo number.
Trial registration number: None.

P-230 Effect of sperm DNA fragmentation on embryo quality; a morphology dynamics analysis

M. Esbert Algam[1], A. Pacheco[2], D. Amorós[3], G. Gutierrez[3], N. Menendez[3], S. Martinez[3], C. Llop[3], M. Quera[1], M. Florensa[1], A. Ballesteros[4], M. Meseguer[5]
[1]IVI Barcelona, IVF Laboratory, Barcelona, Spain
[2]IVI Madrid, Andrology Laboratory, Madrid, Spain
[3]IVI Barcelona, Andrology Laboratory, Barcelona, Spain
[4]IVI Barcelona, Gynecology and Obstetrics Department, Barcelona, Spain
[5]IVI Valencia, IVF Laboratory, Valencia, Spain

Study question: Does sperm DNA fragmentation affect the morphokinetic parameters of embryo development?
Summary answer: Sperm DNA fragmentation delays the time to blastocyst stage but has no impact neither on the chance of suffering abnormal divisions, nor on embryo arrestment.
What is known already: Sperm DNA fragmentation (sDNAf) assessment has been introduced in many ART clinics as a diagnostic tool. Some authors find an increased miscarriage rate in patients with higher sDNAf, but the lack of a unique test to evaluate the damage and an agreed cut-off value make consensus difficult. Damaged DNA can be repaired by the oocyte and the embryo mechanisms, but it is still unclear if the time consumed by this phenomenon affects the embryo morphokinetics. Recent publications correlate irregular cell divisions with poor implantation potential, but we still don't know if they could be related to sDNAf.
Study design, size, duration: Retrospective, cohort study. This study includes 971 embryos from 135 ICSI cycles performed between March and December 2015.
Participants/materials, setting, methods: University-affiliated infertility clinic. Ejaculated samples from patients were processed through density gradients and sDNAf was analyzed by TUNEL assay after the oocytes were microinjected. Cycles were performed using oocytes from patients (56; 41.48%) or donors (79; 58.52%), which were fresh (71; 52.59%) or vitrified (64; 47.41%). Embryos were cultured in an EmbryoScope® incubator. Time of every cell cleavage and irregular division such as direct cleavage, incomplete cleavage, reverse cleavage and asynchronous cleavage were annotated and correlated with sDNAf.
Main results and the role of chance: Mean sDNAf observed in the neat samples was 14.30 ± 10.52%. The origin of oocytes and whether they were fresh or vitrified did not affect results. Length of cell cycles and cell synchrony were unaffected by the percentage of sDNAf, but embryos reached the blastocyst stage later when were obtained from samples with higher sDNAf ($p = 0.028$). The percentage of sDNAf was similar in embryos that blastulated compared to the ones that did not (13.80 ± 10.27% vs. 14.65 ± 11.12%). Normal cleavage was observed in 740 embryos (76.21%); direct cleavage from 1 to 3 blastomeres in 104 embryos (10.71%); direct cleavage from 1 to 4 blastomeres in 11 embryos (1.13%); incomplete cleavage in 44 embryos (4.53%); reverse cleavage in 42 embryos (4.32%) and asynchronous cleavage in 29 embryos (2.99%). Percentage of sDNAf was independent of the cleavage pattern, being 14.26 ± 10.52; 16.28 ± 11.65; 14.54 ± 13.93; 12.50 ± 8.82; 12.64 ± 9.55 and 13.64 ± 8.75, respectively.
Limitations, reasons for caution: The main limitation of this study is that female factor cannot be avoided, although we observed that results were independent of the origin of the oocytes and whether they were fresh or vitrified.
Wider implications of the findings: According to our results, embryos that come from samples with higher sDNAf present a delayed blastulation. In consequence we demonstrated how sDNAf affects embryo development and should be taken into consideration as a diagnostic tool of sperm quality. Reference values for sDNAf remain to be elucidated.
Trial registration number: Not applicable.

P-231 The impact of ovarian stimulation protocol on embryo morphokinetic parameters

I. Rangelov[1], S. Nikolova[1], I. Ivanova[1], K. Nikolova[1], D. Parvanov[2], G. Stamenov[3], T. Chaushev[2]
[1]Medical Center Nadezhda Reproductive Sofia, Embryology, Sofia, Bulgaria
[2]Medical Center Nadezhda Reproductive Sofia, Research, Sofia, Bulgaria
[3]Medical Center Nadezhda Reproductive Sofia, Obstetrics and Gynecology, Sofia, Bulgaria

Study question: Which morphokinetic parameters are affected by the ovarian stimulation protocol?
Summary answer: Three morphokinetic parameters – s2, tM and SSBM showed significant difference, according to the ovarian stimulation protocol.
What is known already: The use of morphokinetic variables of human embryos as potential predictors of IVF outcome is becoming a promising tool for embryo selection in recent ART procedures. Many authors discuss the crucial importance of specific parameters, such as synchrony of the second cell cycle (s2), morula formation time (tM) and blastocyst formation time (tB). However, little is known about the effect of different concomitant factors (BMI, age, basal FSH levels and stimulation protocol) that may affect the early stages of embryo development and can subsequently influence the success of the applied ICSI or IVF procedures.
Study design, size, duration: This retrospective study was conducted from January 2012 to February 2015. A total of 420 embryos from 286 patients were studied.
Participants/materials, setting, methods: Patients were classified into two groups according to the ovarian stimulation protocols: (1) long protocol

(n = 138) and (2) short protocol (n = 148). The two groups were selected to be comparable and did not differ significantly with regard to age, BMI, or basal FSH levels. Embryos were cultured in a one-step medium and analyzed in Embryoscope™. 36 morphokinetic variables were analyzed. All statistical analyses were performed in SPSS-21 software.

Main results and the role of chance: Three of thirty six morphokinetic variables showed statistically significant difference ($p < 0.05$) between the studied groups of patients with long and short stimulation protocol, respectively: (1) Synchrony of the second cell cycle (s2), (2) morula formation time (tM) and (3) the period of time between the beginning of blastocyst formation and full blastocyst stage (SSBM = tSB − tM). The mean time-points in hours for the patients with long and short stimulation protocol were: 2.57 vs. 2.04 (s2), 99.82 vs. 87.80 (tM) and 10.92 vs. 15.00 (SSBM).

Limitations, reasons for caution: Data were collected from one laboratory and for this reason should not be assumed to be representative and applicable to all IVF laboratories before external validation. Choosing the specific culture medium, time-lapse system, control and monitoring software could lead to different time points and target morphokinetic parameters in each laboratory.

Wider implications of the findings: Better understanding of the direction and intensity of the impact of environmental factors on embryo development, such as patient treatment procedures would give an opportunity to improve the embryo selection, implantation outcome and to increase the live birth rate.

Trial registration number: NA.

P-232 Age dependent gene expression profiles of human ICSI blastocysts

K. Takagi[1,2,3], T. Kubota[3], F. Ishino[2], O. Tsutsumi[4], A. Yoshida[5], T. Kawamura[6], T. Harada[3], R. Sugiyama[7], T. Kohda[2]

[1]*Kameda Medical Center, Center for assisted reproductive technologies, Chiba, Japan*

[2]*Tokyo Medical and Dental University, Department of Epigenetics, Tokyo, Japan*

[3]*Tokyo Medical and Dental University, Department of Obsterics and Gynecology, Tokyo, Japan*

[4]*Sanno Hospital, Center of Reproduction and Gynecologic Endoscopic Surgery, Tokyo, Japan*

[5]*Kiba Park Clinic, Reproduction Center, Tokyo, Japan*

[6]*Denentoshi Ladies Clinic, Reproductive Medical Center, Kanagawa, Japan*

[7]*Sugiyama Clinic, Division of Reproductive Medicine, Tokyo, Japan*

Study question: What is are the effective factors on the gene expression profiles of human intracytoplasmic sperm injection (ICSI) blastocysts ?

Summary answer: Maternal age had a larger effect on the gene expression profiles of single human ICSI blastocysts than the other considered factors (e.g., sperm motility rate).

What is known already: For humans, numerous studies indicate that detecting chromosomal abnormalities in embryos has beneficial effects on both the clinical implantation rate and the abortion rate. However, the relations between the human embryos' transcriptome profiles and the implantation rate and the live birth rate are unknown. Studies on mouse embryos have shown that the conditions of in vitro cultures and ICSI procedures can lead to alteration of the gene expression profiles. For humans, the joint effect of metaphase II (MII) oocytes and age has been demonstrated, but the joint effect of human blastocysts and age has been rarely considered.

Study design, size, duration: We analyzed 22 high quality day 5–6 cryopreserved embryos donated from patients who provided informed consent from three assisted reproduction centers in Japan between 2011 and 2015. The fertilization method only involved the ICSI procedure using fresh ejaculated spermatozoa.

Participants/materials, setting, methods: Ribonucleic acid (RNA) extraction from a single blastocyst was performed using the Arcturus PicoPure isolation kit. Gene expression profiles were analyzed with RNA sequencing using T7 RNA polymerase linear amplification. Statistical analyses of the gene expression data were performed with R software. We used Spearman's rank correlation coefficient to test for any association between age and the gene expression profiles.

Main results and the role of chance: We investigated 16 vitrified blastocysts from day 5, and 6 from day 6. The mean maternal age was 35.3 (31–43 years) and the mean paternal age was 37.6 (32–49 years). In the principal component analysis, the first and second principal components were correlated more strongly with maternal age and paternal age than with either the sperm motility rate, the speed of embryo development, embryo gender, or the timing of cryopreservation. The number of differentially expressed genes of maternal age is 990, and that of paternal age is 485. In most of those genes, maternal age and gene expression show a certain degree of inverse correlation. Gene ontology analysis by DAVID bioinformatics disclosed that maternal age dependent genes were involved in the eicosanoid metabolic process ($p < 0.01$), chromosome organization ($p < 0.01$), and nucleosome assembly ($p = 0.01$). Paternal age dependent genes were involved in amine transport ($p < 0.01$), T cell activation ($p < 0.01$), and negative regulation of proteolysis ($p < 0.01$). Maternal age dependent genes contain Aurora Kinase A (AURKA) ($p = 0.03$), Aurora Kinase C (AURKC) ($p < 0.01$), Pituitary Tumor-Transforming 1 (PTTG1) ($p < 0.01$), and Pituitary Tumor-Transforming 2 (PTTG2) ($p < 0.01$), which play crucial roles in cell cycle regulation, and therefore these genes have a higher possibility of human aneuploidy.

Limitations, reasons for caution: The link between gene expression and aneuploidy has not been adequately investigated. Furthermore, the freezing/thawing and the ICSI procedure might have caused changes to the gene expression profiles. Because of the small amount of materials, reverse transcription polymerase chain reaction (RT-PCR) was not performed.

Wider implications of the findings: We detected age-dependent gene expression profiles. Furthermore, when only euploid embryos were transferred, the implantation rate improved up to approximately 50–70%. Moreover, we believe that the combination of transcriptome assessment and preimplantation genetic screening (PGS) may potentially increase the implantation rate and live birth rate in the future.

Trial registration number: The study was approved by the Institutional Review Board of Tokyo Medical and Dental University in 2011 (IRB reference number: 2011-27-3-3).

P-233 Development and validation of a new Next Generation Sequencing-based Protocol to distinguish between balanced translocation and normal chromosomes embryos from robertsonian translocation carriers

Q. Zhao[1], Y. Xu[1], K. Yang[2], Y. Zeng[1], R. Li[1], J. Wang[1], X. Liu[2], L. Xing[2], T. Feng[2], C. Zhou[1]

[1]*The First Affiliated Hospital of Sun Yat Sen University, Reproductive Medicine Center, Guangzhou-Guangdong, China*

[2]*Peking Jabrehoo Med Tech. Ltd, Preimplantation Genetic Screening, Beijing, China*

Study question: Can a new next generation sequencing (NGS)-based protocol be used for distinguishing between balanced translocation and normal chromosomes embros from robertsonian translocation carriers?

Summary answer: The results of this retrospective study demonstrate that this new protocol is accurate and reliable, allowing identification of balanced translocation embryos from robertsonian translocation carriers.

What is known already: Robertsonian translocation carriers do not normally have phenotypic manifestation, but lead to increased risk of infertility, miscarriage and live birth of chromosomally unbalanced offsprings. Preimplantation genetic screen (PGS) is an effective way to improve pregnant outcome for those couples. The detection of embryonic aneuploidy abnormality by PGS has been widely used in clinical. However, it can't distinguish between balanced translocation and normal chromosomes in embryos from robertsonian translocation carriers yet. Now we developed a new protocol based on NGS platform to resolve this problem and designed a retrospective study to evaluate it's accuracy and reliability.

Study design, size, duration: The study consisted of a retrospective study involving a double blind parallel evaluation, with our new NGS-based protocol, STR-based haplotype analyses and fetal karyotype validation, of 49 blastocysts obtained from 4 robertsonian translocation familes during the period of January to October 2015. Consistency of results from the NGS-based protocol was compared with the results obtained by short tanderm repeat markers (STR)-based haplotype analysis or fetal karyotype from prenatal diagnosis.

Participants/materials, setting, methods: Four robertsonian translocation familes undergoing comprehensive aneuploidy screening by NGS-based PGS were enrolled in the study. Written informed consent was obtained and the study was approved by the Ethics Committee. A high depth NGS on the region near the centromere of chromosomes involving robertsonian translocation is adopted

to build the haplotype of these robertsonian translocation chromosomes. Finally, according to the haplotype, we can accurately distinguish between normal embryos, balanced translocation embryos and non-equilibrium translocation embryos.

Main results and the role of chance: Forty nine blastocysts from four robertsonian translocation carriers' couples were successfully detected aneuploidies by comprehensive chromosomes screening using low depth NGS, 17 (34.7%) of which carried a copy number imbalance. Our high depth NGS in targeted Robertersonian chromosomes region was also successfully applied to all these embryos. Then we constructed the haplotype of these robertsonian translocation chromosomes according to the above NGS results. Among the other 32 euploid embros, 18 (56.3%) carried the derivative robertsonian chromosome haplotype and 14 (43.7%) carried normal robertsonian chromosome haplotype. These results were exactly the same as STR markers based haplotype analysis and fetal karyotype.

Limitations, reasons for caution: This protocol is not capable of applying for the familes which lack of abnormal robertsonian chromosomes' embryos. Although this result validate the new protocol can accurately identify the normal chromosomes embryos from robertsonian translocation carriers' embros, broad-based clinical data are need to define the role of the new protocol.

Wider implications of the findings: This is the first report, to our knowledge, of successful clinical application of targeted NGS-based protocol to distinguish between balanced and normal chromosomes embryos from robertsonian translocation carriers' couples.

Trial registration number: Not applicable.

P-234 Is allowing Metaphase I oocytes time to progress to metaphase II a waste of time? A cohort analysis of 9,632 oocytes (25)

L. Tilia[1], C. Venetis[2], S. Kilani[3], S. Cooke[4], M. Chapman[2]
[1]*Maroubra, NSW, Australia*
[2]*University of New South Wales, Department of Women's and Children's Health, Sydney, NSW, Australia*
[3]*IVF Australia, Eastern Suburbs, Sydney, NSW, Australia*
[4]*IVF Australia, North Sydney, Sydney, NSW, Australia*

Study question: What is the developmental potential of Metaphase I oocytes and are the timings of oocyte pick-up (OPU) post-trigger, denudation and intracytoplasmic sperm injection (ICSI) important?

Summary answer: Late maturing oocytes have reasonable potential to produce euploid embryos and prolonging time-to-ICSI is associated with higher probability of first polar body extrusion and fertilization.

What is known already: Oocytes observed to be at metaphase I (MI) following denudation are thought to be severely compromised due to their lack of nuclear maturity. In vitro culture permits oocytes to continue their development, extrude the first polar body and progress to metaphase II (MII) hence allowing for ICSI to be performed. As a group, these oocytes, are believed to result in poor outcome potentially due to increased incidence of embryo aneuploidy. However, there are documented live births from oocytes originally assessed as immature following OPU. Currently, the exact developmental potential and the optimal management of these oocytes has not been established.

Study design, size, duration: This is a retrospective cohort analysis of 9,632 oocytes originating from all day-3 PGD/S cycles between 2011 and 2014. The exact time between the administration of the trigger for final oocyte maturation and the OPU (range: 33.7–40.4 h), between OPU and denudation (range: 0.2–6.2 h) and that between denudation and ICSI (range: 0.2–6.2 h) was recorded and extracted for each case. Furthermore, the nuclear maturation was assessed after denudation and extracted for the purposes of this study.

Participants/materials, setting, methods: Out of 9,632 oocytes collected, 1,225 were MIs (12.7%, 95% CI: 12.1–13.4) and at the time of ICSI 690 MIs had progressed to MIIs (56.3%, 95% CI: 53.5–59.1). These were followed up and fertilization rates, development of a good-or-top quality day-3 embryo and ploidy were assessed. Multivariable logistic regression analyses controlling for multiple confounders were performed with the use of the GEE framework in order to account for the non-independent nature of data.

Main results and the role of chance: As expected, the probability of MI-to-MII progression was increased with every additional hour between denudation and ICSI (odds ratio-OR: 1.72, 95% CI: 1.49–2.00), while it was reduced for every additional hour between OPU and denudation (OR: 0.43, 95% CI: 0.34–0.56) even after controlling for female age, type of protocol, type of trigger and time from trigger-to-OPU. Interestingly, the probability of fertilization was also higher in cases where the time between denudation and ICSI was longer (OR: 1.40, 95% CI: 1.06–1.83) after controlling for female age, type of protocol, type of trigger and time from trigger-to-OPU.

Trigger-to-OPU, OPU to denudation or denudation to ICSI was not associated with the probability of a good-or-top quality day-3 embryo formation or the presence of a euploid day-3 embryo after controlling for female age, type of protocol, type of trigger and time from trigger-to-OPU.

Out of all MI-to-MII oocytes injected, 5.3% (95% CI: 3.3–7.4) formed day-3 euploid embryos which was lower (OR: 0.39, 95% CI: 0.27–0.56) as compared to the proportion of MIIs that formed day-3 euploid embryos (12.6%; 95% CI: 11.5–13.6).

Ongoing pregnancy rates following a transfer of a single euploid blastocyst were not significantly different between embryos originating from MI-to-MII oocytes (6/24) and MII oocytes (172/487) (rate difference:-10.3%, 95% CI: −24.0 to +10.0%).

Limitations, reasons for caution: These patients have various indications requiring PGD/S and may not reflect the general subfertile population. Furthermore, solid conclusions regarding ongoing pregnancy rates cannot be drawn due to the small number of embryo transfers from the MI-to-MII cohort of embryos.

Wider implications of the findings: Delaying the timing of ICSI for MI oocytes seems to allow them to progress to MII oocytes and also seems to increase fertilization rates. These embryos, although less likely to be euploid compared to those originating from MII oocytes, can still add to the reproductive potential of an ICSI cycle.

Trial registration number: None.

P-235 Single Day 3 Embryo Transfer (D3SET) versus Single Blastocyst Transfer (SBLT) in young patients

E. Kasterstein[1], D. Strassburger[1], B. Maslansky[1], D. Komarovsky[1], O. Bern[1], D. Hadari[1], O. Lemberberg[1], A. Raziel[1], Y. Gidoni[1], J. Barkat[1], I. Ben Ami[1], M. Youngster[1], R. Ron-El[1]
[1]*Assaf Harofe Medical Center, IVF, Zerifin, Israel*

Study question: Comparison of the pregnancy rate in single embryo transfer on day 3 (D3SET) with single blastocyst transfer (SBLT) in young patients in terms of pregnancy rate.

Summary answer: D3SET pregnancy rate compared to SBLT was comparable. Significantly higher number of frozen embryos was achieved in D3SET but cumulative pregnancy rate should be examined.

What is known already: The trend of blastocysts transfer on Day 5 rather than day 3 embryos transfer has been recently more in use, since results seem to be better. Chocrane review on this topic showed live birth of 29.4% with Day 2 or3 ET compared with 36.0% in BLT. The cumulative pregnancy rate is even more complicated to follow because of the long period of time which these studies demand. In terms of multiples and missed abortions no differences were found between transfer of D2/D3 embryos and blastcysts.

Study design, size, duration: A prospective study of D3SET versus D5 SBLT was started 2 years ago. All patients at the age of ≤ 30 years were offered a single embryo transfer. After giving them the information of the possibility that no blastocyst development can lead to no transfer they could choose between D3SET and SBLT. Patients were allocated to this study only if it was their first cycle and had at least two top quality embryos on day3.

Participants/materials, setting, methods: The patients, who fulfilled the inclusion criteria, had to choose between D3SET and SBLT. Those who decided for D3SET, underwent the transfer, the remaining top quality embryos were vitrified. The intermediate qualified embryos were cultured to the BL stage and were frozen once they reached blastulation with Gardner Score (3–5AA, 3–5AB, 3–5BA). In the SBLT group the remaining blastocysts qualified with the same Gardner Score were also vitrified.

Main results and the role of chance: Twenty five patients at the age of 27.7 ± 4.27 y were in the D3SET group and 16 patients aged 25.6 ± 4.35 y in the SBLT one. Mean number of injected oocytes was 14.1 ± 7.8 compared with 18.0 ± 6.9. Fertilization and cleavage rates were comparable 10.7 ± 6.12, 14.2 ± 6.20 and 10.5 ± 6.23, 13.8 ± 6.32), respectively.

In the D3SET group; out of 263 embryos, 25 were transferred, 121 were frozen (46.0%), 44 of 109 cultured embryos, developed into BL (40.4%) of them 22 BLs were frozen (50%).

In the SBLT group; out of 221 embryos, 123 developed into BLs (58.3), 94 D5 AND 29 D6 (76.4% and 23.6% respectively). 16 BLs were transferred and 41 BLs (33%) were frozen. Altogether 143 (54.4%) embryos and BLs were frozen in the D3SET group and 41 (33%) BLs were frozen in the SBLT group ($p < 0.0001$). Eleven (44%) clinical pregnancies were achieved in the D3SET group, and 8 (50%) in the SBLT group (NS).

Limitations, reasons for caution: Since the study is based on SET, the time needed to get well established data is very long. Moreover, to examine the cumulative pregnancy rate in such groups in which the pregnancy rate are so high needs many years of follow up

Wider implications of the findings: In view of the results, the advantage of SBLT has still to be examined. The fact that pregnancy rate in these groups with such inclusion criteria demonstrated comparable results with significantly more frozen embryos on D3SET put in doubt the advantage of BLT in young patients

Trial registration number: NA.

P-236 Establishment of appropriate methods for human oocyte-activation by PLCZ1 cRNA (PLCZ) injection

T. Yamaguchi[1], A. Tanaka[1], M. Nagayoshi[1], T. Miki[1], T. Ichiyama[1], M. Ito[2], K. Kuroda[3]

[1]*Saint Mother Hospital, Department of Obstetrics and Gynecology, Kitakyushu, Japan*

[2]*Hamamatsu University School of Medicine, Department of Infectious Diseases, Hamamatsu, Japan*

[3]*Juntendo University School of Medicine, Department of Obstetrics and Gynecology, Tokyo, Japan*

Study question: Is PLCZ injection into human oocyte a better method for oocyte-activation compared to other methods like Electrical stimulation or Ionomycin?

Summary answer: We found the optimal concentrations of PLCZ to activate oocytes physiologically, with a similar pattern of Ca^{2+} oscillations to that of in vitro fertilization oocytes.

What is known already: At fertilization, mammalian oocytes show repetitive transient Ca^{2+} transients each of which is due to Ca^{2+} release from the endoplasmic reticulum through Inositol 1,4,5-trisphosphate (IP_3) receptors. During fertilization, the so called sperm factor, is released into the oocyte and induces series of Ca^{2+} spikes that are required for oocyte activation. They are called Ca^{2+} oscillations. IP_3-producing enzyme phospholipase C zeta (PLCZ1) is a strong candidate to be the sperm factor.

Study design, size, duration: We performed this retrospective study to investigate the usefulness of PLCZ injection into human oocyte. 94 fresh M-II oocytes from 34 patients were used to find optimal concentration to activate human oocytes and 67 oocytes from 29 patients were used to compare with the other oocyte activation methods from January 2013 to December 2015.

Participants/materials, setting, methods: Optimal RNA concentration for oocyte activation was examined by injection with various concentrations of PLCZ into human oocytes from IVF patients who had consented to this experiments. After injection, the rate of PN formation was checked and the intracellular Ca^{2+} concentration of injected oocytes was monitored by Fluo8H AM fluorescent Ca^{2+} indicator.

Main results and the role of chance: Optimal concentration of PLCZ1 to activate human oocytes was 100 ng/μl in the examination using 94 fresh M-II oocytes (Table 1).

	Concentration of PLCZ (ng/μl)	0.01 (*n*=13)	0.05 (*n*=14)	0.1 (*n*=4)	1 (*n*=6)	5 (*n*=25)	10 (*n*=11)	100 (*n*=18)	1000 (*n*=3)
Day 1	Second polar body (%)	23.1	14.3	0	0	16.0	9.1	66.7	66.7
1PN (%)	23.1	14.3	0	0	8.0	9.1	66.7	66.7	

The pattern of Ca^{2+} oscillations by PLCZ injection was similar to the pattern of Ca^{2+} oscillations seen in the in vitro fertilized oocytes (Table 2).

	Oocytes (*n*)	Day 1	Day3 (≥7 cell)
1PN+ First polar body number (%)	Cleaved embryos number (%)		
Ionomycin	15	66.7 (10/15)	40.0 (4/10)
PLCZ1	35	65.7 (23/35)	60.1 (14/23)
Electrical stimulation	17	52.9 (9/17)	44.4 (4/9)

In comparison with the other oocyte activation methods, cleavage rate was the highest in the oocytes activated by PLCZ. However it showed no significant differences in pregnancy rates.

Limitations, reasons for caution: Birth of healthy offspring and reproduction of healthy second generation from mouse oocytes activated by PLCZ was reported in 2008. However healthy human births have not been reported after using this method. The safety of PLCZ injection to human health should be further examined for future clinical applications.

Wider implications of the findings: First it will rescue the unfertilized oocytes after ICSI due to insufficient oocyte activation, which accounts for approximately 40% of all unfertilized oocytes. Secondly, this new oocyte activating method which is more physiologically oocyte activation will be beneficial for improving clinical outcome of ROSI.

Trial registration number: None.

P-237 The moment of early cleavage in embryos originating from donor eggs, captured by time-lapse, determines morphological quality on days 2, 3 and 5

Á. Martínez Moro[1], N. Uriarte[1], E. Padilla[1], J. Garcia[1], F. Rodriguez[1], J. Rayward[1], L. Lopez Yañez[1]

[1]*Procreatec SLP, Laboratorio, Madrid, Spain*

Study question: The study's purpose was to establish a relationship between the moment of early cleavage and morphological embryo quality on days 2, 3 and 5.

Summary answer: Embryos that divided between 23.5–25.5 hours have a greater probability of developing good morphological quality on days 2, 3 and 5.

What is known already: Early cleavage can be used as an embryo selection factor. It is a morphokinetic marker directly linked to embryo morphology, implantation potential and pregnancy rate. The evolution of assisted reproduction has permitted the establishment of new non-invasive embryo selection methods such as time-lapse analysis systems (EmbryoScope®). The markers that this technology has helped define have displaced the first mitotic division as a non-invasive indicator of good embryo quality to using other indicators such as t3 and t5, which correspond to the appearance of the third and the fifth blastomere.

Study design, size, duration: Between November 2013 and March 2015, embryos originating from 879 donor eggs retrieved from 104 donors were retrospectively observed using a time-lapse system: EmbryoScope®. Out of the total, 481 embryos were expanded blastocysts on day 5. The moment of early cleavage of these embryos was analyzed in relation to their morphological quality. The ASEBIR (Spanish Association of Reproduction Biology) classification was used for day 2 and 3 embryos. For day 5, Gardner's classification was utilized.

Participants/materials, setting, methods: This study took place in a private fertility clinic in Madrid, Spain. Embryos originating from 879 donor eggs were included in this analysis. Exclusion criteria were cryopreserved ovocytes, severe masculine factor and PGD. Embryos were classified according to the moment of the first cellular division and their morphological quality on days 2, 3 and 5. The time of early cleavage was analyzed based on sensitivity, specificity, predictive value, probability coefficient and efficiency.

Main results and the role of chance: According to our results, embryos that divide between 23 and 26 hours present good morphological quality on days 2 and 3. In the analysis of blastocysts, better morphological quality is found in those embryos with early division between 24 and 25 hours (Specificity; 0.86, Sensitivity 0.17). In studying the relation between embryo development on days 2, 3 and achieving the blastocyst stage, our data show better embryo quality in those whose first division took place between 24 and 25 hours (Specificity = 0.90 Sensitivity = 0.22). Moreover, we observed that those embryos with inferior quality presented early division before 23 hours on day 2 and 3 and after 25.5 hours when analyzing the intervals on day 5.

Limitations, reasons for caution: Our study only evaluated healthy women between 19 and 29. Due the fact that not all transfers were single embryo transfers pregnancy rates were not reported.

Wider implications of the findings: Because early cleavage is a morphokinetic feature, its exact time can be observed almost exclusively using time-lapse systems. The optimum time for cleavage to take place has been defined in this study. It is an easy, non-invasive prediction marker of embryo quality on days 2, 3 and 5.

Trial registration number: None.

P-238 Is pregnancy rate following transfer of high quality blastocysts vitrified at day 6 comparable to that of blastocysts vitrified at day 5?

J. Meriano[1], J. Haas[2], R. Casper[2], C. Laskin[2], K. Cadesky[2]
[1]*TRIO Fertility, Embryology, Toronto, ON, Canada*
[2]*TRIO Fertility, IVF Clinic, Toronto, ON, Canada*

Study question: Is there a difference in pregnancy rates between high quality blastocysts vitrified on day 6 versus blastocysts vitrified on day 5 after fertilization?
Summary answer: Transferring blastocysts vitrified on day 5 gave a higher clinical pregnancy rate compared to high quality blastocysts vitrified on day 6.
What is known already: The implantation rate and clinical pregnancy rate is higher after transferring blastocysts compared to cleavage stage embryos, during fresh and frozen cycles. Previous studies have showed decreased pregnancy rate for transferring blastocysts day 6 compared to blastocysts day 5 during fresh cycles. However, studies involving frozen thawed blastocyst transfers have reported conflicting results regarding whether the rate of blastocyst formation prior to cryopreservation affects treatment outcome.
Study design, size, duration: This was a retrospective cohort study of 820 freeze/thaw cycles of blastocysts vitrified either on day 5 or day 6 and transferred between January 2012 and October 2015. Vitrification in these cases was carried out on day 6 due to insufficient expansion of the embryos on day 5.
Participants/materials, setting, methods: 820 vitrification warming cycles and embryo transfers were included in the study. 555 of the cycles included blastocysts vitrified at day 5 and 265 cycles included blastocysts vitrified at day 6. The embryos were warmed and, transferred on day 6 of progesterone in hormonally prepared cycles.
Main results and the role of chance: The age of the patients and the proportion of embryos that survived the warming process were comparable between the two groups. More top quality embryos were transferred in the group in which blastocysts were vitrified day 6 (1 vs. 1.1, $p < 0.001$) but the clinical pregnancy rate (32% vs. 44%, $p = 0.002$) and the ongoing pregnancy rate (28% vs. 41%, $p < 0.001$) were higher in the group in which blastocysts were vitrified on day 5. Multivariate regression analysis adjusting for patient's age, number of embryos transferred, number of top quality embryos transferred (≥3BB) and treatment protocol demonstrated that the day 6 vitrified group had a significantly lower clinical pregnancy rate compared to the day 5 vitrified group (OR 0.54, 95% CI 0.38–0.76).
Limitations, reasons for caution: There are other factors that can influence the pregnancy rate such as the physician or the embryologist performing the transfer, difficulty inserting the transfer catheter, endometrial thickness and patter, subendometrial contractions to name a few. Those factors were not controlled for in the study.
Wider implications of the findings: Although the day 6 blastocyst morphology after warming is at least as good as that of blastocysts vitrified on day 5, the clinical pregnancy rate following frozen embryo transfer is significantly lower with blastocysts vitrified on day 6 compared to blastocysts vitrified on day 5.
Trial registration number: none.

P-239 A comparative analysis of fertilization rate and clinical outcome in sibling human oocytes fertilized by split insemination in patients with teratozoospermia

W.Y. Son[1], G. Younes[1], M.H. Dahan[1]
[1]*MUHC McGill University Health Center Reproductive Centre, Obstetrics and Gynecology, McGill University Health Center, McGill University, Montreal, QC, Canada*

Study question: What are the laboratory and clinical outcomes of intracytoplasmic sperm injection (ICSI) vs. conventional insemination using sibling oocytes in IVF cycles for patients with teratozoospermia?
Summary answer: The fertilization-rate and blastocyst quantity are statistically higher with ICSI than with conventional IVF. Sub-analysis showed this was due to those with strict morphology ≤ 4%.
What is known already: Kruger proposed that sperm classification on the basis of strict morphologic criteria is a predictor for fertilization. However, this has fallen out of favor with some studies having shown fertilization rates are unaffected by morphology. Few studies have evaluated ICSI and spontaneous sperm penetration at IVF cycles in sibling oocytes.
Study design, size, duration: All patients treated by a physician with Kruger morphology ≤ 9% on semen analysis from 01-2013 to 12-2015, had 50% ICSI, 50% IVF ordered, for their first IVF cycle. Up until 2013 all patients with morphology ≤ 5% had 100% ICSI ordered. Felling evidence no longer supported this, but fearing fertilization failure, 50% ICSI was ordered instead. Subsequently permission was obtained to evaluate the database retrospectively. Patients with orders were recorded prospectively. 140 had IVF ordered.
Participants/materials, setting, methods: 124 patients underwent IVF, 103 patients underwent 50% ICSI, 50% IVF and were included in the study. 20 patients had 100% ICSI due to poor sperm quality as determined by the laboratory at the day of insemination. One patient had 100% IVF performed due to immature oocytes.

Paired samples statistics were used for laboratory outcome comparisons. Chi squared tests were used for pregnancy outcomes. Data is presented as mean ± standard deviation.
Main results and the role of chance: A total of 1162 mature oocytes were obtained: 606 were assigned to IVF and 556 to ICSI by the embryologists in a blinded fashion. The mean number of oocytes per patient was 14.2 ± 8.6, mean MII oocytes were 5.9 ± 4.2 and 5.4 ± 3.8 in the conventional IVF and ICSI groups respectively ($p = 0.04$), favoring IVF.

The fertilization rate in ICSI was higher than in conventional IVF (74.28% vs. 47.02%, $p < 0.0001$). 100% fertilization failure was reported in 25 patients' IVF and 6 patients' in ICSI ($p < 0.0001$).

The mean number of day 2 embryos was higher in ICSI as compared to IVF (3.95 ± 3.26 vs. 2.76 ± 2.93, $p = 0.001$) and similarly day 3 embryos ($p < 0.0001$). There were more blastocysts from ICSI that with IVF ($p = 0.006$) and they were better grade ($p = 0.049$).

Sub-analysis showed that ICSI was statistically favored over IVF only in cases with morphology ≤ 4. Comparison of fertilization rates, embryo quantity and quality lost significance when evaluate couples with morphology ≥5.

Best embryo for transfer was selected blinded by the embryologists. No difference occurred between ICSI and IVF for: pregnancy rates ($p = 0.189$), clinical pregnancy rates ($p = 0.487$), miscarriage rates ($p = 0.465$), and live birth rates ($p = 0.44$).
Limitations, reasons for caution: The study's main limitations are the relative small sample size and its retrospective design. Nevertheless, this drawback seems to be outweighed by the fact that medical records included complete clinical information, and no patients were lost since they were prospectively enrolled in the database.
Wider implications of the findings: ICSI should be used when normal sperm morphology ≤ 4%. ICSI improves fertilization and embryo quality and quantity in this group. Conclusions cannot be drawn from pregnancy outcomes due to the bias created by not randomizing choice with intention to treat, which fails to account for no fertilization in IVF.
Trial registration number: No trial registration.

P-240 Group vs. individual culture performed in single medium: a prospective randomized sibling-oocyte study

A. Oliva[1], E. Rega[1], M.F. Starita[1], M.G. Amendola[1], A. Colicchia[1], P. Giannini[1], C. Piscitelli[1], G. Fabozzi[1]
[1]*Casa di Cura Villa Margherita, FertiClinic, Rome, Italy*

Study question: Does group culture perform better than individual culture using single medium in term of blastocyst formation rate (BFR) and overall blastocyst quality?
Summary answer: Group culture does not show any improvement compared to individual culture in term of BFR and overall blastocyst quality when performed in single culture medium.
What is known already: Individual culture offers an easy way to follow embryo development individually, however, different authors have demonstrated that group culture improves embryo viability in mice, cattle, felids and mammals. These studies have been conducted using different media, mainly belonging to the category of sequential ones. To our knowledge no studies applying a prospective comparison between individual and group culture have been conducted in human IVF using single medium without refreshment and leaving embryos undisturbed from day-0 up to the blastocyst stage.
Study design, size, duration: This was a prospective randomized study of 163 sibling oocytes conducted from September to December 2015. Injected oocytes were randomly assigned to Group A and Group B and allocated individually or

in groups of 3–4 oocytes respectively in dish wells. Randomization was performed by splitting the oocytes under a stereomicroscope not allowing for identification of oocyte quality.
Participants/materials, setting, methods: A total of 21 women (aged ≤ 39 years) undergoing oocyte retrieval procedure for intracytoplasmic sperm injection (ICSI) at Ferticlinic, Villa Margherita, were involved in the study. Culture was performed without refreshment in 35 µl of single-step medium (One-Step, SAGE) up to blastocyst stage in multi-gas incubators (Sanyo) at 37°C, 5% 02, 5.5% CO2. Blastocyst formation rate was the main outcome measure.
Main results and the role of chance: No statistically significant difference was detected in the fertilization rate between group A and B, 74.6% vs. 77.1% respectively, ($p = 0.755$). No statistically significant difference was detected on day-3 with regard to cleavage rate, 100% vs. 96.4% ± 12.0 ($p = 0.186$) and top quality embryo rate, 70.6 ± 36.8% vs. 69.2% ± 28.9 ($p = 0.853$) for group A and group B respectively. On day-5, no significant difference was detected between the two groups with respect to BFR (group A 69.7% ± 31.3 vs. group B 66.3% ± 9.9, 95% CI = −11.3–18, $p = 0.638$) and top-quality blastocyst rate (group A 35.2% ± 42.1 vs. group B 30.2% ± 42.6, $p = 0.686$).
Limitations, reasons for caution: This was a prospective randomized study with a limited sample size. The number of patients should be increased in order to confirm these preliminary data and clinical outcomes should be examined as well.
Wider implications of the findings: We speculate that individual culture in single medium probably recreates a sort of "group effect": in group-culture the beneficial effect is due to paracrine interactions that enhance autocrine factors, while in single-culture it is determined by the accumulation of autocrine factors thanks to the use of single medium without refreshment.
Trial registration number: None.

P-241 Cell exclusion during embryo development: is there an incidence? Analyse of more than 1500 time-lapse recording

C. Splingart[1], J. Lammers[2], A. Catteau[2], A. Reignier[2], T. Freour[2]
[1]*CHU Nantes, Nantes, France*
[2]*CHU Nantes, 44, Nantes, France*

Study question: The study aim to evaluate the impact of cell exclusion during compaction on blastocyst formation and implantation using the Embryoscope®, a time lapse monitoring system.
Summary answer: Cell exclusion impacts blastocyst formation and the proportion of good quality blastocyst obtained but it does not show an effect on implantation rate.
What is known already: The onset of compaction can occur from the 4-cell to the 16-cell stage embryo follows the activation of the embryonic genome. At this stage, blastomeres begin to compact tightly and cell boundaries progressively disappear until the fully compaction, this, having an important influence on the subsequent processes of blastocyst formation.
Study design, size, duration: We retrospectively analysed all the embryos obtained after ICSI cycles cultured up to the blastocyst stage in the Embryoscope® over a 3 years period in our IVF unit. Embryos were classified according to morphological aspect at the compaction stage, i.e., with or without cells out of the morula. 1552 videos of embryo development were analysed with 570 embryos in the cell exclusion group and 982 in the control group.
Participants/materials, setting, methods: Immediately after ICSI, oocytes were placed into the Embryoscope®. Each embryo was investigated by detailed time-lapse analysis measuring the exact timing of the developmental events in hours after ICSI procedure. We particularly observed the time of compaction and the number of cells involved in it in order to see any cell exclusion.
Main results and the role of chance: No difference was found in embryos characteristics of both groups in kinetic development until the onset of compaction, where embryos showing excluded cells reached compaction later than the control group: 101.9 ± 11.9 h vs. 95.9 ± 10.5 h to reach compaction, $p < 0.01$. Moreover, we also noted a significantly higher proportion of abnormal cleavage (1 to 3 or 2 to 5 cells) in cell exclusion group compared to the control group (24.2% vs. 10.2%, $p < 0.01$) In addition, we observed significantly fewer good quality blastocysts (i.e., eligible for transfer or cryopreservation) in the cell exclusion group than in the control group (33.8% vs. 58.5%, $p < 0.01$). Nevertheless, regarding single embryo transfer, no difference was found in terms of pregnancy rate (41.7% vs. 48.7%) or on on-going pregnancy (31.6% vs. 33.6%).
Limitations, reasons for caution: This study was retrospective and monocentric, preventing from generalizing our results to other ART centres.
Wider implications of the findings: Time-lapse systems are known to optimize embryo culture thanks to uninterrupted culture and continuous surveillance. In this study we reported that although cell exclusion seems to delay compaction and impact blastocyst formation, it has, no effect on the result implantation rate.
Trial registration number: none.

P-242 PI3K signaling Pathway gene expression analysis in cumulus cells by Real-Time PCR

V. Gatta[1], P. G. Artini[2], C. Tatone[3], M. Vento[4], R. Ciriminna[5], C. Di Pietro[6], M. D'Aurora[1], S. Sperduti[1], L. Stuppia[1]
[1]*University of Chieti, Department of Psychological, Health and Territorial Sciences, Chieti, Italy*
[2]*University of Pisa, Department of Clinical and Experimental Medicine University of Pisa, Pisa, Italy*
[3]*University of L'Aquila, Department of Life, Health, and Environmental Sciences, L'Aquila, Italy*
[4]*Canizzaro Hospital, IVF Unit, Catania, Italy*
[5]*AMBRA-Associazione Medici e Biologi per la Riproduzione Assistita, IVF Unit, Palermo, Italy*
[6]*University of Catania, Department of BioMedicine and BioTechnology, Catania, Italy*

Study question: Could be cumulus cells gene expression profile explored as potential markers of oocyte competence?
Summary answer: Data have shown selective modulation of transcripts involved in the PI3K signaling pathway in relation to IVF outcome.
What is known already: CCs closely interact with the oocyte and share the same microenvironment. CCs gene expression analysis provides an indication of the microenvironment in which oocyte maturation undergoes. DNA microarray technology has been used to analyze the CCs transcriptome obtained from ART patients receiving different stimulation protocols. Differential gene expression has been taken as evidence of modifications in signaling and metabolic pathways that could potentially affect oocyte quality. In particular we recently evidenced the expression modulation of the AKT/PI3K pathway, important mediator of cumulus-oocyte complex development.
Study design, size, duration: To understand if the expression of CCs genes in the PI3K pathway could be potential markers of oocyte competence we analyzed the expression of 92 transcripts of this pathway in 10 CCs from patients with negative IVF outcome and 10 CCs associated to positive outcome. Samples inclusion criteria: derived from cumulus-oocyte complexes containing mature oocytes showing polar body and associated to single embryo transfer. The negative/positive outcome has been respectively defined by implantation failure/success.
Participants/materials, setting, methods: Cumulus-oocyte complexes were collected at the University of Pisa and Hospital of Catania IVF laboratories from 20 healthy patients undergoing standard IVF protocols. Total RNA was extracted from CCs using the Arcturus Pico Pure RNA Isolation Kit. A Real Time approach was used to analyze PI3K pathwaygene expression loading a 96-well custom TaqMan Array. Expression data of CCs associated with positive IVF outcome were compared to data from negative outcome samples.
Main results and the role of chance: Data analysis showed the selective modulation of transcripts involved in the PI3K Signaling Pathway in relation to IVF outcome. In particular our analysis demonstrated that 11 transcripts in this pathway were significantly down-regulated in all samples of positive CCs when compared to negative CCs. This expression pattern seems to modulate mainly the apoptotic processes in CCs. Among these genes, AKT1, BCL2L1, and SHC1are particularly interesting; they, in fact, are known to regulate CCs growth and apoptosis. These data could indicate that CCs associated to positive outcome oocytes show specifically a reduced expression of genes involved in apoptosis regulation, whereas higher expression of the same transcripts in CCs associated to negative outcome, could reflect oocyte with low rate of maturation and quality.
Limitations, reasons for caution: High sensitivity of CCs transcriptome to intrinsic and extrinsic factors related to the patient, such as metabolic status, reproductive health and hormonal stimulation.
Wider implications of the findings: The selected non-invasive biomarkers could represent prognostic factors to assess oocyte competence in IVF patients

to increase live birth rate. Moreover, a final extensive analysis of the specific role of the modulated transcripts could be useful to unravel the molecular basis linking oocyte quality and developmental CCs.
Trial registration number: NA.

P-243 Embryo development after continuous culture in two commercial single-step media: a prospective randomized study with sibling oocytes

Study question: Is embryo development different after continuous culture in Sage 1-step vs. Continuous Single Culture (CSC) media?
Summary answer: Embryo development is similar after continuous culture in Sage 1-step or CSC media.
What is known already: The formulation of single-step media has allowed the culture of preimplantation human embryos to the blastocyst stage in an uninterrupted and continuous manner without media renewal. Several single media have recently become commercially available, and therefore comparison of their efficacy is justified.
Study design, size, duration: Prospective randomized study including 633 oocytes retrieved from 42 IVF patients between October 2014 and April 2015. Randomization software was used to allocate oocytes from each cohort between groups in a 1:1 ratio.
Participants/materials, setting, methods: A total of 633 metaphase-II oocytes from 42 women (aged ≤ 40 years, with ^{3}10 oocytes retrieved) were randomly allocated to continuous culture in either Sage 1-step medium (Origio) ($n = 316$) or CSC medium (Irvine Scientific) ($n = 317$). Embryo transfers were performed on Day 3 (9 patients) or Day 5 (31 patients). Two patients had all blastocysts frozen on Day 5 due to occurrence of severe OHSS. Values are expressed as mean (95% CI).
Main results and the role of chance: Fertilization rates [65.8% (58.4–73.2) vs. 67.1% (60.5–73.7), $p = 0.749$] and cleavage rates [95.1% (92.2–98.0) vs. 98.3% (96.3–100), $p = 0.076$] were similar in Sage 1-step and CSC groups. On Day 3, proportion of embryos with good morphology [62.5% (52.4–72.6) vs. 64.3% (54.9–73.7), $p = 684$], proportion of embryos with ≥6-cells [81.5% (74.0–89.0) vs. 83.3% (75.9–90.7), $p = 0.734$] and proportion of embryos with ≤ 10% fragmentation [68.8% (58.6–79.1) vs. 68.6% (59.2–78.0), $p = 0.975$] did not differ. In the subgroup of 33 patients who had embryo culture/transfer on Day 5, blastocyst formation rates [53.6% (45.0–62.2) vs. 51.9 (42.6–61.2), $p = 0.755$], proportion of at least full blastocysts [45.0% (36.5–53.5) vs. 44.0% (35.5–52.50, $p = 0.850$], proportion of good quality blastocysts (≥3BB) [36.8% (28.5–45.1) vs. 36.1% (27.5–44.7), $p = 0.897$], and proportion of blastocysts with grade A inner cell mass [64.6% (52.7–76.5) vs. 56.7% (43.6–69.8), $p = 0.372$] were comparable in Sage 1-step and CSC media, respectively. The proportion of blastocysts with grade A trophectoderm [67.2% (56.9–77.5) vs. 48.7% (36.4–61.0)] appeared to be higher in Sage 1-step medium compared to CSC medium ($p = 0.037$). The proportion of embryos transferred [26.1% (20.4–31.9) vs. 21.0% (14.6–27.4)], and frozen [28.8% (21.0–36.6) vs. 33.8% (24.5–43.1)], as well as embryo utilization rates [55.6% (47.7–63.5) vs. 54.8% (45.7–63.9)] were similar in Sage 1-step and CSC media.
Limitations, reasons for caution: This is a prospective randomized study with sibling oocytes comparing embryo characteristics in Sage 1-step and CSC media. In order to study the comparative effect of these two single-step media on the probability of pregnancy it is necessary to perform an RCT in which the randomization unit will be patients.
Wider implications of the findings: Continuous culture of embryos in Sage 1-step and CSC media is associated with similar embryo development and utilization. Both single-step media appear to provide adequate support during in-vitro preimplantation embryo development.
Trial registration number: NCT02302638.

P-244 A prospective randomized controlled study (RCT) depicting better blastocyst outcome and pregnancy rate after single step media culture vs sequential media culture in IVF-ICSI Cycles

R. Singh[1], M. Singh[2], A. Jindal[3], P.C. Jindal[3]
[1]Bhopal Test-Tube-Baby Centre, Embryology, Bhopal, India
[2]BTTBC, Embryology, Bhopal, India
[3]BTTBC, Infertility, Bhopal, India

Study question: This study was to encourage a minimum of embryo manipulation and to determine if sequential media are really necessary in order to meet the changing requirements of embryo?
Summary answer: Study shows Better blastocyst outcome after use of single-step-media, allowing the embryo itself to choose the necessary nutrients while maintaining a more stable culture environment.
What is known already: It has been suggested that sequential-media that mimic the physiological conditions in the female reproductive tract are required for optimal development of the human embryo to the blastocyst stage. Sequential-media were introduced in order to meet the changing requirements of the developing embryo in vitro. However, there has been renewed interest in the use of single-step-media, which allow the embryo itself to choose the necessary nutrients while maintaining a more stable culture environment. Previous studies suggest that sequential media do not appear superior to single-step media. Use of culture media that encourage a minimum of embryo manipulation must be explored.
Study design, size, duration: To compare blastulation and pregnancy rates in two different embryo culture systems: single step Versus Sequential culture from day 1 to day 5, 184 patients below 40 years of age were included between 2014 and 2015, who were randomised into two groups by a computer generated list, after IVF-ICSI. The same protocol was applied. Primary outcome measured were number of Blastocysts obtain at Day 5 and kinetics of blastocyst. Secondary outcome were pregnancy rates. Participants/materials, setting, methods: 84 infertile patients below 40 years of age were included between 2014 and 2015, were randomised into two groups by a computer, after IVF-ICSI cycles. In random half of the oocytes were treated with a sequential system the other half with a single step. All embryos are cultured by group under oil overlay. Primary outcome measured were number of Blastocysts obtain at Day 5. Secondary outcome measured were implantation and pregnancy rates.
Main results and the role of chance: The blastulation rate obtained with the Single-Step-Media are 43% vs. 40% with the Sequential-Media. Pregnancy rates with the Single-Step-Media are 39% vs. 37% with the Sequential-Media. Results also show faster kinetics with more bastocytes with the single steps culture but clinical pregnancy rate were not significantly different in the two groups ($p > 0.05$). (Student *t*-test and chi square test). The objective of this study was to determine if sequential media are really necessary.
Limitations, reasons for caution: This study shows an effect of culture-Media for human preimplantation embryos on embryo quality and success-rates. The existing data are insufficient to allow the selection of the best culture medium and thus more designed RCTs are necessary for both currently used culture media as well as newly introduced culture media.
Wider implications of the findings: Results show more blastocysts available for transfer and vitrification with the use of Single-Step-Media although clinical pregnancy rate were not significantly different in the two groups. The continuous uninterrupted protocol, without medium renewal remains in effect without detriment to clinical outcomes. Less manipulation of embryos remains a priority in order to reduce epigenetic risks.
Trial registration number: BTTBC/2014/09.

P-245 Predictive value of human calcium pattern analysis on the benefit of assisted oocyte activation in cases of failed fertilization after ICSI

M. Ferrer Buitrago[1], Y. Lu[1], S. Lierman[1], E. Van den Abbeel[1], M. Van der Jeught[1], D. Deforce[2], L. Leybaert[3], P. De Sutter[1], B. Heindryckx[1]
[1]Ghent University Hospital, For Reproductive Medicine, Ghent, Belgium
[2]Ghent University, Pharmaceutical Biotechnology, Ghent, Belgium
[3]Ghent University, Basic Medical Sciences, Ghent, Belgium

Study question: Does human calcium pattern analysis contribute to predict the benefit of assisted oocyte activation (AOA) after ICSI-failed fertilization?

Summary answer: Human Oocyte Calcium Analysis (HOCA) predicts AOA outcome. HOCA is more sensitive than heterologous-ICSI tests to reveal sperm-related oocyte-activation deficiencies in sperm causing failed-fertilization after ICSI.

What is known already: Heterologous ICSI-based tests such as mouse oocyte activation test (MOAT) and mouse oocyte calcium analysis (MOCA) are used to discern whether ICSI-failed fertilization is due to sperm or oocyte factors. The diagnosis is valuable to counsel AOA in following cycles. Although they can reveal severe sperm deficiencies, presumably related to the oocyte-activation factor PLCζ, AOA doesn't benefit all cases in which sperm activation capacity was considered normal. Human-PLCζ shows greater potency than mouse-PLCζ and certain sperm defects could remain undetected due to this variability. Thus, human sperm capable of activating mouse oocytes, may still fail to induce human oocyte activation.

Study design, size, duration: Patients included showed fertilization failure after ICSI and moderate (70–84%) to normal (>85%) oocyte activation rate after MOAT. As is practiced in our setting, ionophore based-AOA was applied to 50% or 100% of the oocytes depending on the MOAT result. All patients were further analysed by MOCA and HOCA to determine the calcium oscillations profile compared to sperm samples with known fertilization potential as control. The results were retrospectively contrasted with the AOA outcome.

Participants/materials, setting, methods: Donated oocytes discarded from IVF/ICSI, as oocytes containing *smooth endoplasmic reticulum aggregates (SER)* and GV or MI in vitro matured MII were collected and vitrified. After ICSI, Ca^{+2}-oscillations were detected using a radiometric method for a duration of 2 h (MOCA) or 10 h (HOCA) using the Ca^{+2}-indicators Fura2/P3E-AM (λ_{exc}340/380 nm), respectively. Product of amplitude (ΔFluorescence from baseline, A) and frequency (total number oscillations, F), and area under the curve (total calcium released, AUC) were calculated using Clampfit_10.2.

Main results and the role of chance: Patients studied (n = 10) showed moderate (n = 3) to normal activation rates (n = 7) after MOAT. For MOCA, AxF >9 was established as normality threshold by previous studies. According to this, AxF was <9 in 4 cases (AxF_{mean} = 6.38 ± 2.60 a.u), including the 3 patients with moderated MOAT. For HOCA, control sperm showed the following results: n oocytes = 20; AxF = 6.77 a.u. and AUC = 5.10 a.u. Interestingly, 6 patients showed a significant reduced sperm activation capacity compared to the control (n oocytes = 7.83 ± 1.17; AxF_{mean} = 0.07 ± 0.13 a.u. and AUC 0.08 ± 0.13 a.u.), including the 4 cases with reduced MOCA score. The other 4 patients showed similar sperm activation capacity compared to the control (n oocytes = 9.25 ± 0.96; AxF_{mean} =6.78 ± 1.25 a.u. and AUC = 7.82 ± 1.44 a.u.). Clinical data showed that AOA-ICSI had a significant benefit in all 6 patients with a reduced sperm activation potential, resulting in a mean fertilization rate of 79.5 ± 17.64%; n oocytes/ICSI = 9.83 ± 4.06 after ICSI-AOA. In the 4 patients with normal HOCA score the application of AOA-ICSI did not restore fertilization rates (7.58 ± 15.15%; n oocytes/ICSI = 14.50 ± 12.34).

Limitations, reasons for caution: *IVM* conditions might impair oocyte quality, however, their use to study calcium dynamics after fertilization has been already validated. Although the use of SER-oocytes can lead to healthy babies, their clinical use is still a concern due to certain reported malformations and genetic abnormalities.

Wider implications of the findings: Our data support the added-value of calcium analysis, especially using human oocytes, to uncover sperm-related activation deficiencies in cases of failed fertilization after ICSI. HOCA indicates whether AOA would be beneficial in a following cycle. When failed fertilization occurs and the Ca^{2+}-analysis shows normal patterns, oocyte deficiency could be suspected.

Trial registration number: n/a.

P-246 Karyokinesis without cytokinesis in human embryo – A time-lapse study

Q. Zhan[1], C. Norberg[1], Z. Rosenwaks[1], N. Zaninovic[1]
[1]*Weill Cornell Medicine, Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, NY, USA*

Study question: To investigate the prevalence of karyokinesis without cytokinesis (NUK) in early cleavage stage human embryos and their developmental competence and implantation potential.

Summary answer: The incidence of NUK in the first three cleavage stages ranged from 0.26% to 5.09%. Blastocyst development and implantation rates were impaired.

What is known already: Bovine embryos exposed to a protein kinase inhibitor exhibited karyokinesis without cytokinesis during the first mitotic cell cycle, resulting in polyploid blastocysts. This phenomenon was also observed in human embryos resulting in the formation of multinucleated blastomeres, which are associated with higher aneuploid rates and lower developmental potential.

Study design, size, duration: A retrospective cohort study of IVF patients between January and June 2015. A total of 6,464 normally fertilized embryos from 783 cycles (674 ICSI and 109 IVF) were included in the study All embryos were cultured in time-lapse incubator.

Participants/materials, setting, methods: Embryos were cultured in time-lapse incubators (EmbryoScope®, Vitrolife, Sweden). One or more blastomeres exhibiting karyokinesis without cytokinesis (nuclear division only – NUK) were identified. These embryos were classified into NUK-1 (at first cleavage), NUK-2 (at second cleavage), NUK-3 (at third cleavage) or NUKPlus (occurring at more than once). Blastocyst rate and clinical outcome were analyzed using Chi-square test.

Main results and the role of chance: The NUK incidence in the early embryo cleavage stages were 0.26% (at first), 2.90% (at second), 5.09% (at third) and 0.58% (at fourth), with 1.61% of the embryos having two or more episodes (NUKPlus). Overall NUK incidence was not significantly different between IVF and ICSI (10.80% vs. 10.25%, p = 0.60) or between oocyte age groups (9.12%–12.52%, p = 0.27). The good blastocyst formation rate was significantly lower in NUK embryos (35.29%) compared to embryos without NUKS (64.80%, p < 0.001). Fetal heart implantation rates, based on known implantation data (KID), were lower in NUK groups (D3-ET 5.88%; D5-ET 20.00%) compared to NUK-free groups (D3-ET 15.10%; D5-ET 37.50%). Due to the smaller KID sample size (D3 n = 17, D5 n = 5), they were not reaching significance (D3 p = 0.29 D5 p = 0.41).

Limitations, reasons for caution: The non-significance for implantation data is due to the small KID sample size and multiple embryos transferred.

Wider implications of the findings: Embryos demonstrating karyokinesis without cytokinesis should be exclude from embryo transfer selection and may improve the success rate in SET.

Trial registration number: None.

P-247 Low lactate culture benefits the in vitro development of preimplantation mammalian embryos

R. Gilbert[1], E. White[1], H.T. Ni[1]
[1]*Irvine Scientific, R&D, Santa Ana, CA, USA*

Study question: Is lower lactate in the culture media beneficial to in vitro embryo development?

Summary answer: Continuous culture in medium containing a low lactate concentration benefits the quality of in vitro mammalian embryo development when compared to higher concentrations of lactate**.**

What is known already: Preimplantation mammalian embryos primarily metabolize pyruvate during the cleavage stage, when glucose utilization is relatively low. Glucose metabolism increases steadily during compaction and becomes the predominant metabolite at the blastocyst stage, with increased production of lactate. The interaction of lactate and pyruvate utilization at different stages of development appears to play a role in the regulation of pyruvate and glucose metabolism during embryo development. Current lactate levels used in human embryo continuous culture media were developed based on physiological levels determined from analysis of mouse tubal fluid, which differs from lactate levels determined in human tubal fluid.

Study design, size, duration: Mouse (1-cell) or bovine (2-cell) embryos were cultured to blastocysts (day 4 or day 7, respectively) in continuous single culture medium containing HSA (5 mg/mL) with varied concentrations of lactate. Seven experiments were conducted for each animal model. The criterion for validity of the Mouse Embryo Assay (MEA) is ≥80% blastocyst rate and for Bovine Embryo Assay (BEA) is ≥30% blastocyst rate. Spent media were collected and analyzed for lactate, pyruvate and glucose levels.

Participants/materials, setting, methods: Mouse embryos (1-cell fresh or frozen) were pooled and randomly allocated (n = 25–30/medium) into low and high lactate media (3–4 embryos/20 µl) under oil. In vitro produced fresh

bovine 2-cell embryos were pooled and randomly divided (n = 30–40) among media conditions (10 embryos/50 µL) under oil. Blastocyst development rates were graded by morphology on day 4 for mouse embryos and day 7 for bovine embryos. Kits (Bioassay Systems) were used for lactate, pyruvate and glucose analysis.

Main results and the role of chance: In seven experiments with MEA the mean blastocyst rate was 92.0%, with 83.6% hatching rate for low lactate and 87.3%, with 62.0% hatching rate for high lactate. In seven BEA experiments the mean blastocyst rate was 52.4% for low lactate and 38.6% for high lactate. In addition, the grade of bovine blastocysts based on morphology was superior in low lactate than in high lactate culture. In all tests overall, the blastocyst rates for mouse and bovine experiments were higher for the low lactate than the high lactate media. These results suggest lower lactate in culture benefits overall rates of blastocyst development, and hatching in particular. Analysis of lactate production and consumption of pyruvate and glucose in spent embryo culture media collected from a subset of experiments further demonstrated different metabolic profiles of embryo resulting from media containing varied lactate concentrations.

Limitations, reasons for caution: These results suggest that lower lactate concentrations can benefit in vitro embryo development in both mouse and bovine embryo model system. Additional studies are required to determine if these findings are statistically significant, and how such benefits may translate to human embryo culture in vitro.

Wider implications of the findings: The apparent benefit to embryo development of low lactate medium represents a targeted approach to help elucidate how preimplantation embryo metabolism may be influenced by the culture environment, and how culture conditions may support and promote utilization of Warburg effect mechanisms to improve in vitro embryo development and viability.

Trial registration number: NA.

P-248 Zinc chelation promotes oocyte activation in human oocytes

D. Bonte[1], M. Ferrer-Buitrago[1], E. Van den Abbeel[1], M. Van der Jeught[1], D. Deforce[2], L. Leybaert[3], P. De Sutter[1], B. Heindryckx[1]
[1]Ghent University Hospital, Reproductive Medicine, Gent, Belgium
[2]Ghent University, Pharmaceutical Biotechnology, Gent, Belgium
[3]Ghent University, Basic Medical Sciences, Gent, Belgium

Study question: Does Zinc (Zn^{+2}) depletion play a role during oocyte activation and meiotic resumption in human oocytes?

Summary answer: Zn^{+2}-depletion induces successful oocyte activation bypassing Ca^{+2} mobilization in human oocytes. TPEN (N,N,N′,N′-tetrakis (2-pyridylmethyl)ethane-1,2-diamine) is presented as a potential activation agent for assisted oocyte activation strategies.

What is known already: The Zn^2-ion has been identified within oocyte cytoplasm in different mammalian species, including human. Intracytoplasmic Zn^{2+} increases during oocyte maturation and upon fertilization, a drastic Zn^{+2}-efflux has been described as a gatekeeper-event for meiosis resumption occurring downstream of the Ca^{+2}-oscillations. MII oocytes treated with TPEN, a specific Zn^{+2}-chelator, promoted meiotic resumption and parthenogenetic development that in turn resulted in full-term development in murine and porcine models. The presence of Zn^{+2}-sparks during human oocyte activation has been described, but the question remains whether artificial Zn^{+2}-depletion could be used as an assisted oocyte activation strategy to overcome failed fertilization after ICSI.

Study design, size, duration: The effect of TPEN on oocyte activation was first validated using mouse oocytes. Two-cell formation was evaluated 20 h after activation and compared to a control group ($SrCl_2$-10 mM). Human oocytes were exposed to TPEN and ionomycin (control). PN-formation and cleavage rates were registered at 20 h and 44 h after activation. The absence of Ca^{+2}-oscillations was confirmed using a radiometric method using Fura2-AM (λ_{exc}340/380 nm) as the Ca^{+2}-indicator during TPEN exposure (1 h) in mouse and human oocytes.

Participants/materials, setting, methods: Mouse oocytes (B6D2F1) were exposed to TPEN (100 µM; 45 min). After washing, test and control groups were cultured in media containing Cytochalasin-D (2 µg/ml) for a duration of 6 h. Both groups were transferred to KSOM-BSA (4%). Donated human oocytes containing *smooth endoplasmic-reticulum aggregates (SER),* were collected and vitrified. After thawing, oocytes were cultured for 2 h before activation. Oocytes were then exposed to TPEN (100 µM; 45 min) and ionomycin (10 µM; 2 × 10 min, control) and cultured in *Cook-Cleavage*. PN-formation and cleavage rates were evaluated.

Main results and the role of chance: Mouse oocytes exposed to TPEN and $SrCl_2$ showed similar activation rate: 92% (12/13) and 93% (14/15), respectively. In human oocytes, TPEN (100 µM) induced parthenogenetic activation in 54% (7/13) of the oocytes whereas ionomycin activated 75% (6/8) of the oocytes in the control. All the oocytes activated showed 2 to 4 cells at D+2. Cleavage rate was 57% (4/7) and 83% (5/6), for TPEN and control groups, respectively. To investigate whether TPEN induces artificial activation bypassing the calcium oscillations, the calcium profile was determined in mouse and human oocytes during their exposure to the activation agents: $SrCl_2$, ionomycin, and TPEN. No oscillations were observed after exposure of mouse and human oocytes to TPEN for a duration of 45 min. Control mouse oocytes exposed to $SrCl_2$ showed normal calcium activity for a duration of 2 h. Ionomycin induced a large peak of calcium in human oocytes.

Limitations, reasons for caution: Although the use of SER-oocytes can lead to healthy babies, their clinical use is still a concern due to certain reported genetic abnormalities. The influence of different concentrations of TPEN on activation and morphokinetics needs to be further analysed.

Wider implications of the findings: Current AOA protocols promote intracytoplasmic calcium rise to induce the oocyte activation. Our results show that artificial depletion of Zn^{+2} can successfully activate human oocytes by circumventing the event of calcium oscillations. It remains to be investigated whether this novel strategy could be optimized for AOA to overcome ICSI-fertilization failures.

Trial registration number: n/a.

P-249 Blastocyst morphology correlates differently with ploidy in relation to maternal age

C. Lagalla[1], F. Pennetta[1], N. Tarozzi[1], R. Sciajno[1], M. Di Santo[1], V. Distratis[1], M. Nadalini[1], M.A. Bonu[1], A. Borini[2]
[1]9.baby Family and Fertility Center, Reproductive Medicine IVF Laboratory Unit, Bologna, Italy
[2]9.baby Family and Fertility Center, Reproductive Medicine Clinical Unit, Bologna, Italy

Study question: Does blastocyst morphology correlate with ploidy? If yes, how? Is there any difference between parameters involved in relation to maternal age?

Summary answer: Blastocysts with lower morphological scores were aneuploid with higher frequency. Aneuploidy correlated with trophectoderm quality in older patients and with expansion degree in younger ones.

What is known already: Aneuploidy is one of the most important causes of implantation failure and miscarriage. The association between morphological appearance and aneuploidy risk has been already studied with the aim to assist in identifying the most competent embryos to transfer during standard IVF procedures. Morphology seems to correlate with ploidy. At the blastocyst stage, aneuploidies were found to be significantly more frequent among embryos with poor morphological scores except for those able to achieve clinical pregnancies. Aneuploidy seemed to correlate with poorer trophectoderm scores also. Up today no correlation between blastocyst morphology and ploidy was studied in relation to patient's age.

Study design, size, duration: Relationship between age, morphology and ploidy was assessed retrospectively on arrayCGH data of 287 blastocysts subdivided in 4 groups: 1 (excellent), 2 (good), 3 (average) and 4 (poor) quality. Secondly, blastocysts were divided in 2 groups based on maternal age: 83 from women ≤ 35 years old (A) and 204 from women >35 years old (B). Expansion, inner cell mass and trophectoderm quality scores were assessed individually in groups A and B and associated with ploidy.

Participants/materials, setting, methods: Blastocyst morphology was assessed on day 5/6 according to Gardner and Schoolcraft grading system modified by Cornell University and trophectoderm biopsy was carried out. Array comparative genomic hybridization (aCGH) was performed for Comprehensive Chromosome Screening (CCS) for biopsied samples. Logistic regression analysis was used to assess the relationship between variables of blastocyst morphology and aneuploidy.

Main results and the role of chance: Blastocysts with lower morphological scores showed a stronger link to aneuploidy (group 3: p = 0.005, OR = 3.370,

95% CI 1.453–7.818; group 4: $p = 0.02$, OR = 2.815 95% CI 1.156–6.854). Maternal age was significantly associated with aneuploidy ($p = 0.0001$, OR = 1.187 95% CI 1.109–1.270) infact, aneuploidy rate was statistically different among group A and B (19.6% vs. 80.4%, $p = 0.0001$). Analyzing separately each single morphological blastocyst parameter (expansions, inner cell mass and trophectoderm), expansion degree was statistically associated to ploidy in Group A (mean age = 32.3, 95% CI 31.4–33.2): more expanded blastocysts were less aneuploidy (expansion 3, $p = 0.016$; OR = O.2; 95% CI 0.054–0.745) with euploid/aneuplod ratio of 1:0.2; on the contrary in less expanded blastocysts (expansion 1), euploid/aneuploid ratio was 1:1.3. In Group B (mean age = 40.3, 95% CI 39.7–41) logistic regression analysis showed that only trophectoderm quality was predictive of ploidy: worst quality trophectoderm was associated to aneuploidy (TE Grade B: $p = 0.001$, OR = 3.6 95% CI 1.746–7.664; TE Grade C: $p = 0.028$, OR = 2.5 95% CI 1.103–5.765).

Limitations, reasons for caution: Limited number of cases of the younger study group.

Wider implications of the findings: In the vast majority of IVF laboratories of the world the choice of the most suitable embryos to transfer is still based upon morphological evaluation. The findings of this CCS study can provide additional information helpful in creating a more accurate methodology for blastocyst grading when PGS is not used.

Trial registration number: none.

P-250 Comparing blastocyst expansion dynamics between euploid vs. aneuploid embryos: A quantitative and automated analysis of time-lapse cinematography

M. Chian[1], L. Tan[2], V. Suraj[3], S. Shen[2]
[1]*Progyny Inc, Engineering, Menlo Park, CA, USA*
[2]*Progyny Inc, Medical and Scientific Affairs, Menlo Park, CA, USA*
[3]*Progyny Inc, Database and Statistics, Menlo Park, CA, USA*

Study question: What are expansion dynamics for human blastocysts cultured in vitro? Is there an association between blastocyst expansion patterns and embryonic aneuploidy?

Summary answer: In embryos biopsied on Day5/6, 89% expanded >10% on Day5. Euploid blastocysts had a higher degree and faster rate of expansion than aneuploid blastocysts.

What is known already: Blastocyst collapses have been found to associate with a lower likelihood to hatch and/or implant in animal and human studies. However, quantitative characterization of blastocyst expansion, including the degree and rate of expansion, has not been systematically performed. Furthermore, the relationship between blastocyst expansion dynamics and aneuploidy remains unknown.

Study design, size, duration: Prospective observational cohort study. One hundred and two patients were enrolled (August 2012 to November 2013), out of which seventy patients did not have laser-assisted hatching performed on Day 3 and were included for analysis. Sixty-six patients with 374 biopsied blastocysts had complete image analysis and ploidy outcome ($n = 258$ euploid and $n = 116$ aneuploid).

Participants/materials, setting, methods: Entire cohorts of embryos from patients were imaged using the Eeva System (111 hours post ICSI). Time-lapse images were automatically processed by proprietary computer programmes to extract dynamic parameters including the degree and rates of single expansion events. Forty embryos were excluded as they did not reach 10% expansion criteria on Day 5 ($n = 25$ euploid and $n = 15$ aneuploid), and the final dataset comprises of 334 embryos that expanded more than 10% ($n = 233$ euploid and $n = 101$ aneuploid).

Main results and the role of chance: Blastocysts spent a median of 86% time in expansion phase vs. collapse, which was not different between euploid and aneuploidy blastocysts (87% vs. 86%, $p = 0.1$). The median maximum volume increase of a single expansion event was 1.43 ± 1.09 nanoliters (nL), which is more than the volume of an average human zygote (0.9 nL, 120 μm in diameter). Interestingly, the median maximum volume increase in a single expansion event in euploid blastocysts was 34% higher than aneuploid blastocysts (1.61 vs. 1.07 nL, $p = 0.0002$). The average volume increase of a single expansion event was 0.56 ± 0.47 nL, with euploid blastocysts having a 23% higher average volume increase during a single expansion than aneuploid blastocysts (0.59 vs. 0.45 nL, $p = 0.0002$). During single expansion events, euploid blastocysts, compared to aneuploid blastocysts, also had a faster maximum rates (0.46 vs. 0.38 nL/hour, $p = 0.006$) and average expansion rates (0.28 vs. 0.24 nL/hour, $p = 0.02$). When collapses were included, the overall expansion rate was 0.15 ± 0.10 nL/hour, with euploid blastocysts having an overall faster rate than aneuploid blastocysts (0.16 vs. 0.12 nL/hour, $p = 0.002$).

Limitations, reasons for caution: This is an observational study performed in a single centre, and therefore the clinical significance of the finding needs to be validated in a multi-centered study with a larger sample size.

Wider implications of the findings: This is the first study that quantitatively and systematically characterized expansion dynamics for human blastocysts. The automatic extraction of the dynamic parameters provides an efficient tool for future studies, which may shed new light on the basic biology of human blastocysts.

Trial registration number: Clinicaltrials.gov, NCT01635049.

P-251 Predictive value of blastocyst morphology beyond aneuploidy testing: evidences from a randomized non-selection study

A. Capalbo[1], F.M. Ubaldi[2], L. Dusi[3], R. Maggiulli[2], S. Romano[2], L. Albricci[2], C. Scarica[2], F. Sanges[4], E. Alviggi[4], D. Cimadomo[2], L. Rienzi[2]
[1]*Salus, GENETYX, Molecular Genetics Laboratory, Marostica, VI, Italy*
[2]*Clinica Valle Giulia, GENERA Center for Reproductive Medicine, Roma, Italy*
[3]*Salus, GENERA Center for Reproductive Medicine, Marostica, VI, Italy*
[4]*RUESCH, GENERA Center for Reproductive Medicine, Naples, Italy*

Study question: Does blastocyst stage standard morphology assessment enhance embryo selection beyond aneuploidy testing?

Summary answer: Blastocyst morphology based selection does not significantly enhance live-birth rate in pre-implantation genetic diagnosis cycles for aneuploidy testing (PGD-A) nor predict adverse pregnancy outcomes.

What is known already: Trophectoderm (TE) biopsy and aneuploidy testing is increasingly used to enhance embryo selection in IVF cycles. However, beyond euploidy, no other parameters have been assessed to be used in combination with aneuploidy testing to further enhance the clinical management of PGD-A cycles. Blastocyst morphological evaluation has been extensively validated to predict implantation in IVF cycles and this association has been recently linked to its moderate predictive value on blastocyst aneuploidies. However, it is still unknown whether euploid blastocysts with different morphologies and development implant at a different rate or provide a different risk for biochemical losses, miscarriages or gestational complications.

Study design, size, duration: Randomized non-selection study preformed between December 2013 and December 2014 including all consecutive blastocyst stage PGD-A cycles performed in infertile patients of advanced female age (>35 years). In the randomization period, whenever more than one euploid blastocyst of different morphology was obtained, the embryo selection was subjected to randomization to rule out patient's specific factors (Study group). A subsequent follow-up period (Genuary 2015) where the selection between euploid embryos was based on blastocyst morphology was included (control group).

Participants/materials, setting, methods: ICSI and embryo culture in 5% O2/6% CO2. Prior to trophectoderm biopsy, morphology was assessed and categorized [excellent (≥3AA; group A)/good (3, 4, 5, 6, AB and BA; group B)/average (3, 4, 5, 6 BB, AC and CA; group C)/poor quality (≤3BB)] according to Gardner/Schoolcraft's criteria. Developmental rate was defined according to the day of biopsy post-fertilization (day 5, 6 or 7). Primary outcome was live-birth rate/transfer. Biochemical-losses, miscarriages and gestational outcomes were also compared between morphological classes using logistic regression models adjusted for potential confounding factors.

Main results and the role of chance: In the randomization period 171 cycles were excluded from the analysis since only one euploid blastocyst was obtained. 339 single euploid embryo transfers in 196 patients (female age 37.2 ± 3.1) were subjected to randomization since more than one euploid blastocyst (mean per cycle 2.8 ± 1.1) with different morphology ($N = 199$; 104 excellent, 40 good, 41 average, 20 poor) or with different time of development ($N = 159$; 73 day 5, 72 day 6, 14 day 7) was obtained for that cycle. Logistic regression analysis showed that poor morphology class ($p < 0.01$; OR = 0.09, 95%CI = 0.01–0.77; live-birth rate: 45.2%, 42.5%, 48.8% and 7.1%, for excellent, good average and poor, respectively) and day 7 embryos ($p < 0.01$; OR = 0.16; 95%CI = 0.03–0.85; live birth rate: 47.9%, 33.3% and 14.3% for day 5, 6 and 7, respectively) were significantly associated with reduced live-birth rate. Female age,

sperm parameters, previous IVF failures and miscarriages showed no association. Logistic models showed that morphology and day of development were not related to biochemical losses, miscarriages and gestational outcomes. In the follow-up period, 151 euploid SET were performed where morphological selection was possible. Even though higher percentage of excellent/good quality blastocysts were transferred in the selection group (76% vs 64.5%, respectively, $p < 0.01$), this did not translate in improved live-birth rate (46.3% vs 41.9% respectively; $p = 0.2$).

Limitations, reasons for caution: Not all morphological classes were represented in each cycle when the randomization was performed. Not all euploid embryos from a stimulation cycle were transferred. Even if based on a large dataset, this study is still not sufficiently powered to exclude moderate associations between blastocyst morphology and biochemical losses, miscarriages and neonatal outcomes.

Wider implications of the findings: This study provides class-one data about the limited value of blastocyst morphology selection beyond euploidy. Only very poor morphology and day-7 blastocysts showed lower potentiality. These embryos are usually discarded. However, when euploid they still provide live-births with no increase adverse outcomes strongly suggesting their use in PGD-A cycles.

Trial registration number: ISRCTN81216689.

P-252 Viral-positive patients: treatment outcomes and embryo morphokinetics

A. Burdina[1], A. Barrie[1], K. Schnauffer[1], C. Kingsland[1], S. Troup[1]
[1]*Liverpool Women's NHS Foundation Trust, The Hewitt Fertility Centre, Liverpool, UK*

Study question: Examination of IVF & ICSI treatment outcomes in patients with Hepatitis B, C and Human Immunodeficiency Virus (HIV) and its relationship with early embryo morphokinetics.

Summary answer: Pregnancy rates were significantly lower in viral-positive cohort, together with slower early embryo development for both viral-positive males and females.

What is known already: Time-lapse monitoring allows examination of embryo morphokinetics in various conditions that could impair fertility such as environment, lifestyle, drug effect or disease. Human immunodeficiency virus (HIV), hepatitis C virus (HCV) and hepatitis B (HBV) carriers are at risk of both reduced fertility and the risk of viral transmission to the partner or child. Published data is scarce regarding the fertility outcomes and embryo development characteristics in viral-positive couples, concentrate mostly on safety of the procedure. To our knowledge, morphokinetic analysis of embryos obtained from viral-positive patients has not been previously performed.

Study design, size, duration: Fifty viral-positive patients (24 HBV, 12 HCV, 14 HIV) who underwent fertility treatment over 12 months period were matched to controls. Data were analysed depending on the viral-positive status, origin of the disease (male, female) and treatment type (IVF, ICSI). 122 embryos from viral positive patients were compared against 139 control embryos examining only embryos that were transferred or cryopreserved.

Participants/materials, setting, methods: Controls were matched according to female age at oocyte retrieval (±12 months), treatment type, stimulation protocol and number of oocytes collected (±2). One control was matched to each viral-positive case. Viral-positive group was cultured in a standard incubator with PrimoVision® system, whereas control group was cultured in EmbryoScope® incubator. Morphokinetic data collected for early embryo development was: tPNf (pronuclear fading), t2, t3, t4, t5 (time to cell division).

Main results and the role of chance: Clinical pregnancy rates were reduced for viral-positive couples vs control (26% and 48%, $p = 0.012$, McNemar test for matched pairs), with an odds ratio of 0.380 (95% CI 0.16–0.88) ($p = 0.023$, Pearson's Chi-square). Significantly reduced clinical pregnancy rates were found when male but not female was viral-bearing when compared to control (25% vs 53.1% in males, $p = 0.021$; 25% vs 35% in females, $p = 0.490$, Pearson's Chi-square). Survival analysis (Kaplan-Meyer method and log-rank tests) were performed to analyse morphokinetic parameters. A significant difference in the kinetics of early divisions was observed, with embryos from viral-positive patients reaching the 2-cell ($p = 0.0001$), 3-cell ($p = 0.025$) and 4-cell stages ($p = 0.030$) slower than embryos from control patients. When early division kinetics were analysed separately for each virus-bearing gender, in both males and females embryos divided significantly slower compared to the controls, with the differences being more pronounced in males up to t5 ($p < 0.05$ for t2, 3, 4, 5, log-rank test), whereas in females the differences were decreasing ($p < 0.05$ for t2, t3, t4, log-rank test) as divisions progressed, and were lost by the t5 ($p = 0.727$, log-rank test).

Limitations, reasons for caution: The study is limited by a low number of participants, which at this stage precluded a thorough analysis of each viral condition separately. Morphokinetic parameters were determined using two different time-lapse imaging systems, which could have affected the data collected, although the imaging time-frames were the same.

Wider implications of the findings: These data suggest that the presence of a virus during an assisted conception cycle may compromise embryo development and that this compromised development may be implicated in reduced pregnancy outcome. Furthermore, it may be prudent to consider development of morphokinetic embryo selection algorithms specifically for patients with known viral-positive infections.

Trial registration number: N/A.

P-253 Development of a non-invasive method for selection of human embryos with high implantation potential based on Fourier transform Infrared (FT-IR) spectroscopy and artificial neural networks

G.M. Garcea[1], M. Horton[1], C. Figoli[2], M. Gomez Peña[1], F. Sobral[1], I. de Zúñiga[1], L. Kopcow[1], A. Oubiña[1], M. Papayannis[1], E. De Martino[1], G. Terrado[1], L. Gibbons[3], O. Yantorno[2], A. Bosch[2], C. Bisioli[1]
[1]*Pregna Medicina Reproductiva, IVF, Buenos Aires, Argentina*
[2]*CINDEFI-UNLP-CONICET, Spectroscopy, La Plata, Argentina*
[3]*IECS, Epidemiology, Buenos Aires, Argentina*

Study question: Does FT-IR spectroscopy of spent culture embryo supernatants provide an OMICS–like view of the chemical/biochemical status of the embryo metabolism to be used to evaluate embryo implantation potential?

Summary answer: Multivariate analysis of metabolomic spectral patterns of human IVF embryos developed by an artificial neuronal network system could identify an embryo with high implantation potential.

What is known already: The metaboloma is the chemical print produced in a biological system, representing its functional phenotype, and consists of a set of 2500 to 3000 molecules and potential biomarkers. Metabolomic techniques were used as non-invasive approaches for IVF studies analyzing different metabolites in embryo-culture supernatants. Particularly, near infrared spectroscopy (NIR) has been used to evaluate embryo pregnancy ability. Although these results were initially encouraging, a recent randomized clinical trial did not show benefits of NIR over conventional morphological evaluation. FT-IR has been widely used to study the biochemical composition of biological materials. Nevertheless it has never been applied in IVF technology.

Study design, size, duration: Prospective cohort study, enrolling unselected patients undergoing IVF or ICSI cycles from November 2012 to December 2014. Four hundred fourteen patients were enrolled, 400 of them reached egg retrieval, 346 had appropriate ova for fertilization an 294 achieved embryo transfer (268 on day 3, 26 on day 5). This is an ongoing collaborative project between a private practice ART clinic and a University Research Center.

Participants/materials, setting, methods: Participants with up to 3 previous IVF cycles, and up to 41 years of age were excluded. Embryos were cultured individually in trigas incubators, and 1 or 2 embryos were transferred under conventional clinical and embryological criteria on day 3 or 5. An aliquot of spent culture media was frozen in liquid nitrogen for future spectral acquirement and data analysis. A total of 497 embryos were transferred on day 3, and 38 on day 5.

Main results and the role of chance: Five hundred and thirty-five embryos were transferred, and 136 of them implanted (25.4%). After thawing, the sample was centrifuged for oil extraction, droplets were transferred to a ZnSe plate, and vacuum dried for 40 min. Due to technical problems with oil extraction in day 5 embryos, only day 3 embryos were finally evaluated. Spectra coming from a total of 1315 embryos, comprising the 497 day 3 transferred embryos and the non-transferred, vitrified embryos, were used to construct the database. Spectra from transferred embryos were classified as Class I (belonging to full implantation embryos, i.e., singletons in sET or twins in DET), Class II (non implanted) and Class III (50%, 1 of 2 embryos implanted). Multivariate methods were applied in order to obtain a model able to discriminate spectra belonging to Class I from Class II supernatants, using ***Opus 3.1*** and ***4.5*** software (Bruker Optics, Germany), that include the IDENT package for cluster analysis and principal component analysis and ***NeuroDeveloper***® (Synthon Analytics, Germany) for the development of artificial neural networks applied in the construction of

libraries and other databases. This showed a 76% accuracy rate, 75% sensitivity and 76% specificity in predicting implantation.
Limitations, reasons for caution: Due to the characteristics of ANNs, needing a huge number of cases to "learn" during the process, clinical validation of these results still need a larger dataset of cases, to increase accuracy through further analysis of full implantation cases (singletons in sET, or twins after DET)
Wider implications of the findings: Addition of other non-invasive embryo selection techniques like morphokinetics could improve the accuracy rate and positive and negative predictive value of metabolomic assessment and help in the construction of predictive models to improve embryo selection and secondarily pregnancy rate.
Trial registration number: Non randomized trial.

P-254 Effect of dual trigger with gonadotropin-releasing hormone agonist (GnRH-a) and human chorionic gonadotropin (hCG) in embryo quality

M.A. Guembe Echarri[1], L. Crisol Ortiz[1], M.J. Iñarra Velasco[1], M. Lure[1]
[1]*Hospital Donostia, Assisted Reproduction Unit, Gynecology and Obstetric Department, San Sebastian, Spain*

Study question: Does dual trigger of final oocyte maturation improve the embryo quality in IVF cycles?
Summary answer: Co-administration of GnRH-a and hCG for final oocyte maturation does not significantly modify embryo quality in IVF cycles.
What is known already: Oocyte maturation for IVF cycles is commonly induced by hCG as a surrogate for the natural LH surge. In the last years, the use of GnRH-a for final follicular maturation has been shown to significantly reduce the occurrence of ovarian hyperstimulation syndrome compared with hCG triggering, however, a poor reproductive outcome was reported after GnRHa triggering. More recently, the so-called "dual trigger" that combines GnRH-a with hCG has been investigated in IVF with promising results.
Study design, size, duration: Prospective randomized study. The population under study consisted of 73 consecutive patients treated by IVF or ICSI at Hospital Donostia Assisted Reproduction Unit, from January to March 2014. Participants were randomly assigned to two groups: 1) hCG trigger group ($n = 39$) and 2) dual trigger (GnRH-a + hCG) group ($n = 34$).
Participants/materials, setting, methods: Final oocyte maturation was triggered by either 250 μg of recombinant hCG (Ovitrelle; Merck Serono) alone, or by 250 μg of recombinant hCG plus 0.2 mg of triptorelin (Decapeptyl; Ipsen Pharma), depending on the assigned group. The embryo morphology classification criteria of the Association for Reproduction Biology Studies (ASEBIR, according to its initials in Spanish) were followed. All embryo transfers were performed 48 h after oocyte retrieval. Statistical analysis was performed using SPSS 21.0.
Main results and the role of chance: Female mean age, corporal mass index, basal FSH levels, number of antral follicles and AMH levels, as well as cycle stimulation characteristics (estradiol, progesterone) were similar in both groups. We found a higher proportion of good quality embryos transferred in patients who received the double trigger compared to hCG trigger group (43.8% vs 35% respectively). However, the differences were not statistically significant.
Limitations, reasons for caution: Our results are limited by the small sample size; therefore, it was not possible to analyze the effects of dual triggering in IVF results of different subgroups of patients. A larger data set is needed to provide more information about dual triggering potential use. This is not a blinded study.
Wider implications of the findings: The results from the present study indicate that the transferred embryo quality was not modified by dual trigger of final oocyte maturation. However, further large prospective studies are needed to elucidate the aforementioned recommendation.
Trial registration number: Not applicable.

P-255 Embryos with delayed development at day 5 must be frozen. Improving implantation rates of early blastocysts after elective vitrification

A. Rodríguez-Arnedo[1], J. Llácer[2], J.A. Ortiz[3], J. Ten[1], M.C. Tió[1], J. Guerrero[1], R. Bernabeu[2]
[1]*Instituto Bernabeu, Embryology Department, Alicante, Spain*
[2]*Instituto Bernabeu, Reproductive Medicine, Alicante, Spain*
[3]*Instituto Bernabeu, Instituto Bernabeu Biotech, Alicante, Spain*

Study question: What are the best endometrial conditions for the transfer of embryos delayed in development during the culture to the blastocyst stage? (synchronous vs substitutive cycle).
Summary answer: Embryos with good morphology but delayed development benefit for elective FET with customized endometrial preparation increasing their chances to implant.
What is known already: There are growing evidence about the impairment on the endometrial receptivity caused by ovarian stimulation. The advanced histology and down regulation of the progesterone receptor are suspected indicators of an advanced receptive phase with effect on embryo-endometrium asynchrony causing implantation failure. In view of these facts, "freezing all" strategies have been proposed but is controversial because its use makes treatments longer in time and more expensive increasing the burden supported by the patients.
Study design, size, duration: Retrospective analysis of transfers performed in our institution from January 2013 to September 2015 in patients using their own oocytes. For the analysis, we select only cases that receiving 1 or 2 embryos with the same stage of development at day 5: 159 ET with embryos classified as early (grade 1 Istanbul Classification) and 601 transfers where only good quality blastocyst were transferred (grade 2, 3 or 4 Istanbul Classification).
Participants/materials, setting, methods: All the cases included were patients using their own oocytes and transferred at day 5 of embryo development. We made two groups, embryos delayed (grade 1), comparing fresh and frozen-thawed transfers, and good quality embryos (grade ≥ 2), fresh and frozen-thawed transfers. We compared implantation rates between transfers in fresh and after freezing. Chemical and clinical pregnancies and miscarriages rates were analysed as secondary endpoints. Logistic regression and Pearson's χ^2-test were applied to evaluate differences.
Main results and the role of chance: We analysed a total 159 transfers of delayed embryos, 105 fresh and 54 freeze-thawed transfers. We observe an increase in implantation rate (9.77% vs 30.34%, $p = 0.00002$), clinical pregnancy (12.5% vs 44%, $p = 0.0003$), positive test (21.0% vs 46.3%, $p = 0.005$) and miscarriages (15.4% vs 40.0%, $p = 0.085$) in freeze-thawed transfers. We try to verify if the same effect occurs in good quality embryos transfers. A total of 601 treatments were analysed, 488 fresh and 113 freeze-thawed transfers. We can't observe differences between implantation rate (28.57% vs 27.07%, $p = 0.69$), clinical pregnancy (37.4% vs 39.8%, $p = 0.65$), positive test (50.0% vs 54.9%, $p = 0.89$) and miscarriages (14.0% vs 27.6%, $p = 0.026$).
Limitations, reasons for caution: The main limitation is that this is a retrospective analysis.
Wider implications of the findings: Embryos with slower development in the culture may be falsely classified as low-implantation capacity when the problem really is the endometrial asynchrony. These embryos have higher implantation rates in a FET with substitutive endometrial preparation and must be electively frozen.
Trial registration number: No trial registration number.

P-256 Comparison of implantation rate and pregnancy rates of frozen/thawed embryos at blastocyst stage and frozen/thawed embryos at cleavage stage, cultured for transfer on blastocyst stage

E.R. Horrillo Murillo[1], J.C. García Lozano[2], M.D. Lozano Arana[3], J. Guisado Fernandez[2], B. Sanchez Andujar[3], J.L. Moliní Rivera[2], P. Moreno De Acevedo Yagüe[3], S. Borrego López[4], G. Antiñolo Gil[2]
[1]*Hospital Virgen del Rocío, Resident Obstetrics and Gynecology, Seville, Spain*
[2]*Hospital Virgen del Rocío, Gynecologist, Seville, Spain*
[3]*Hospital Virgen del Rocío, Embriologist, Seville, Spain*
[4]*Hospital Virgen del Rocío, Genetics Department, Seville, Spain*

Study question: Implantation rate (IR) and clinical pregnancy rates (CPR) of frozen/thawed embryos at blastocyst stage versus thawed embryos at cleavage stage, cultured for transfer on blastocyst.
Summary answer: Neither the IR nor the CPR differed between both groups. However more embryos were needed to obtain pregnancies when embryos were frozen at cleavage stages.
What is known already: Cochrane data base information published in 2013 established that fresh blastocyst stage transfers improved IR rates, but it is unknown if this difference persists with frozen/thawed embryos transferred on blastocyst stage.
Study design, size, duration: A retrospective study of 147 thawing cycles was performed from January 2009 to December 2015.

Participants/materials, setting, methods: We compared the outcomes of 49 thawing cycles done with embryos at blastocyst stage (Group A) with 98 thawing cycles where embryos at cleavage stage (day 2 or day 3) were thawed and grown to blastocyst stage (Group B). All frozen embryos were surplus embryos from IVF cycles with one fresh embryo transfer.
Main results and the role of chance: A total of 493 embryos were thawed, 90 at blastocyst stage and 403 at cleavage stage. In Group A, 74% of the embryos were replaced (67/90) versus 40% in Group B (161/403) ($p < 0.001$). The mean number of embryos thawed for transfer was four times larger in Group B (4.11) than Group A (1.84). Furthermore, the mean number of blastocyst transferred was also larger in Group B (1.64) than Group A (1.36) ($p > 0.001$). However, no significant differences were found neither for IR (18% in group A versus 16% in Group B) ($p > 0.05$) nor CPR (18% in group A and 11% in group B) ($p > 0.005$). Twenty five clinical pregnancies were obtained, 9 in Group A (6 singleton, 3 multiple) versus 16 in Group B (14 singleton, 2 multiple).
Limitations, reasons for caution: The main limitation was the low number of thawing cycles in Group A, so results need to be confirmed in larger studies. Embryos replaced were surplus embryos of IVF cycles with one fresh embryo transfer, so their quality could be suboptimal.
Wider implications of the findings: Due to no significant differences in CPR, transfer of frozen/thawed embryos in blastocyst stage could reduce the surplus of cryopreserved embryos, selecting for freezing only those embryos with more chances to obtain pregnancies.
Trial registration number: Not applicable.

P-257 Is there a room for lowering miscarriage rates in time-lapse cycles?

P. Mazur[1], V. Nagornyy[1], L. Semenyuk[1], D. Mykytenko[2], V. Zukin[1]
[1]*Clinic of Reproductive Medicine 'NADIYA', Embryology, Kyiv, Ukraine*
[2]*Clinic of Reproductive Medicine 'NADIYA', Genetics, Kyiv, Ukraine*

Study question: What is the probable reason for consistent miscarriage rates after applying time-lapse techniques?
Summary answer: Overall miscarriage rates while using time-lapse techniques could be achieved by inappropriate embryo selection.
What is known already: Time-lapse observation of embryo development from zygote stage to blastocyst stage is believed to be an effective tool in embryo deselection and, thus, could improve pregnancy rates. But the recent data remains controversial and needs to be verified. Still, miscarriage rates after performing time-lapse techniques is comparable with so called "conventional" incubation.
Study design, size, duration: For this retrospective cohort study we have analysed pregnancy outcomes after 579 embryo transfers (cycles) of 572 patients in the three-year period. Oocyte donation cycles were excluded from the study. All embryos were cultivated within commercial time-lapse incubator. Fabricator's recommendations were used for further embryo selection. Only first attempt (embryo transfer) of each cycle was included to this study. ICSI or IMSI were applied in all cases.
Participants/materials, setting, methods: Patients were aged 23 to 44 years (mean age 34.0 ± 4.5 years). We have compared three groups of patients: Group A – cycles, where array comparative genomic hybridization (aCGH) was performed with the consideration of morphokinetic features of embryo development. Group B – Fresh Day 5 selected embryo transfer (ET). Group C – Cryo Day 5–7 selected ET. One or two good quality blastocysts were transferred on day 5, 6 or 7 regarding to Group.
Main results and the role of chance: Although the ongoing pregnancy rates were similar within all three groups (Group A – 48.6% vs Group B – 38.9% vs Group C – 46.9%, NS), miscarriage rate in aCGH group was dramatically lower (Group A – 2.7% vs Group B – 11%, $p < 0.05$ and Group A – 2.7% vs Group C – 12%, $p < 0.05$), whereas there was no statistically significant difference between Groups B and C. Euploid embryos, mostly, show strict binary behaviour: they implant or do not implant, whereas aneuploid embryos maintain the ability to implant causing early pregnancy loss (7–12 weeks). Thereby, the possible reason for relatively high miscarriage level while using time-lapse techniques is the accidental selection of aneuploid embryo. For now, time-lapse techniques cannot overcome their limitations in choosing the euploid embryos and substitute the performing of preimplantation genetic screening.
Limitations, reasons for caution: In this study, we did not include cumulative pregnancy rates and biochemical pregnancy was stated as the absence of pregnancy. It should be taken to consideration that aCGH group is consisted of poor-prognosis patients with no regards to their age.
Wider implications of the findings: Long-term cultivation itself doesn't have an adverse effect on embryo implantation and further development. There is obvious need in creating better algorithms for embryo selection by time-lapse techniques.
Trial registration number: None.

P-258 Using Eeva combined with morphology to select a single blastocyst for transfer achieved higher live-birth rates compared to using morphology alone: a matched case-control study

K. Schnauffer[1], H. Newby[1], R. Wheeler[1], M. Lee[1], C. Kingsland[1], S. Troup[1]
[1]*Liverpool Women's NHS Foundation Trust, The Hewitt Fertility Centre, Liverpool, UK*

Study question: To what extent can live birth rates be improved by using the Eeva Test to help select a single blastocyst for transfer?
Summary answer: Patients using the Eeva Test with morphology to select a single blastocyst for transfer achieved higher live birth rates compared to patients using morphology alone.
What is known already: Improved embryo assessment will help increase the utilisation of elective single embryo transfer (eSET). Preimplantation genetic screening is effective in selecting euploid embryos, showing promise in improving live birth rate, however, it is invasive and not available in certain countries. Time-lapse technology has been recently applied to clinical embryology practice, but definitive clinical data to demonstrate improved live birth outcome is still needed. Here we attempted to assess to what extent using the Eeva Test, an automated time-lapse technology that measures early cleavage timings, could improve pregnancy and live birth rates for Day 5 eSET.
Study design, size, duration: A retrospective matched case-control study was conducted in a single IVF centre between September 2012-September 2014 Four hundred and thirty one patients undergoing their first IVF cycle with Day 5 eSET were included in the study.
Participants/materials, setting, methods: A total of 114 patients used the Eeva Test. Both Eeva results and morphology were used to select a single blastocyst for transfer. Three hundred and seventeen control patients, where only morphology was used for embryo selection, were propensity-matched to the Eeva group based on age, number of eggs retrieved, and number of fertilised eggs (2PN). Clinical pregnancy was defined by fetal heartbeat at 6–8 weeks by ultrasound. Live birth was confirmed for each patient.
Main results and the role of chance: Following propensity matching, patient age, number of eggs retrieved and number of 2PN per patient were similar between the Eeva Test vs matched-control Group (age: 33.2 ± 3.8 vs 33.0 ± 3.8, $p = 0.6$; number of eggs: 12.3 ± 5.3 vs 13.0 ± 5.0, $p = 0.3$; number of 2PN: 7.7 ± 4.0 vs 7.3 ± 3.8, $p = 0.4$). However, patients using the Eeva Test achieved significantly higher rates of clinical pregnancy (49%, 56/114, vs 38%, 119/317, $p = 0.035$). Furthermore, follow-up of patients' live birth outcome revealed that patients in the Eeva Group had a 45% relative increase in live birth rate compared to that of the matched-control group using morphology alone (45%, 51/114, vs 31%, 99/317, $p = 0.012$).
Limitations, reasons for caution: This study is not a randomised controlled trial (RCT). In addition, the control patients had embryos cultured in conventional incubator without time-lapse monitoring.
Wider implications of the findings: This study is the first to show that using the Eeva Test may improve live birth rates for Day 5 eSET, validating the relationship of early cleavage timings to embryo viability. As the Eeva Test is non-invasive and easy to adopt, it may facilitate the practice of eSET more broadly.
Trial registration number: None.

P-259 Impact of male BMI on IVF outcome after elective single blastocyst transfer. A prospective study

R. Mushtaq[1], T. El- Toukhy[1], Y. Khalaf[1], R. Gebhardt[1], V. Rittenberg[2]

[2]*Lister Fertility Clinic, Assisted Conception Unit, London, UK*

Study question: Does male Body mass index (BMI) affect IVF outcome after elective single blastocyst transfer (eSBT)?

Summary answer: Raised male BMI does not negatively impact the clinical pregnancy rate in IVF cycles in which a good quality single blastocyst is electively transferred.
What is known already: Whilst raised female BMI (≥25 kg/m^2) has been associated with a negative effect on IVF outcome, there is conflicting evidence regarding the impact of male BMI. Most of the available studies were retrospective, used self-reported male BMI records and included outcomes following transfer of embryos at various stages of development without adjusting for important confounders.
Study design, size, duration: This is a prospective observational study conducted in a tertiary assisted conception unit in teaching hospital between June 2015 and January 2016. Both male and female BMI measurements were recorded at the beginning of the treatment cycle. Cycles with self reported BMI, cycles in which frozen or surgically-retrieved sperm, donor gamete or PGD was used, embryo transfer took place prior to the blastocyst stage or more than one blastocyst transferred were excluded from the analysis.
Participants/materials, setting, methods: Couples with female age below 40 years, having one cycle of IVF/ICSI with eSBT during the study period were included. All blastocysts transferred were of good quality (grade 3CC or higher). Patients were divided into two groups according to male BMI; group 1 in whom male BMI was normal (18.5–24.9 kg/m^2), group 2 in whom male BMI was raised (≥25 kg/m^2). BMI was objectively measured for all couples by trained nurses on two equally calibrated machines.
Main results and the role of chance: A total of 163 couples were included in the study; 65 in group 1 (normal BMI) and 98 in group 2 (raised BMI). The pregnancy (51% vs 52%, p = 0.88), and clinical pregnancy (39% vs 41%, p = 0.87) rates were similar in the two groups, respectively. After adjusting for important confounding variables, including female age, female BMI, cause of infertility, baseline female serum AMH level, total gonadotrophin dose used during ovarian stimulation, number of oocytes retrieved and fertilised normally, method of fertilisation used (whether IVF or ICSI) and the number of surplus blastocysts cryopreserved following eSBT, the likelihood of achieving a clinical pregnancy in group 2 was not significantly different from that in group 1 (adjusted OR = 1.87, 95% CI 0.84 – 4.19, p = 0.13).
Limitations, reasons for caution: Although this was a prospective study with strict inclusion criteria and the results were adjusted for important confounders, it is a single-center study and the analysis was limited to cycles in which female age was below 40 years and elective single blastocyst transfer took place on day 5.
Wider implications of the findings: Our study suggests that raised male BMI does not impact IVF outcome after a good quality blastocyst transfer. Further research is needed to confirm these findings and impact of male BMI on live birth rate.
Trial registration number: Not Applicable.

P-260 Alginate-matrigel scaffold usage for in vitro development of preantral follicles

S.Z. Sadr[1], B. Ebrahimi[1], R. Fatehi[1], N.S. Abtahi[1]
[1]*Department of Embryology, Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Iran*

Study question: In vitro culture (IVC) of ovarian follicles is a new strategy in reproductive technology which helps to a better understanding of the complicated folliculogenesis process.
Summary answer: Three dimensionally follicle culture through alginate-matrigel scaffold could mimic the ovarian tissue stroma regarding extracellular matrix components and similar morphologic growth.
What is known already: It has been achieved that proper selection of the matrix and also culture media could increase the survival and maturation rate of the follicles. Also, vitrification is an important step in preserving the ovarian tissue for later usage.
Study design, size, duration: To conduct the study, 250 ovaries from 12-day-old NMRI mice were distributed into control and vitrification groups.
Participants/materials, setting, methods: Ovaries of the vitrification group were vitrified by Needle Immersed method. At first, in both groups, ovarian tissue morphology was evaluated. In the second stage, preantral follicles (Mean diameter:120–140 μm) were mechanically isolated from control and vitrified ovaries, then encapsulated in alginate-matrigel scaffold and cultured for 12 days. Follicles survival, growth and maturation rate, also quantitative expression of oocyte maturation genes (*Gdf9*, *Bmp15* and *Fgf8*) and protein expression were assessed.
Main results and the role of chance: Morphological integrity of vitrified warmed ovaries was well preserved as like as the fresh control one. Although survival rate of culture preantral follcles in control group was significantly higher than the vitrification one (94% versus 81.6%), antrum formation was similar in both groups. Also, during culture period, follicle diameter was significantly increase in both groups. In assessment of oocyte maturation genes expression during 12 days of follicle culture, the decreasing pattern was observed in both groups. No significant difference was observed between control and vitrification groups at the first and last days of culture in genes expression. This trend was assured by protein expression evaluation (*Gdf9* and *Bmp15*) which were indicated sharp staining in 12 days of culture in both groups. At the end, maturation rates were indicated a non significant difference between control and vitrification groups (32% versus 33%).
Limitations, reasons for caution: None.
Wider implications of the findings: Considering the same outcome of vitrification group compared to control one, as well as the supporting role of alginate-matrigel matrix in preantral follcle development and subsequently maturation, it seems that this scaffold could be an acceptable one for preantral follicle in vitro culture.
Trial registration number: Registration number is not required for this study.

P-261 Study of Tnp1, Tekt1 and Plzf genes expression during in vitro three dimensional neonate mouse testis culture

A. Alrahel[1], M. Movahedin[1], Z. Mazaheri[1], F. Amidi[2]
[1]*Tarbiat Modares University, Anatomy, Tehran, Iran*
[2]*Tehran University, Anatomy, Tehran, Iran*

Study question: Can post-meiotic genes express in the three dimensional testis culture?
Summary answer: *Tnp1* as a post-meiotic gene can be expressed during in vitro three dimensional neonate mouse testis culture.
What is known already: In vitro spermatogenesis has a long research history beginning in the early twentieth century. This process did not proceed beyond the meiotic pachytene stage. The organ culture method was therefore abandoned, and alternative of cell culture methods were then chosen by many researchers. Study of the genes involved in different stage of spermatogenesis are very important. Here we assessed whether *Tnp1*, *Tekt1* and *Plzf*, with crucial role in spermatogenesis can express during organ culture of testis. So, we used organ culture of neonate mouse to understand of spermatogenesis process in molecular level during 12 weeks culture.
Study design, size, duration: Sampling procedures: 10 mouse pup, testis were removed. The tunica was removed after fully exposing the seminiferous tubules. The testis tissue was separated into smaller pieces of seminiferous tubules. The size of the pieces was arbitrary, approximately 1 mg in weight or 1 mm^3 in size when compacted. One to three testis tissue fragments were transferred to the hexahedrons, and incubated by placing the 6-well plates in a culture incubator. And cultured for 12 weeks.
Participants/materials, setting, methods: Total RNA was extracted from the 12 weeks 3D cultured tissue of neonatal mouse. The cDNAs were synthesized. For PCR reactions, primers were adapted from other primers (designed by the NCBI website). The quality of the PCR reactions was confirmed by melting curve analyses. Efficiency was determined for each gene using a standard curve. For each sample, the target genes were normalized to a reference gene and calibrated to an adult or neonatal testis.
Main results and the role of chance: The results showed that expression of *Tekt1* as a mitotic gene decreased comparing to adult mouse testis, significantly ($p \leq 0.05$). Meanwhile expression of *Tnp1*, as meiotic gene, increased significantly comparing with neonate mouse testis in beginning of culture ($p \leq 0.05$). Expression of *Plzf* showed no significant difference during 12 weeks culture ($p \geq 0.05$). Histological study showed only different types of spermatocytes and post-meiotic stages of germ cells could not be detected. This kind of three dimensional culture can induce expression of post-meiotic gene, *Tnp1*, but May it remains in molecular level and could not pass beyond meiosis.
Limitations, reasons for caution: The limitation of research is that only gene expression is not strong tool for assessing the functionality and it is necessary to have final product, functional spermatozoa, to interrupt about cultural system.

Wider implications of the findings: Previous studies in the in vitro spermatogenesis using an organ culture technique are few. Recently, Yokonishi et al. (2013) used 6 – 8 weeks of culture and evaluated spermatogenesis by histological and Immunohistochemical techniques.
Trial registration number: it is basic science.

P-262 The impact of laser assisted hatching in an oocyte donation program using egg cryobanking: a prospective, randomized, comparatrive study

A. Papatheodorou[1], P. Vanderzwalmen[2], Y. Panagiotidis[1], S. Petousis[1], M. Goudakou[1], G. Gullo[3], K. Ravanos[1], N. Prapas[1], Y. Prapas[1]
[1]Iakentro Fertility Centre, IVF, Thessaloniki, Greece
[2]Centers Prof. Zech, IVF, Bregenz, Austria
[3]Univesrita di Messina, Department of Obstetrics and Gynecology, Messina, Italy

Study question: Is beneficial the performance of laser assisted hatching prior transfer in embryos derived from aseptically vitrified/warmed oocytes in an oocyte donation program?
Summary answer: Clinical results is significantly improved when laser assisted hatching is being performed in embryos which derived from vitrified/warmed oocytes.
What is known already: Lately, studies show very promising results after vitrification of oocytes. However, a recent review on oocyte vitrification (Potdar et al., 2014) shows great heterogeneity in the reported clinical results after oocyte vitrification and thus highlights that there is space for improving the clinical outcome. An important parameter that could influence negatively the clinical outcome of the vitrified oocytes is the hardening of their zona after vitrification/warming procedure and the failure of the resulting embryos to hatch and implant. There are not enough studies which evaluate the clinical impact of assisted hatching in human embryos deriving from vitrified oocytes.
Study design, size, duration: A prospective, randomized, comparatrive study was performed from January 2015 to December 2015. All cases were participating in oocyte donation program of Iakentro IVF Center. Two groups were under study. In group A we included cases were embryos derived from donated, vitrified oocytes were transferred without assisted hatching. In group B we include cases in which embryos derived from vitrified oocytes were hatched prior transfer using a laser system.
Participants/materials, setting, methods: The two under study groups were formed after a randomization procedure. Seventy cases were included in each group. In all cases, recipients were donated oocytes which were vitrified using a closed system vitrification. After warming, oocytes were fertilized and cultured to day 5. All transfers were performed on day 5 (blastocyst stage). Group A embryos were transferred without assisted hatching. Group B embryos were hatched with the use of laser pulses 2 h before transfer.
Main results and the role of chance: Pregnancy rate (48.5% vs 74.28%), clinical pregnancy rate (45.7% vs 68.5%) and ongoing pregnancy rate (40.2% vs 66.5%) were significantly higher in group B. Furthermore implantation rate was significantly higher in group B (29.2% vs 58.8%). In fact the IR is doubled when laser assisted hatching was used. This study shows that laser assisted hatching is beneficial for embryos that derive from aseptically vitrified oocytes.
Limitations, reasons for caution: This study includes cases in which donated oocytes from healthy fertile women were used. The results of this study should not be extrapolated to any other female group.
Wider implications of the findings: The findings of this study are very interesting: vitrification/warming procedure of oocytes could induce hardening of the zona pellucida of the resulting embryo and this could affect the clinical outcome. The use of a laser assisted hatching before embryo transfer should be highly recommended in oocyte cryo cycles.
Trial registration number: The study was approved by the Institutional Review Board (Ref. no. 3/2015, granted 7 January 2015).

P-263 Are embryo morphokinetics affected by patient age?

A. Barrie[1], K. Schnauffer[1], C. Kingsland[1], G. McDowell[2], J. Brown[2], S. Troup[1]
[1]Liverpool Women's NHS Foundation Trust, The Hewitt Fertility Centre, Liverpool, UK
[2]Edge Hill University, Ormskirk, UK

Study question: When twelve morphokinetic parameters are examined from utilised embryos, can differences in two patient age groups be seen and could these differences be used to improve current embryo selection methods?
Summary answer: Variations in morphokinetic parameters can be seen between two age groups; younger patient's embryos have a significantly different morphokinetic profile to those from older patients.
What is known already: With the advent of time-lapse systems, many are seeking to determine more effective mechanisms for embryo selection. Data presented thus far suggests that treatment, environment and patient parameters can affect an embryo's early morphokinetic profile. However, these apparent differences are yet to be used to aid embryo selection clinically. In addition, to our knowledge, there is yet to be a large cohort of embryos analysed for apparent morphokinetic differences when considering patient parameters such as age.
Study design, size, duration: Images from embryos cultured in an EmbryoScope® incubator over a 40-month period were retrospectively analysed. Analysis of two patient groups (younger; <35, older; ≥35) comprised two stages; differences in morphokinetic parameters in all utilised embryos (transferred or cryopreserved); differences in morphokinetic parameters in embryos that created a fetal heartbeat.
Participants/materials, setting, methods: Embryos (n = 2069) from patients undergoing treatment at a single study site were included. Culture comprised Vitrolife sequential media (G1-Plus™ and G2-Plus™) at 5% O_2, 6% CO_2, 37°C throughout in an EmbryoScope® incubator. Morphokinetic data for twelve parameters (tPNf (pronuclei fading), time to n cell (tn) (t2, t3, t4, t5, t6, t7, t8, t9+), time to morula (tM), start of blastulation (tSB) and blastocyst (tB) were derived retrospectively and collated for analysis.
Main results and the role of chance: The morphokinetic profiles (shown as median hours post-insemination for tPNf and median hours post-tPNf for all other morphokinetic parameters) of utilised embryos from younger patients were statistically significantly different to those from older patients when considering tPNf (23.3 vs 24.0), t3 (13.6 vs 13.8), t4 (14.3 vs 14.5), t5 (26.6 vs 27.0), t6 (27.7 vs 28.1), t7 (29.0 vs 29.3), t9+ (46.8 vs 47.5), tM (58.5 vs 59.9), tSB (71.1 vs 72.5) and tB (81.8 vs 83.4) (significant at $p < 0.05$, Mann-Whitney U test). In addition, embryos that created a fetal heartbeat displayed statistically significant morphokinetic differences between younger and older patients when considering tPNf (23.4 vs 23.8), t3 (13.6 vs 13.8), t5 (26.3 vs 26.7) and t6 (27.2 vs 27.8) (significant at $p < 0.05$, Mann–Whitney U test). Overall, embryos from younger patients appear to develop faster than those from older patients.
Limitations, reasons for caution: Morphokinetic analyses are, by their nature, subjective therefore caution should be taken. This study is a retrospective analysis and prospective trials are required to elucidate the effect of including patient age in embryo selection algorithms. Further analyses will be performed to investigate the significance of cell cycle length and synchrony.
Wider implications of the findings: These data suggest that an embryo's morphokinetic profile can be affected by patient age. These results could inform the development of patient age-specific embryo selection methods resulting in individualised treatment and ultimately an increased chance of selecting embryos with the highest implantation potential.
Trial registration number: n/a.

P-264 High implantation and pregnancy rate after blastocyst transfer in natural cycles

J. Michelon[1], R. Azambuja[1], D. Kvitko[1], L. Okada[1], V. Reig[1], A. Tagliani-Ribeiro[1], P. Rafaella[1], B. Fernando[1], P. Leticia[1], F. Shana[1], M. Badalotti[1], A. Petracco[1]
[1]Fertilitat-Centro de Medicina Reprodutiva, Reproductive Medicine Center, Porto Alegre, Brazil

Study question: The transfer of frozen blastocyst in natural cycles may increase the pregnancy and implantation rate?
Summary answer: High pregnancy and implantation rates are observed following transfer of frozen blastocysts, utilizing natural cycles.
What is known already: The high progesterone level before HCG in IVF cycles causes advanced endometrium. Therefore it is suggested that embryo cryopreservation for later transfer.
Study design, size, duration: Retrospective study to evaluate clinical pregnancy and implantation rates in women that transferred frozen blastocysts using natural cycle during the year of 2015 at Clinica Fertilitat.

Participants/materials, setting, methods: Forty-four women with no pregnancy when transferred fresh blastocysts, were submitted to transfer of one or two blastocysts using natural cycle. Five days after spontaneous ovulation, the embryo transfer were performed. No medication was utilized during this process.
Main results and the role of chance: The women average age was 33.6 years. The endometrium thickness was de 10.5 mm at the time of transfer. The pregnancy and implantation rate was the 72.7 and 59.1%, respectively. Twenty seven women transferred two embryos and 17 (38.7%) transferred only one embryo. Women that transferred only one embryo had a pregnancy rate of 52.9, while women that transferred two embryos, 85.2% were pregnant. The percentage of twins, abortion, and ectopic pregnancy were 37%, 18.7% and 12.5% respectively.
Limitations, reasons for caution: The natural cycle utilization, without the use of hormones, it is a brake of paradigmas with the patients that are used to mainly interventions in IVF procedures.
Wider implications of the findings: It seems that there is a negative effect of the hyperstimulation on the endometrium maturation, moving the implantation window. The natural cycle physiology seems to favor to a better synchrony to embryo implantation.
Trial registration number: Not necessary.

P-265 A prospective multicentre comparison of two different single step culture media using sibling embryos

A. Campbell[1], R. Smith[2], S. Montgomery[1], L. Jenner[3], L. Nice[4], S. Rhodes[4], K. Dowell[3], S. Fishel[3]
[1]*Care Fertility Group, Embryology, Manchester, UK*
[2]*CARE Fertility, Embryology, Sheffield, UK*
[3]*CARE Fertility, Embryology, Nottingham, UK*
[4]*CARE Fertility, Embryology, Northampton, UK*

Study question: Can G-TL™, a CE-marked medium specifically designed for extended and undisturbed embryo culture, replace the clinics standard global® medium, supplemented with dextran serum substitute (DSS)?
Summary answer: As no statistical difference in blastocyst development was detected and a significantly lower miscarriage rate was observed with G-TL™ medium, there is evidence to support change.
What is known already: Single step embryo culture media do not generally require media changes during embryo culture, a feature which makes them attractive for time-lapse culture and minimises handling stress. There are several media for undisturbed culture commercially available; however, despite being well established and effective in IVF laboratories, all are not appropriately CE-marked. G-TL™(Vitrolife) is a complete medium that is CE-marked, as a class II medical device, providing regulatory compliance for the European market. Global® medium (LifeGlobal), supplemented with DSS (Irvine), is a non-CE marked combination. Increasing demands from regulatory bodies for approved products justifies this comparison of two media alternatives.
Study design, size, duration: The study was designed as a prospective multicentre sibling embryo study. Four clinics following standard laboratory protocol participated. The primary endpoint was blastocyst formation. Secondary endpoints included blastocyst utilisation and clinical outcomes. To improve the outcome of the primary endpoint by 12%, the number of blastocysts required was 482 (241 in each arm). The embryos recruited for the study were cultured between June 2014 and December 2015.
Participants/materials, setting, methods: 1033 embryos fertilized by both IVF and ICSI were included in the study. Embryos subjected to PGD or PGS were excluded. Allocation to the different culture media was done randomly at low magnification after fertilization check on day 1. Embryos were cultured in both standard incubators (Miri, ESCO) and in EmbryoScope® time lapse systems (Vitrolife). G-TL™ is a ready-to-use culture medium; global® medium was supplemented with DSS as a protein source.
Main results and the role of chance: 576 blastocysts developed from the 1033 2PNs. The data analysis revealed no significant difference in 2PN to blastocyst development on day 5 between G-TL™ and global®, 60.3% and 63.3% respectively ($p = 0.3455$). The results were also comparable between G-TL™ and global® when assessing good quality blastocyst formation (GQB) per 2PN (equivalent to 3BB or better using the Gardner score) (19.9% and 20.2%, $p = 0.9447$). Analysing GQB per blastocysts formed, results were 31.7% and 28.0% ($p = 0.5406$) for G-TL™ and global® respectively. Utilisation rate of blastocysts (transferred or cryopreserved) per 2PN for G-TL™ and global® were 43.3% and 45.7% respectively ($p = 0.4870$).)

Interestingly, there was, a significantly lower miscarriage rate for G-TL™, 5.0% compared to 17.7% for global®/DSS ($p = 0.0279$) for all embryo transfers ($n = 122$). The clinical pregnancy rate per transfer (53.3% and 54.8%, $p = 0.8681$) and implantation rate (48.5% and 45.6%, $p = 0.7209$), were comparable between G-TL™ and global®.
Limitations, reasons for caution: The study did not reach the targeted difference for the primary endpoint. Assessing blastocyst formation as primary outcome may not relate to clinical outcome, however, since miscarriage rate reached statistical significance, aside from meeting regulatory compliance, introduction of G-TL® may minimise the burden of miscarriage for patients in participating clinics.
Wider implications of the findings: No significant difference in blastocyst formation between G-TL™ and the global®/DSS combination was seen but the results support the use of G-TL™ as a single step culture medium for markets where regulatory compliance is required, compared with global®/DSS for embryo culture and avoids the need for protein supplementation.
Trial registration number: not applicable.

P-266 Correlation of cumulus gene expression of AKT1, BCL2L2 and SHC1 with murine oocyte maturation

C. Tatone[1], G. Di Emidio[1], P.G. Artini[2], M. Vento[3], C. Di Pietro[4], R. Ciriminna[5], M. D'Aurora[6], L. Stuppia[6], V. Gatta[6]
[1]*University of L'Aquila, Department of Life, Health and Environmental Sciences, L'Aquila, Italy*
[2]*University of Pisa, Department of Clinical and Experimental Medicine, Pisa, Italy*
[3]*Cannizzaro Hospital, IVF Unit, Catania, Italy*
[4]*University of Catania, BioMolecular, Genome and Complex Systems BioMedicine Unit BMGS, Section of Biology and Genetics G Sichel, Department of BioMedicine and BioTechnology, Catania, Italy*
[5]*AMBRA, Associazione Medici e Biologi per la Riproduzione Assistita, Palermo, Italy*
[6]*CeSI, Center for Research on Ageing "G. d'Annunzio" Foundation, Chieti, Italy*

Study question: Could be cumulus cells (CCs) gene expression profile explored as potential markers of oocyte maturation?
Summary answer: Data have shown a CC gene expression associated with oocyte maturation timing.
What is known already: It is widely recognized that the production of competent oocytes is related to the bidirectional communication existing between the oocyte and CCs. It has been observed that CC apoptosis rates from morphologically abnormal oocytes were significantly higher than normal oocytes. An increase in CC apoptosis has also been associated with immaturity of oocytes and impaired fertilization. PI3K/Akt pathways is utilized by cumulus cells to support development and maturation of the oocyte. AKT1, BCL2L2 and SHC1, involved in the PI-3-K/Akt pathway, were reported to be associate with CC growth and apoptosis and could play a central role in oocyte maturation.
Study design, size, duration: This study was conducted to evaluate the correlation of cumulus AKT1, BCL2L2 and SHC1 gene expression levels with oocyte maturation. To test this hypothesis we collected CCs at different oocyte maturation profile (6 h, 12 h, 15 h, 21 h) for a total of 30 cumuli for each condition. Gene expression levels in cumulus cells were assessed using quantitative real-time polymerase chain reaction.
Participants/materials, setting, methods: CD1 mice aged 24–30 weeks were stimulated by PMSG followed by hCG 48 h later. Cumulus-oocyte complexes were collected at different after hCG (6 h, 12 h, 15 h, 21 h), for a total of 30 cumuli for each condition. Total RNA was extracted from CCs using the Arcturus Pico Pure RNA Isolation Kit. A Taq-Man Real Time approach was used to analyze gene expression on the selected transcripts.
Main results and the role of chance: We measured the gene expression levels of AKT1, BCL2L2 and SHC1 in 4 pools containing each 30 cumulus cells. Statistical analyses were performed to evaluate the correlations between CCs gene expression and oocyte maturation status. All the analyzed transcripts resulted significantly higher in CCs associated to non-mature or old oocytes (6 h and 21 h, respectively) when compared to expression levels in CCs associated to oocyte with correct timing of maturation (12–15 h). These results are in line with

our unpublished data, showing a reduced expression levels of AKT1, BCL2L2 and SHC1 in human CCs associated to positive IVF outcome. These data support the idea that CCs gene expression is strictly related to oocyte competence and could represent potential non-invasive biomarkers of oocyte quality.
Limitations, reasons for caution: Lack of information about oocyte morphometric parameters.
Wider implications of the findings: The expression of AKT1, BCL2L2 and SHC1 in CCs could represent non-invasive biomarkers to assess oocyte competence. These findings could be useful to unravel the molecular basis of cumulus-oocyte complex correct development.
Trial registration number: Not required.

P-267 Comparison between gene expression of in vivo or in vitro matured bovine oocytes and impact of vitrification in this expression

L. Caetano Da Silva[1], F.L.V. Pinaffi[2], I.B. Jardim[2], L.A. Batista[1], C.P. Pitangui-Molina[1], C.L. Miranda-Furtado[1], T.T. Higa[1], L.A. Silva[2], A.C. Rosa-e-Silva[1]
[1]*FMRP, University of São Paulo, Gynecology and Obstetrics, Ribeirão Preto, Brazil*
[2]*FZEA, University of São Paulo USP, Department of Veterinary Medicine, Pirassununga, São Paulo, Brazil*

Study question: Influence of In vitro maturation (IVM) and vitrification processes in the expression of genes related to oocyte competence, in a bovine experimental model.
Summary answer: IVM and vitrification techniques showed reduced levels of gene expression in oocytes. The impact was more significant after vitrification, possibly due to degradation of mRNA.
What is known already: IVM and cryopreservation of oocytes have been applied for fertility preservation, however the reproductive results are still limited, probably secondary to partial damages in the oocyte. The role of IVM and vitrification techniques in the RNA levels of genes related to oocytes structure, viability and/or function is not completely elucidated. Modifications in stocks of the specific mRNA these oocytes after IVM and vitrification may be helpful in elucidating the mechanisms of injury when these techniques are applied. The bovine model is justified by its similarity to human's physiology and also due to the scarcity of human oocytes for research.
Study design, size, duration: It is a sectional study performed in two periods to analyze the gene expression of: A) oocytes matured in vivo recovered by Ovum Pick up (OPU) (control group 1) versus oocytes submitted to IVM (treatment group 1) and B) oocytes from IVM (control group 2) versus oocytes from IVM plus vitrification (treatment group 2). A total of 20 oocytes/group, obtained from different animals, were processed individually to obtain the gene expression level.
Participants/materials, setting, methods: The expression of 42 genes related to oocyte structure, viability and/or function from Nelore cattle (Bos indicus) was analyzed. RNA extraction, cDNA synthesis and preamplification of target genes were performed followed by quantification by real time PCR (2-ddCT). Mann-Whitney test was used to compare the gene expression between groups ($\alpha = 0.05$). The relation between gene expression and the age of the donor animal from the in vivo group was also analyzed using the Spearman correlation coefficient.
Main results and the role of chance: A. in vivo X IVM oocytes: The expression was positive for 36 genes, and RNA values were statistically different between the groups (in vivo with higher expression than IVM oocytes for all differently expressed genes). ANXA2 (growth factor and intracellular signaling) and MAPK13 genes (cell cycle and cytoskeletal organization) showed lower expression in oocytes from older cows. **B. Vitrified X non-vitrified oocytes**: ANXA2, ARL6IP6, BCAP31, BMP15, BTG1, CD97, CDC20, CETN3, CKS2, DDR1, EEF1A1, GDF9, HK1, HSPA8, MSX1, NOBOX, PLIN2, PPA1, PSEN1, RPS15, TXN, and ZP2 genes showed lower levels of expression, while ATP5A1, CLU, DNMT3, F11R, GJA, GOT1, IGF2R, MAPK13, RPSK6B, SERPINE1, TCF4, TMIGD1, ZDHHC16 genes showed similar RNA levels between groups.
Limitations, reasons for caution: The IVM oocytes were obtained from different animals, and although they were from the same race they were not pared by age.
Wider implications of the findings: Although there is no transcriptional activity in the oocyte after resumption of meiosis, the mRNA is undergoing post-transcriptional regulatory mechanisms and it can be also degraded. Our analysis may be a tool for the development of more suitable maturation and/or cryopreservation mediums to prevent the alteration of mRNA levels.
Trial registration number: no.

P-268 The cumulative pregnancy rate is higher after fresh eSET than after eDET of top quality cleavage stage embryos

F. Prados Mondéjar[1], G. Perez-Bermejo[1], V. Santos[1], A. Díaz-Morales[2], A. Fuertes[2], I. Bruna[1]
[1]*Hospital HM Montepríncipe, HM Fertility Center, Boadilla del Monte, Spain*
[2]*Hospital HM Puerta del Sur, HM Fertility Center, Móstoles, Spain*

Study question: For good prognosis patients, is cleavage-stage fresh eSET an optimum strategy for reducing multiple pregnancies without a reduction in pregnancies?
Summary answer: Fresh transfer of one instead of two top-quality cleavage-stage embryos leads not only to less multiple pregnancies, but to a higher overall pregnancy rate.
What is known already: Elective single embryo transfer (eSET) reduces multiple pregnancy rates but can decrease the pregnancy rate. In good prognosis cases such as in oocyte donation, when selection is done at the blastocyst stage, eSET is considered a very reasonable approach, however, it is not widely used when transfer and cryopreservation are performed at the cleavage stage (day 2–3 embryos).
Study design, size, duration: Retrospective analysis of IVF cases with own oocytes between 2007 and 2015. Patients age <38 years, with fresh transfer of either one (eSET group) or two (eDET group) top quality embryos according to the ASEBIR classification. In all cases, at least another top quality embryo was frozen at cleavage stage.
Participants/materials, setting, methods: The mean age was 33.5 for the eSET and 34.6 for the eDET group, total top quality embryos per cycle were 3.3 and 3.6, fresh + frozen embryos were 5.9 and 5.2 respectively. In both groups 3.7 embryos per cycle were used in total, either on fresh or on frozen embryo transfers. Cumulative (fresh + frozen) pregnancy rates (gestational sac with heart activity) were compared between both groups.
Main results and the role of chance: A total of 119 fresh transfers were performed in group eSET and 108 in eDET. The pregnancy rates (FHB +ve) were 46.2% for eSET and 55.6% for eDET ($p > 0.05$), with an implantation rate of 46.2% and 37.0% $p > 0.05$) and with a multiple pregnancy rate of 1.8% and 33.3% ($p < 0.0001$) respectively. The cumulative pregnancy rate per cycle was 98.3% (117/119) in the eSET group and 88.0% (95/108) in the eDET ($p < 0.01$). Both groups of cycles were similar in terms of patient age and quality of embryos. The same number of embryos was used in both groups. The slight (non significant) increase in the implantation rate in the eSET group suggests a lack of positive cooperation for implantation between embryos.
Limitations, reasons for caution: Not being a prospective randomized trial, the patients are not randomly distributed in both groups. Although the main characteristics of the groups are similar, slightly better prognosis cases could have been allocated to the eSET group.
Wider implications of the findings: A significant increase in cumulative pregnancy rate was obtained in the eSET group. This increase, together with the decrease in the risk of multiple pregnancies, indicates the superiority of the day 2–3 eSET plus freezing approach in good prognosis cases.
Trial registration number: NA.

P-269 Vitrification of non blastulating day 5 embryos. A method to resynchronize endometrium with embryos presenting late blastocyst formation

Y. Panagiotidis[1], P. Vanderzwalmen[1], E. Kasapi[1], A. Papatheodorou[1], M. Goudakou[1], S. Petousis[1], G. Papatzikas[1], K. Ravanos[1], N. Prapas[1], Y. Prapas[1]
[1]*Iakentro Fertility Centre, IVF Laboratory, Thessaloniki, Greece*

Study question: Can we increase the implantation potential of non blastulating day 5 embryos by expanding culture, before vitrify them as full blastocysts and replace them in a consecutive frozen embryo transfer?
Summary answer: Expanding cumulative culture time, before or/and after cryopreservation of late blastulating embryos increases their implantation rate when replaced to a resynchronized endometrium.
What is known already: Although embryos developing to full blastocysts on Day5 vs Day6 present similar aneuploidy rates, they have different implantation

potential when transferred in fresh cycles, favoring those embryos that develop faster. On the other hand when replaced in frozen cycles, day 5 and day 6 blastocysts present comparable implantation competence. Additionally, non blastulating day 5 embryos, have very low implantation rates compared to full blastocysts when they are replaced during a fresh, stimulated cycle.

Study design, size, duration: A two year, retrospective, observational study including 73 fresh and 125 frozen cycles that no blastulating embryo was observed after 120 h of culture. In all fresh cycles (group1, n = 73), the replaced embryos, presented no blastocoel formation. In the vitrified/warmed cycles, during their fresh cycle, non blastulating day 5 embryos where either cultured and vitrified on day 6 (group2, $n = 56$) or vitrified on day 5 and further cultured for 24 h post warming (group3, $n = 79$).

Participants/materials, setting, methods: The study included infertility cases of various etiologies, from two private ART settings of the same clinic, where similar protocols of controlled ovarian hyperstimulation were applied. Severe male factor cases were excluded. The mean age of women was 36.8 years. Where applicable, embryos were vitrified using the FertiPro vitrification kit combined with a closed carrier system (VitriSafe).

Main results and the role of chance: Clinical pregnancy rate was the main outcome and was compared between Group 1 vs Group 2 and Group1 vs Group 3. Statistically significant differences were observed in the clinical pregnancy rate of fresh transfers of non blastulating embryos in Group 1 vs transferring day 6 vitrified-warmed blastocysts in Group 2 (27.4% vs 53.7%, $p = 0.002$) and respectively for transferring vitrified morulae on day 5, which were further cultured for 24 h post warming, in Group 3 (27.4% vs 55.1% $p = 0.001$). Extending cumulative culture duration, before or after cryopreservation, giving more time to fully compacted day 5 embryos to develop to full blastocysts, while replacing them to a resynchronized, day 5 progesterone endometrium, increases the implantation potential of such embryos.

Limitations, reasons for caution: Allocation of cases to the fresh or the vitrified-warmed embryo transfer groups was based on couple's acceptance to cancel the fresh transfer, on the workload of the lab and finally on the day of the week but in general it cannot be considered as a random process.

Wider implications of the findings: Findings seem to agree with the small amount of published data. Further larger studies need to be conducted to verify whether cryopreservation of embryos should be performed only at a predefined developmental stage, appropriate for the endometrial synchronization.

Trial registration number: n/a.

P-270 In vitro coculture system of autologous endometrial cells and human early embryo development: randomized study update

I.J. Kadoch[1], C. Le Saint[1], S. Phillips[1], A. Neymon Sesques[1], S. Bisotto[1], C. Lévesque[1], B. Couturier[1], J.N. Gouze[2], S. Hamamah[3], F. Bissonnette[1]
[1]*clinique ovo, ovo r&d, Montréal, QC, Canada*
[2]*Genbiotech, Genbiotech, Sophia Antipolis, France*
[3]*CHRU Montpellier, Hôpital Arnaud-de-Villeneuve, ART-PGD, Montpellier, France*

Study question: What is the influence of an autologous endometrial cell co-culture system on the rate of top quality blastocysts compared with conventional culture medium in IVF?

Summary answer: Autologous endometrial cell co-culture significantly improved the rate of top quality blastocysts (TQB) compared with conventional culture medium.

What is known already: In vitro culture conditions, including culture medium, affect early embryo quality. Autologous endometrial co-culture (ECC) using the patient's own endometrial cells (EC) has been reported in order to mimic the microenvironment of early embryo development under IVF conditions.

Study design, size, duration: This interventional, monocentric, randomized, double-blind controlled trial was conducted at our clinic from April 2013 to March 2015 and is still ongoing. Eighty-five IVF couples were enrolled into the study: 48 patients cultured in conventional culture medium (control group) and 37 patients using an autologous co-culture system of EC (study group).

Participants/materials, setting, methods: For each patient, an endometrial biopsy was performed during the luteal phase of the cycle prior to ongoing IVF. For the co-culture group, EC were isolated from biopsies and cultured from the day after ovulation triggering. At day 2, embryos were placed either on ECC or in conventional culture medium according to patient randomisation. The results confirm an increase in TQB for a similar blastulation rate.

Main results and the role of chance: At day 2, a total of 261 and 217 top quality embryos were obtained in the control and co-culture group (mean ± SD per patient 5.4 ± 2.4 and 5.9 ± 2.1 respectively). The blastulation rate was 65.5% (171/261) versus 64.1% (139/217) in the control and co-culture groups respectively. Considering blastocyst quality, the proportion of usable blastocysts (for fresh replacement or cryopreservation) in the co-culture group was significantly higher (77.0%) compared to the control group (62.6%) ($p < 0.05$). In single patient comparison (control group randomized patient coming back for co-culture), the rate of TQB (D5/6) using co-culture was 43.5% compared to 18.9% in conventional culture medium ($p < 0.05$).

Limitations, reasons for caution: N/A.

Wider implications of the findings: Based on these data the use of a co-culture system of EC could potentially lead to the need for less IVF cycles per patient by increasing the number of available embryos per cycle. This hypothesis remains to be demonstrated by further analysis.

Trial registration number: NCT01886118.

P-271 Blastomere nuclear fading morphokinetic: a new perspective of early embryo biology

J.M. Moreno-Moya[1], C. Olmedo Illueca[1], R. Dasí Crespo[1], J.G. Descals Ferrando[1], I. Cuevas Saiz[1]
[1]*Hospital General Universitario de Valencia, Unidad de Reproducción Humana, Valencia, Spain*

Study question: Is it possible to obtain individual blastomere cell cycle information taking into consideration its nuclear fading as a time-point?

Summary answer: Determination of blastomere nuclear fading morphokinetics indicates an elongation of interphases and shortage of mitosis across cell divisions up to 8-cell stage.

What is known already: Time-lapse systems have been widely introduced in clinical routine, however there is no common consent on improvements on embryo selection and pregnancy rates. In addition, sibling embryos have a cell division pattern close to each other independently from its quality. Related to human embryonic genome activation, some studies indicate that embryo starts transcription as early as 2-cell stage. Also, first mitosis requires organization and polymerization of the mitotic spindle for the first time. Recent studies have shown correlation between morphokinetics and embryo genome activation, but none of them have considered the duration of mitosis and interphases across early embryo development.

Study design, size, duration: Retrospective clinical study. A total of 185 embryos from 113 IVF/ICSI cycles performed between January and December 2015. Embryos were cultured and analyzed morphokinetically. From 185 embryos, 124 were transferred. Only embryos with 100% ($n = 28$) or 0% ($n = 96$) of implantation were included to analyze. In addition, embryos that reached blastocyst stage were also analyzed ($n = 60$ from those transferred and $n = 61$ from those non-transferred, but frozen).

Participants/materials, setting, methods: Embryos were cultured in single step culture media (Irvine®) in a benchtop incubator with time-lapse system (Miri-TL. Esco systems®). Morphokinetic data from embryos were used to calculate interval parameters (cc2, s2, cc3 and s3). Regarding blastomeres, its nuclear fadings were used to calculate interphases and mitosis at every stage from 2 to 8 cells. Inter-parameter and inter-group comparisons were tested for normal distribution and statistically evaluated using non-parametric *U*-Mann Whitney test.

Main results and the role of chance: Comprehensive time-lapse analysis for interval parameters regarding blastomere dynamic (cc2, s2, cc3 and s3) showed a significant difference for cc3 between "Blastocyst reaching embryos" and "Not implanted" (13.67 ± 4.45 vs 13.01 ± 5.57 respectively). Intra-group analysis of interphases from blastomeres at 4-cell stage compared to interphases of respective progenitor cells (at 2-cell stage) were significantly larger, in all cases for the three different groups of embryos. Inter-group interphases analysis of parameters did not show significant differences only for just one blastomere interphase at 4-cell stage between "Blastocysts reaching embryos" and "Not implanted" (13.43 ± 3.2 vs 12.07 ± 2.67 respectively). Intra-group analysis of mitosis showed that first mitosis was significantly larger than second mitosis in all groups of embryos; Second round of mitosis was significantly larger than third round of mitosis in "Not implanted" and "Blastocyst reaching embryos" but not in the "implanted" group. Inter-group analysis of mitosis did not show any difference between groups.

Limitations, reasons for caution: No embryo quality was taken into consideration for embryo group stratification. Impaired endometrial receptivity could have drawn potentially good embryos to the "Not implanted" group. Sample size limits the study to non-parametric analysis.
Wider implications of the findings: This new parameters are reflecting biological events of early development. First mitosis is significantly longer than the following ones. This could be due to higher complexity in first spindle organization. Interphase duration seems to be longer in daughter cells, this could be explained as a result of embryonic genome activation.
Trial registration number: 0.

POSTER VIEWING SESSION

ENDOMETRIOSIS, ENDOMETRIUM, IMPLANTATION AND FALLOPIAN TUBE

P-272 Syndecan-4 expression is upregulated in endometriosis and contributes to an invasive phenotype

M. Götte[1], A. Chelariu-Raicu[2], C. Wilke[2], M. Brand[2], A. Starzinski-Powitz[3], L. Kiesel[2], A. Schüring[2]
[1]*Münster, Germany*
[2]*Münster University Hospital, Gynecology and Obstetrics, Münster, Germany*
[3]*Johann-Wolfgang-Goethe University of Frankfurt, Institute of Anthropology and Human Genetics for Biologists, Frankfurt, Germany*

Study question: Does altered expression of the transmembrane proteoglycan Syndecan-4 contribute to the pathogenesis of endometriosis?
Summary answer: Upregulation of Syndecan-4 in endometriosis may facilitate establishment of ectopic lesions by promoting invasive growth via Rac1, ATF2 and MMP3.
What is known already: Syndecan-4 is a regulator of cell motility and invasiveness in fibroblasts and in malignant diseases. Endometrial Syndecan-4 mRNA expression varies in a menstrual-cycle-dependent manner, suggesting hormonal regulation.
Study design, size, duration: Histopathological investigation of eutopic endometrium and experimental laboratory study on an endometriotic cell line (12Z). For the immunohistological investigation of Syndecan-4-expression, eutopic endometrium of 106 women (62 controls/44 endometriosis) from the IVF centre of Münster University Hospital aged 23–44 undergoing Pipelle Biopsy and diagnostic exploratory laparoscopy were studied (Ethical appoval number 1 IX Greb). The human endometriotic cell line 12Z was transiently transfected with Syndecan-4 small interfering RNA and investigated for changes in cell behaviour.
Participants/materials, setting, methods: Syndecan-4 expression in eutopic endometrium was evaluated immunohistochemically in endometrial glands and stroma. Scoring results were correlated with the stages of the menstrual cycle and presence or absence of endometriosis. Quantitative polymerase chain reaction was used to measure Syndecan-4-dependent expression changes of MMP2, MMP3, MMP9, Rac1 and ATF2. Altered cell behavior was monitored by Matrigel invasion assays and cell viability assays.
Main results and the role of chance: Syndecan-4 expression was significantly higher in the glands and stroma of endometriosis patients compared to controls ($p < 0.001$), whereas no menstrual-cycle dependent expression was observed. In 12Z cells, Syndecan-4 depletion did not affect cell viability, but resulted in a significantly reduced matrigel invasiveness ($p < 0.05$), and reduced expression of the small GTPase Rac1, the transcription factor ATF-2, and MMP3 ($p < 0.05$).
Limitations, reasons for caution: The patient collective investigated is derived from an IVF centre, which may have introduced a bias. Only eutopic endometrium, but no ectopic lesions have been studied. The functional in vitro data have been generated on an immortalized cell line, which may partially differ from results generated in primary cells.
Wider implications of the findings: The upregulation of Syndecan-4 in the eutopic endometrium of endometriosis patients may facilitate the pathogenetic process by promoting invasive cell growth via Rac1, MMP3 and ATF-2.
Trial registration number: Not applicable.

P-273 The use of resveratrol for pain in endometriosis – a randomized clinical trial

R. Savaris[1], D.M. da Silva[1], L. Gross[1], B. Lessey[2]
[1]*Universidade Federal do Rio Grande do Sul, Gynecology and Obstetrics, Porto Alegre, Brazil*
[2]*Greenville Health System, Gynecology and Obstetrics, Greenville, SC, USA*

Study question: Compared to placebo, does resveratrol (40 mg/day) reduce pain scores after 42 days of use in women with endometriosis?
Summary answer: In women with endometriosis, pain scores after 42 days of daily use of 40 mg of resveratrol are not significantly different from placebo.
What is known already: Pelvic pain is the major complaint among patients with endometriosis. An open label, not randomised trial, has shown that resveratrol reduces up to 90% pain levels of women with endometriosis, compared to placebo.
Study design, size, duration: This randomised, double blinded, placebo controlled trial enrolled 44 subjects. Allocation sequence was concealed in coded sequenced opaque sealed envelopes. Sample size was calculated to have a 95% chance of detecting, as significant at the 1% level, a 90% reduction comparing placebo and resveratrol in a 0 to 10 pain scale (i.e., a final pain score of 3.5 in the placebo group to 0.5 in the resveratrol group).
Participants/materials, setting, methods: Women between 18–50 years old with laparoscopic diagnosis of endometriosis were eligible for the study. All subjects received an COC for 42 days, to be taken with 42 identical capsules containing 40 mg of resveratrol or placebo in coded bottles. Pain scores were measured using an analog visual scale (AVS) on day 42. Side effects and use of additional pain medication was recorded. Compliance was verified by inspection of returned blisters and bottles.
Main results and the role of chance: Mean (95%CI) pain scores at day 0 were 5.4 (4.2 to 6.6) and 5.7 (4.8 to 6.6) in placebo and resveratrol groups. After 42 days of treatment, mean pain values were [3.5 (2.2 to 4.9); $n = 22$] and [2.9(1.8 to 4); $n = 22$] in the placebo and in the resveratrol groups, respectively ($p = 0.7$–2-way ANOVA with repeated measurement -2WA-RM). However, a significant reduction in pain levels was found between day 0 and day 42, in placebo ($p = 0.01$ -2WA-RM) and in the resveratrol group ($p = 0.0007$ -2WA-RM
Limitations, reasons for caution: These results were limited to the use of resveratrol at this dosage and for 42 days of use.
Wider implications of the findings: Pain difference between both groups after 42 days of treatment was 18%, a lower reduction compared to previous study. Such reduction casts doubt on its clinical significance and the need to seek further research.
Trial registration number: ClinicalTrials.gov, number NCT02475564.

P-274 The prevalence of high risk human papillomavirus in ovarian endometriosis

M. Heidarpour[1], M. derakhshan[1], M. Kheirollahi[2], S. Dashti[2], M. Derakhshan-Horeh[3]
[1]*Isfahan University of Medical Sciences, Pathology, Isfahan, Iran*
[2]*Isfahan University of Medical Sciences, Pediatric Inherited Diseases Research Center & Medical Genetics, Isfahan, Iran*
[3]*Tehran University of Medical Sciences, Anatomy, Tehran, Iran*

Study question: To investigate whether human papilloma viruses (HPV) are associated with ovarian endometriosis lesions.
Summary answer: Findings indicated a higher rate of high risk HPV infection among patients with endometriosis but it was not associated with age, marital status, and parity.
What is known already: Endometriosis affects approximately one in ten women of reproductive age. The exact pathogenesis of the disease has not been known clearly. One of the main reasons is retrograde menstruation of endometrial cells into the peritoneal cavity. It is also suggested that intrauterine infection could initiate the endometriosis process by activating pro-inflammatory pathways and innate immunity. Beside the role of HPV in the pathogenesis of many malignant and non malignant diseases has been reported. The concept of viral infection as origin of endometriosis developed recently. It seems necessary to determine the prevalence of HPV infection in ovarian endometriosis.
Study design, size, duration: Tissue sections of 50 ovarian endometriosis and 49 ovaries without endometriosis (control group) were selected. The mean age in the case and control groups was 43.02 ± 7.64 and 42.24 ± 13.13,

respectively. Samples of ovarian endometriosis were obtained by laparoscopic surgery of the involved patients and control samples were from ovarian tissue of women of reproductive age undergone ovarian surgery for reasons other than endometriosis.
Participants/materials, setting, methods: Tissue sections of paraffin embedded samples were deparaffinized with xylene and rehydrated by graded ethanol and Double Distilled Water (DDW). HPV DNA detection was performed using HPV Screening PCR Kit. High risk HPV was detected using HPV High Risk Typing PCR Kit. The kit was used for a multiplex in vitro nucleic amplification test for genotyping of HPV types 16, 18, 31, 33, 35, 39, 45, 52, 56, 58 and 59 in clinical specimens.
Main results and the role of chance: Samples with and without endometriosis were not different significantly regarding age ($p = 0.71$), marital status ($p = 0.05$) and parity ($p = 0.46$). High risk HPV infection was detected in 42(84%) and 27(55.1%) of samples with and without endometriosis, respectively ($p = 0.02$, X2 = 8.32). Mean of age and parity was not significantly different in subjects with and without HPV infection in both studied groups ($p = 0.7$ and $p = 0.06$ for age in case and control groups, respectively and $p = 0.32$ and $p = 0.09$ for parity in case and control groups, respectively).
Limitations, reasons for caution: In this study we have no accessibility to record more detailed information from studied patients. The high rate observed in both groups may be due to errors of laboratory measurements and other environmental, genetic, or ethnic background of studied population which should be investigated in our future studies.
Wider implications of the findings: HPV may increase the capacity for invasiveness of the endometrial cells into the peritoneal cavity along with retrograde menstruation. Therefore, the findings could provide us baseline information regarding the pathogenesis of endometriosis and the role of viral infection and their impact on future cancer development in this group of patients.
Trial registration number: research project number 391374.

P-275 MK2206 and U0126 synergistically inhibit proliferation of deep endometriotic stromal cells and autophagy inhibition enhances the therapeutic effects of the combination therapy in vitro

S. Matsuzaki[1], C. Darcha[2], J.L. Pouly[1], M. Canis[1]
[1]*CHU Clermont-Ferrand, Obstetrics and Gynecology, Clermont-Ferrand, France*
[2]*CHU Clermont-Ferrand, Pathology, Clermont-Ferrand, France*

Study question: Is co-targeting the serine/threonine kinase AKT and extracellular regulated kinase (ERK) signaling pathways effective treatment in deep infiltrating endometriosis (DIE)?
Summary answer: MK2206 (an AKT inhibitor) and U0126 (a MEK inhibitor) synergistically inhibit proliferation of deep endometriotic stromal cells (DES) and autophagy inhibition enhances the effects.
What is known already: We previously showed that the serine/threonine kinase AKT and ERK signaling pathways may cooperate to support growth of DIE by enhancing cell proliferation and survival of DES in vitro. In addition, we showed that increased matrix stiffness promoted cell proliferation of DES in vitro. Studies showed that matrix stiffness affects responsiveness to cytotoxic drugs in a cell-dependent manner. Current drug screening assays are performed in rigid plastic, which is much stiffer than that occurring in vivo. To investigate cell responses to drugs, it is critical to model in vivo tissue compliance conditions in vitro.
Study design, size, duration: For this laboratory study, endometrial and/or endometriotic tissues from 46 patients who had histological evidence of DIE and endometrial samples from 24 patients without endometriosis were analyzed.
Participants/materials, setting, methods: We evaluated the effects of MK2206 and U0126 on inhibition of cell proliferation, apoptosis, cellular senescence, autophagy and the actin cytoskeleton of DES and endometrial stromal cells of patients with (EES) or without (NEES) endometriosis on polyacrylamide gel substrates of varying stiffness (2-, or 30 kilopascal (kPa)) or plastic. Synergism was determined by calculation of the combination index (CI) according to the median-effect method of Chou and Talalay using the CompuSyn software.
Main results and the role of chance: MK2206 and U0126 synergistically (CI < 1) inhibit proliferation of DES, but antagonistically inhibit that of EES and NEES. U0126 induced significantly higher percentages of Annexin V-positive cells than MK2206 ($p < 0.003$) and the combination of MK2206 and U0126 ($p < 0.04$) in DES. The combination therapy induced significantly higher percentages of Annexin V-positive cells in DES compared with EES derived from the proliferative ($p < 0.002$) and secretory ($p < 0.03$) phases. Expression of beta galactosidase and LC3A/B were induced in MK-2206 treated cells. The combination therapy induced a significantly higher inhibition of cell proliferation in EES compared with DES, when grown on 30-kPa (<0.03) or plastic (<0.03). Recovery rate from cell proliferation inhibition after the combination therapy was significantly higher in DES compared with EES, when grown on 30-kPa (<0.03) or plastic (<0.03). There was no significant difference in either inhibition or recovery of cell proliferation rate between DES and EES grown on 2-kPa after the combination therapy. Autophagy inhibitors enhanced inhibition of cell proliferation induced by the combination therapy, and more importantly, significantly decreased recovery rate in DES, when compared to cells grown on a substrate of the same stiffness (2- or 30-kPa, or plastic, with versus without autophagy inhibitor, $p < 0.05$).
Limitations, reasons for caution: Further animal experiments are required to evaluate in vivo efficacy and toxicity of the combined therapy of MK2206 and U0126 with autophagy inhibitor in endometriosis.
Wider implications of the findings: Recurrent rate is high after medical treatment with or without surgery in patients with endometriosis. The present findings suggested that the combination therapy of MK2206 and U0126 with autophagy inhibitor may be effective for treatment and prevention of recurrences in patients with endometriosis.
Trial registration number: N.A.

P-276 A meta-analysis of impact of endometrial cavity fluid on assisted reproductive technology outcomes

S. Liu[1], J. Shi[2]
[1]*Xi'an, China*
[2]*Northwest Women's and Children's Hospital, ART Center, Xi'an, China*

Study question: To evaluate the impact of the presence of endometrial cavity fluid (ECF) on the outcome of ART cycles.
Summary answer: CPR is significantly lower in patients with ECF than that without ECF. The factors include etiological factor, the development time and the amount of ECF.
What is known already: Endometrial cavity fluid (ECF) is a fluid accumulation in the uterine cavity. The frequency of ECF among patients in some studies depended on the study population, ranging from 3.0%–8.2%, but there is no agreement on the impact of ECF on clinical pregnancy rate.
Study design, size, duration: Literature searches were conducted in the following databases: PubMed, China Academic Journals Full-text Database, China Doctoral and Masters' Dissertations Full-text Database. The selection criteria were study population of women undergoing ART cycles with ECF. Databases were searched for reports published before January 2015. Data were analyzed with RevMan 5.2.7 version. The odds ratio with a 95% confidence interval was calculated using the Mantel-Haenszel method. Six studies involving 4255 cycles were included in the meta-analysis.
Participants/materials, setting, methods: Search strategy: Literature searches were conducted in the following databases: PubMed, China Academic Journals Full-text Database, China Doctoral and Masters' Dissertations Full-text Database.
Selection criteria: The selection criteria were study population of women undergoing ART cycles with ECF. Databases were searched for reports published before January 2015.
Main results and the role of chance: Results: (1) Pregnancy rate was significantly lower in ECF group compared with NO-ECF group ($p = 0.03$). (2) Among the patients with hydrosalpinx, pregnancy rate was significantly lower in ECF group in comparison with NO-ECF group ($p = 0.02$). (3) The percentage of tubal infertility in ECF group was significantly higher than that in NO-ECF group ($p < 0.0001$). (4) After the patients with hydrosalpinx were excluded from tubal infertility, no statistical difference in the percentage of non-hydrosalpinx tubal infertility was found between the ECF and NO-ECF group ($p = 0.69$). The main factors impacting on clinical pregnant outcome include etiological factor of infertility, the time of ECF development and the amount of ECF. In addition, it was hydrosalpinx, not tubal infertility, which was related to the development of ECF.
Limitations, reasons for caution: Some studies did not clearly report the number of implantation embryo. As a result, implantation rate in patients with ECF

could not be assessed. The sample sizes of the included studies were small, especially for the ECF cases.
Wider implications of the findings: The main factors impacting on clinical pregnant outcome include etiological factor of infertility, the time of ECF development and the amount of ECF. In addition, it was hydrosalpinx, not tubal infertility, which was related to the development of ECF.
Trial registration number: none.

P-277 MiR-125b regulates endometrial receptivity by targeting MMP26 in women undergoing IVF-ET with elevated progesterone on HCG priming day

C. Chen[1], Y. Zhao[1], R. Li[1], Y. Yu[1], J. Qiao[1]
[1]Center for Reproductive Medicine, Department of Obstetrics and Gynecology, Beijing, China

Study question: What is the role of miR-125b in endometrial receptivity (ER) in women undergoing IVF-ET with elevated progesterone on human chorionic gonadotrophin (HCG) priming day.
Summary answer: MiR-125b triggers ER decline through reverse regulation of MMP26 function.
What is known already: Elevated progesterone on the day of HCG administration is associated with reduced pregnancy rates. A receptive endometrium is essential for successful embryo implantation. MicroRNAs play important roles in embryo implantation and miR-125b was different-expressed in endometrium in women with elevated progesterone on the day of HCG administration.
Study design, size, duration: The expression profile of miR-125b in endometrium was clarified in human and mouse model. The target gene of miR-125b was predicted by bioinformatics programs and confirmed by dual-luciferase activity assay. The role of miR-125b in cell function and embryo implantation was examined by gain-of-function in endometrial epithelial cells (EECs).
Participants/materials, setting, methods: Human primary EECs and endometrial stromal cells (ESCs) were isolated and cultured in vitro. The expression of miR-125b was detected by real-time PCR. Western blotting and enzyme-linked immunosorbent assay were performed to examine the change of MMP26 in EECs. The effect of miR-125b on cell migration and invasion was tested by transwell assay. The role of miR-125b in embryo implantation was examined by gain-of-function in mouse model.
Main results and the role of chance: The expression of miR-125b was significantly up-regulated in EECs in women with elevated progesterone during the window of implantation, and showed a progesterone-dependent effect in vitro, whereas it was constant in human ESCs. Similarly, the expression of miR-125b was significantly up-regulated in the preimplantation period, and was down-regulated in the implantation period and post-implantation period in mouse EECs. In addition, miR-125b showed a greater decrease at implantation sites than at interimplantation sites. The luciferase report assay showed that MMP26 is a target gene of miR-125b. The expression profile of MMP26 showed an inverse relationship with miR-125b in vivo and in vitro. Overexpression of miR-125b in human EECs inhibited cell migration and invasion by down-regulating MMP26, which may restrain embryo attachment and subsequent invasion of the endometrium. Gain-of-function of miR-125b in mouse model induced a significant decrease in the number of implantation sites.
Limitations, reasons for caution: The role of knock-down of miR-125b in EECs remains to be determined. Other target genes of miR-125b need to be elucidated.
Wider implications of the findings: Our study demonstrates that miR-125b regulates ER by targeting MMP26 in women undergoing IVF-ET with elevated progesterone on HCG priming day. The findings could provide an experimental basis for better understanding of the molecular mechanisms involved in disturbance of ER, and subsequently improve the diagnosis and treatment of infertility.
Trial registration number: This is a basic research without Trial registration number.

P-278 A new innovative method, the uterine immune profiling increases the live birth rate: a non-randomized control study

N. Lédée[1], L. Prat-Ellenberg[1], C. Simon[1], F. Krief[1], R. Balet[1], G. Cassuto[1], D. Bouret[1], L. Chevrier[2], K. Vezmar[2], M. Petitbarat[2]
[1]Hopital des Bluets, Centre de PMA Les bluets-Drouot, Paris, France
[2]MatriceLab Innove, INSERM UMRS-976, Hopital st louis, Paris, France

Study question: Is determination of endometrial immune biomarkers able to improve embryo implantation through better understanding and potentiation of the initial dialogue between uterus and embryo?
Summary answer: Personalization of treatment in function of the patient's immune uterine equilibrium results in a very significant increase of subsequent healthy Live-birth rates.
What is known already: Endometrial remodeling events begin before implantation and are a vital process for pregnancy, preparing future maternal immune tolerance and regulating the placentation process. Within the endometrial environment during this stage, known as "the implantation window", a very peculiar influx of immune cells occurs and nearly completely switches local immunity from the adaptive (Th1) to the innate (Th2) type. This transient immune switch, together with adequate uNK cell activation, appears fundamental in enabling the establishment of local maternal tolerance and survival of the fetus. Nevertheless, the endometrial immune equilibrium has been almost never been considered a key factor to be considered.
Study design, size, duration: Between 2012 and 2014, 193 patients (analyzed group) enrolled in our IVF program benefitted of an endometrial immune profiling. They subsequently had an effective fresh or frozen embryo transfer (ET). If an immune dysregulation have been diagnosed (over or low-endometrial immune activation), the subsequent uterine preparation was personalized accordingly. The analyzed group was paired to a control group (193 patients) according to biological criteria (see below) at the time of ET and their outcome compared.
Participants/materials, setting, methods: Each analyzed patient was paired at the time of the embryo transfer with the closest patient enrolled in our ART program (with no previous endometrial analysis) according to following criteria: same age category; if fresh ET: same method of fertilization, same category of mature oocytes, same stage of ET; if frozen-thawed ET: same stage and number of embryos transferred. Birth rates and Implantation rates were compared between analyzed and control groups.
Main results and the role of chance: While no difference was observed at 3 weeks of pregnancy (WG), implantation rates (IR) at 10 WG and at birth in the analyzed group were significantly higher than observed in the control group (19.4% and 19.4 respectively versus 12.18 and 11.6%, $p = 00.3$ and $p = 0.01$). The most impressive data was the drastic difference regarding miscarriage rate per initiated pregnancy among analyzed and control (respectively 17% versus 41%, $p = 0.003$). Consequently, the live birth rate (LBR) was significantly higher in the analyzed group compared to the control group (27.5% versus 16.6%) despite higher duration of infertility and higher range of previous IVF/ICSI attempts and number of previous ET in the analyzed group.
Among the 193 patients analyzed, 21.7% (42/193) did not have immune deregulation but 78.3% (151/193) showed deregulation of their uterine immune environment at the time of the evaluation and therefore had at their subsequent attempt of ET personalized treatment according to their profile. The birth rate in the deregulated treated group reached 30.46% compared to 16.56% in the respective non-investigated control group ($p = 0.004$). In the analyzed subgroup with no deregulation, no difference was observed. Birth rates were strictly identical between not deregulated and control patients (16.95%).
Limitations, reasons for caution: Only randomized control study may confirm such innovation as well as placebo versus treatment study for each sub-group of immune activation.
Wider implications of the findings: Endometrial immune profiling seems efficient to determine if a woman's uterus is immunologically ready to accept an embryo and, if not, the specific immune mechanisms involved. Such diagnosis may guide physicians through an effective understanding so that they provide treatment that optimizes the conditions of uterine receptivity.
Trial registration number: None.

P-279 Single-cell transcriptome analysis of endometrial tissue

K. Krjutskov[1], S. Katayama[2], M. Saare[1], M. Vera-Rodriguez[3], D. Lubenets[4], K. Samuel[1], T. Laisk-Podar[1], H. Teder[1], E. Einarsdottir[2], A. Salumets[1], J. Kere[2]
[1]Competence Centre on Health Technologies, CCHT, Tartu, Estonia
[2]Karolinska Institutet, Department of Biosciences and Nutrition, and Center for Innovative Medicine, Stockholm, Sweden
[3]Igenomix, Igenomix, Valencia, Spain
[4]University of Tartu, Institute of Molecular and Cell Biology, Tartu, Estonia

Study question: How can we study the full transcriptome of endometrial stromal and epithelial cells at the single-cell level?

Summary answer: By compiling and developing novel analytical tools for biopsy, tissue cryopreservation and disaggregation, single-cell sorting, library preparation, RNA sequencing (RNA-seq) and statistical data analysis.
What is known already: Although single-cell transcriptome analyses from various biopsied tissues have been published recently, corresponding protocols for human endometrium have not been described.
Study design, size, duration: The frozen-thawed endometrial biopsies were fluorescence-activated cell sorted (FACS) to distinguish CD13-positive stromal and CD9-positive epithelial cells and single-cell transcriptome analysis performed from biopsied tissues without culturing the cells. We studied gene transcription, applying a modern and efficient RNA-seq protocol. In parallel, endometrial stromal cells were cultured and global expression profiles were compared with uncultured cells.
Participants/materials, setting, methods: For method validation, we used two endometrial biopsies, one from mid-secretory phase (day 21, LH+8) and another from late-secretory phase (day 25). The samples underwent single-cell FACS sorting, single-cell RNA-seq library preparation and Illumina sequencing.
Main results and the role of chance: Here we present a complete pipeline for single-cell gene-expression studies, from clinical sampling to statistical data analysis. Tissue manipulation, starting from disaggregation and cell-type-specific labelling and ending with single-cell automated sorting, is managed within 90 min at low temperature to minimise changes in the gene expression profile. The single living stromal and epithelial cells were sorted using CD13- and CD9-specific antibodies, respectively. Of the 8,622 detected genes, 2,661 were more active in cultured stromal cells than in biopsy cells. In the comparison of biopsy versus cultured cells, 5,603 commonly expressed genes were detected, with 241 significantly differentially expressed genes. Of these, 231 genes were up- and 10 down-regulated in cultured cells, respectively. In addition, we performed a gene ontology analysis of the differentially expressed genes and found that these genes are mainly related to cell cycle, translational processes and metabolism.
Limitations, reasons for caution: Although epithelial cells sorting was established, the data quality per individual cell was low. This step most likely failed due to the high dose of RNases that are released by the cells' natural processes, or due to rapid turnaround time or the apoptotic conditions in freezing- or single-cell solutions.
Wider implications of the findings: The symbiosis between clinical biopsy and the sophisticated laboratory and bioinformatic protocols described here brings together clinical diagnostic needs and modern laboratory and bioinformatic solutions, enabling us to implement a precise analytical toolbox for studying the endometrial tissue even at the single-cell level.
Trial registration number: No clinical trial.

P-280 Endometrial stromal cell-derived CX3CL1 promotes CX3CR1 expression and differentiation of CD4+Foxp3+ regulatory T cell in the endometriotic milieu

W. Yun[1]
[1]*Shanghai Ninth Hospital, Reproduction, Shanghai, China*

Study question: To investigate the role of chemokine CX3CL1 in the crosstalking between endometrial stromal cell (ESC) and CD4+Foxp3+ regulatory T cell (Treg) in the endometriotic milieu.
Summary answer: ESC-derived CX3CL1 promotes Treg differentiation and IL-10 and TGF-β production by activating the ERK1/2/PTEN signaling pathway.
What is known already: Endometriosis is associated with an abnormal immune response to endometrial cells, which can facilitate the implantation and proliferation of ectopic endometrial tissue. Our previous work showed that proportion of Tregs is significantly increased in the peritoneal fluid of women with endometriosis and CX3CL1 levels in peritoneal fluid are positively correlate with the progress of endometriosis.
Study design, size, duration: All of the eutopic endometrial and endometriotic tissues were obtained by laparoscopy from 59 patients with endometriosis (mean age 38.8 years). The patients had not received any GnRH analog or other hormonal drug in the 6 months prior to the surgical operation. All of the samples were obtained in the proliferative phase of the cycle, which was confirmed histologically according to established criteria. Normal endometrium was obtained from 11 disease-free women as healthy controls.
Participants/materials, setting, methods: Peritoneal fluid was aspirated from the pelvic cavity at the beginning of the standard laparoscopic procedure under general anesthesia. Flow cytometry was performed to analyze the percentage of CD4+Foxp3+ T cells, IL-10 and TGF-β levels, phosphorylation of ERK1/2, PTEN, AKT and MAPK in naïve $CD4^+$ T cells and the expression of Fas, FasL, CTLA-4, GITR, CD39 and CD73 in $CD4^+CD25^+$ Tregs, using isotypic IgG Abs as controls.
Main results and the role of chance: The supernatant from co-cultured human ESCs and macrophages not only induced Treg differentiation and increased Treg expression of CX3CR1, interleukin-10 (IL-10), transforming growth factor-β (TGF-β) and CD73 by activating the ERK1/2/PTEN signaling pathway but also repressed Treg apoptosis by downregulating Fas and FasL expression and enhanced the Treg-mediated suppression of $CD4^+CD25^-$ T cells. In addition, in vitro and in vivo trials confirmed that these effects could be inhibited by anti-CX3CL1 neutralizing Abs. The secretion of IL-10 and TGF-β by Tregs increased MMP2 expression and decreased TIMP1 expression and further stimulated the proliferation and invasion of ESCs and the growth of ectopic lesions.
Limitations, reasons for caution: Owing to the nature of the samples (collected from different patients), there may be some difference between these volunteers. Therefore, the relationship of inter-individual variability in Treg levels in the ectopic milieu is still an open question, and awaits further studies.
Wider implications of the findings: Interference with chemokine regulatory loops such as CX3CL1 may represent a novel therapeutic strategy to reduce the growth of endometriosis.
Trial registration number: None.

P-281 Risk of miscarriage in women with endometriosis: insights from IVF cycles

M. Reschini[1], M. Leonardi[1], E. Papaleo[2], L. Pagliardini[2], L. Benaglia[1], G. Candotti[1], P. Viganò[2], L. Quaranta[2], M. Munaretto[2], M. Candiani[2], P. Vercellini[1], E. Somigliana[1]
[1]*Fondazione Ca' Granda Ospedale Maggiore Policlinico, PMA, Milano, Italy*
[2]*Hospital San Raffaele, Infertility Unit, Milan, Italy*

Study question: To evaluate whether women with endometriosis face an increased risk of miscarriage.
Summary answer: The risk of miscarriage is not increased in women with endometriosis.
What is known already: The observation that the endometrium of women with endometriosis has peculiar characteristics inevitably raises the question of the possible impact on pregnancy outcome and, in particular, on the risk of miscarriage. However, definite conclusions cannot be drawn because the available studies are generally methodologically weak and results inevitably exposed to confounders. According to two recent independent meta-analyses using crude data from in vitro fertilization (IVF) pregnancies, the Relative Risk (RR) of miscarriage in endometriosis women was 1.31 (95%CI: 1.07–1.59) (Barbosa et al., 2014) and 1.26 (95%CI: 0.92–1.70) (Hamdan et al., 2015), respectively.
Study design, size, duration: Women achieving singleton intrauterine clinical pregnancies with the use of IVF at two Italian Infertility units were retrospectively reviewed. Three hundred thirteen women with endometriosis and 313 controls without the disease were selected between January 2008 and June 2014. Biochemical pregnancies and multiple pregnancies were excluded. The main outcome was the rate of miscarriage occurring before 12 weeks' gestation.
Participants/materials, setting, methods: Cases were women with a history of surgery for endometriosis and those who were documented the presence of ovarian endometriomas at the time of the IVF cycle. Controls were matched to cases by age (±6 months), type of cycle (fresh or frozen cycle) and study period. Exclusion criteria included abnormal uterine cavity, uterine malformations, abnormal karyotype of the woman or her partner, multiple pregnancies and clinically relevant maternal pathologies.
Main results and the role of chance: Baseline characteristics of the two study groups were mainly similar. A statistically significant difference was found for the indication to IVF (as expected), the BMI and the duration of infertility. The number of miscarriage in women with and without endometriosis was 48 (15%) and 60 (19%), respectively ($p = 0.25$). The Odds Ratio (OR) of miscarriage in affected women was 0.76 (95%CI: 0.50–1.16). The OR adjusted for BMI, parity, duration of infertility and male factor was 0.81 (95%CI: 0.53–1.25). Subgroup analyses according to the type of cycle (fresh and frozen), the number of embryos transferred, the presence of endometriomas and the history of surgery

for endometriosis did not document any subgroup at significant increased risk of miscarriage.
Limitations, reasons for caution: We do not have reliably data on the presence of adenomyosis and, thus, we could not control for this potential confounder. Moreover, not all women underwent laparoscopy and we cannot exclude some misdiagnoses. Finally, caution is needed for inferences to the more general population of natural pregnancies.
Wider implications of the findings: Women with endometriosis do not appear to face an increased risk of miscarriage. The previously detected alterations of the endometrium in affected women may be important for endometriosis development but would not affect the early development of the implanted embryos.
Trial registration number: Not applicable.

P-282 Pregnancy outcome in women with endometriosis achieving pregnancy with in vitro fertilization

L. Benaglia[1], G. Candotti[1], E. Papaleo[2], L. Pagliardini[2], M. Leonardi[1], M. Reschini[1], L. Quaranta[2], M. Munaretto[2], P. Vigano'[2], M. Candiani[3], P. Vercellini[4], E. Somigliana[1]
[1]*Fondazione Ospedale Maggiore Policlinico U.O. Centro Sterilita, Centro Sterilità, Milano, Italy*
[2]*Hospital San Raffaele, Infertility Unit, Milan, Italy*
[3]*Hospital San Raffaele, Department of Obstetrics and Gynecology, Milan, Italy*
[4]*Fondazione Ospedale Maggiore Policlinico U.O. Centro Sterilita, Department Obstetrics and Gynecology, Milano, Italy*

Study question: To evaluate the impact of endometriosis on obstetric complications occurring during the second and third trimester.
Summary answer: Women with endometriosis have a four-fold increased risk of placenta previa. The risk of the other obstetric complications is conversely not affected.
What is known already: There is biological evidence showing that the endometrium of women with endometriosis differs from the endometrium of healthy unaffected women. There is also cumulating evidence suggesting that complications occurring during the second and third trimester of pregnancy, such as pregnancy-related hypertensive disorders or impeded fetal growth may actually originate from local disturbances occurring at the time of implantation. On these bases, it has been repeatedly hypothesized that pregnancy outcome may be altered in women with endometriosis. However, two recent systematic reviews of the literature highlighted several methodological pitfalls of the available evidence and ultimately failed to draw definite conclusions.
Study design, size, duration: Women achieving in vitro fertilization (IVF) singleton pregnancies that progressed beyond 12 weeks' gestation at two Italian infertility units were reviewed. We recruited as cases 239 women with a history of surgery for endometriosis and/or with a sonographic diagnosis of the disease. Controls were 239 singleton IVF pregnancies without current or past evidence of endometriosis. They were matched to cases by age, type of cycle (fresh or frozen) and study period.
Participants/materials, setting, methods: A questionnaire aimed at collecting data on pregnancy and neonatal outcome and complications was routinely given to women achieving a clinical pregnancy in both involved units. This information was systematically recorded in the clinical charts and used here for data analysis. If inconsistencies emerged or if data was incomplete, charts of the obstetrical units of the two involved hospitals were also consulted and, if doubts persisted, women were contacted for clarifications.
Main results and the role of chance: Baseline characteristics of the two study groups were mainly similar. A statistically significant difference was found only for the BMI and for the duration of infertility. The majority of women with endometriosis (78%) underwent previous surgery for the disease. One-hundred eighty-seven cases and 187 controls achieved pregnancy during a fresh cycle.

We failed to observe statistically significant differences for the main pregnancy and neonatal outcomes. The rate of live birth and the incidence of hypertensive disorders, gestational diabetes, prematurity, small and large for gestational age newborns and neonatal problems did not differ. In contrast, we observed a statistically significant increase in the frequency of placenta previa in women with endometriosis (6% versus 1% in controls; $p = 0.006$). The crude Odds Ratio (OR) of placenta previa in women with the disease was 5.1 (95%CI: 1.4–17.8). The OR adjusted for BMI and duration of infertility was 4.8 (95%CI: 1.4–17.2, $p = 0.015$). All the analyses were repeated excluding women without a definite diagnosis of endometriosis (thus without a history of surgery for the disease) and results were mainly similar (data not shown).
Limitations, reasons for caution: We do not have reliably data on the presence of adenomyosis, a potential important confounder for the association with placenta previa. Moreover, not all women underwent laparoscopy and we cannot thus exclude some misdiagnoses. Finally, caution is needed for inferences to the more general population of natural pregnancies.
Wider implications of the findings: Single embryo transfer is recommended in women with endometriosis because multiple pregnancies independently increase the risk of placenta previa. Noteworthy, cesarean section for placenta previa may be particularly demanding here because of previous pelvic surgeries. On the other hand, women with endometriosis can be reassured regarding other obstetric complications.
Trial registration number: Not applicable.

P-283 Can the intrauterine infusion of hCG improve ART outcomes? Unsafe and conflicting results in meta-analyses

F. Dieamant[1,2], J.B.A. Oliveira[1,2], C.G. Petersen[1,2], A.L. Mauri[1,2], L.D. Vagnini[2], A. Renzi[2], G.R. Oliveira-Pelegrin[2], J. Ricci[1], M. Cavagna[1,2,3], R.L. Baruffi[1,2], J.G. Franco Jr[1,2]
[1]*Centre for Human Reproduction, Prof Franco Jr, Research, Ribeirao Preto, Brazil*
[2]*Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil*
[3]*Women's Health Reference Center Perola Byington Hospital, Research, Sao Paulo, Brazil*

Study question: Does the intrauterine infusion of hCG (IUI-hCG) prior to embryo transfer improve the ongoing pregnancy rate in patients subjected to IVF/ICSI cycles?
Summary answer: IUI-hCG infusion prior to embryo transfer does not improve the ongoing pregnancy rate after IVF/ICSI cycles.
What is known already: hCG triggers a complex signal transduction cascade that allows embryo implantation. Considering this activity, some articles have suggested that IUI-hCG increases pregnancy/implantation rates in IVF/ICSI cycles. A recent meta-analysis (Ye et al., 2015) showed that IUI-hCG infusion prior to embryo transfer increases clinical pregnancy and ongoing pregnancy rates. However, this result was based on few randomised controlled trials (RCTs), which did not include large populations. In addition, further RCT (Wirleitner et al., 2015) did not confirm this beneficial effect of IUI-hCG. Thus, the true role of IUI-hCG in IVF/ICSI outcomes still needs analysis.
Study design, size, duration: A systematic review based on electronic searches of databases up to December 2015 was conducted to identify RCTs that compared the outcomes of IVF/ICSI cycles with IUI-hCG prior to embryo transfer in the dose ≥500 UI (study group) or no injection or placebo (culture medium/control group). The primary outcome was ongoing pregnancy rate/patient. Secondary outcomes included implantation rate, clinical pregnancy rate/patient, and miscarriage rate.
Participants/materials, setting, methods: Six RCTs (2,391 patients) were included as targets for data extraction and meta-analysis. Data were combined for meta-analysis using StatsDirect statistical software. Dichotomous data were expressed as relative risk (RR) with a 95% confidence interval (CI). The measure of heterogeneity was evaluated using Cochran's Q and I^2 tests. Study data were combined using a random-effects model. p-values <0.05 were considered statistically significant.
Main results and the role of chance: Implantation rates were reported by three trials (hCG group: 29.5%, 527/1,786; Control group: 26%, 469/1,803) with no significant between-groups differences found (RR = 1.23; 95% CI = 0.80, 1.87; $p = 0.34$). Heterogeneity: $I^2 = 93.4\%$; Cochran $Q = 30.29$, $p < 0.0001$.

Data regarding clinical pregnancy rates/patient were reported by five studies (hCG group: 47.3%, 493/1,042; Control group: 40.5%, 425/1,049). Pooled analysis found that clinical pregnancy rates were significantly higher in the hCG group compared with the control group (RR = 1.31; 95% CI = 1.01, 1.70; $p = 0.04$). Heterogeneity: $I^2 = 83.6\%$; Cochran $Q = 24.36$, $p < 0.0001$.

Data regarding the rate of miscarriage were reported by four studies (hCG group: 6.0%, 59/982; Control group: 5.6%, 55/987) with no significant between-group differences found (RR = 1.07; 95% CI = 0.75, 1.54; $p = 0.69$). Heterogeneity: $I^2 = 0\%$; Cochran $Q = 2.49$, $p = 0.47$.

The rate of ongoing pregnancy/patient was reported by four studies (hCG group: 41.4%, 407/982; Control group: 36.6%, 361/987). Ongoing pregnancy rates were not significantly different in the hCG group than in the control group (RR = 1.25; 95% CI = 0.94, 1.67; $p = 0.13$). Heterogeneity $I^2 = 82.4\%$; Cochran $Q = 17.01$, $p = 0.0007$).

P-284

Abstract withdrawn by the author

P-285 Long-term treatment of uterine fibroids with ulipristal acetate improves health-related quality of life: findings from the PEARL-III (extension) randomised controlled trial

D. Lancastle[1], P. Arriagada[2], S. Skouby[3]
[1]*University of South Wales, School of Psychology and Therapeutic Studies, Pontypridd, UK*
[2]*PregLem SA, Switzerland, Geneva, Switzerland*
[3]*University of Copenhagen, Faculty of Health Sciences, Copenhagen, Denmark*

Study question: What are the effects of repeated three-month courses of ulipristal acetate (UPA) on the quality of life in women with symptomatic uterine fibroids?
Summary answer: Significant improvements in numerous quality of life indicators were reported after UPA course 1, which were sustained after each consecutive course and at follow-up.
What is known already: Symptomatic uterine fibroids have a profoundly negative impact on the physical, psychological and social well-being of many women with this condition, and although hysterectomy provides a permanent solution to the problems caused by fibroids, it is important that women can also access long-term treatments that improve their quality of life, minimise unwanted side effects, and allow them to retain their fertility. UPA has already been shown to be an effective and safe treatment for symptomatic uterine fibroids.
Study design, size, duration: Data are from the PEARL-III extension study. This Phase III, multicentre, clinical study investigated the efficacy and safety of up to four repeated intermittent consecutive courses of 3-month open-label UPA treatment in women with symptomatic uterine fibroids. Women received UPA (10 mg, once daily), immediately followed by double-blind oral NETA (norethisterone acetate, 10 mg once daily) or matching placebo, for 10 days. Randomisation was managed in a 1:1 ratio, involving 132 women.
Participants/materials, setting, methods: Participants were pre-menopausal women with symptomatic uterine fibroids attending European clinical gynaecology centres who had completed the PEARL-III study. Quality of life was assessed using the Uterine Fibroid Specific and EuroQol-5 questionnaires at six assessments: Baseline, (pre-randomisation); End of Course 1 UPA; 10–18 days after first day of menstruation following Course 2; 10–18 days after the first day of menstruation following Course 3; End of Course 4; and Follow-up (3 months after Course 4).
Main results and the role of chance: Of the 132 women randomised, 100 were included in the final analyses (32 women did not contribute questionnaire data at more than one assessment). No significant differences in quality of life between women in the UPA+NETA group and those in the UPA+Placebo group were found and data from the two groups were pooled for analysis. Within-subjects ANOVAs showed a significant improvement in overall quality of life after UPA Course 1 which was sustained in consecutive courses up to and including Follow-up, $F(3.60, 356.61) = 88.78$, $p < 0.001$, $\eta p^2 = 0.47$, and a significant improvement in current health state after UPA Course 1, $F(3.92, 388.01) = 24.42$, $p < 0.001$, $\eta p^2 = .20$, which was also sustained in consecutive courses up to and including Follow-up. Similar benefits on other fibroid specific quality of life subscales were found.
Limitations, reasons for caution: Responses to UFS-QOL items at each Treatment Stage were made retrospectively for a three month period and thus do not discriminate between the two months of UPA treatment and the off-treatment period of one menstrual cycle preceding completion of the questionnaire.
Wider implications of the findings: Repeated intermittent courses of UPA have significant and sustained benefits on the quality of life of women with symptomatic fibroids. Long-term management of fibroids with UPA could be an important way of improving the quality of life of women with fibroids especially in those who wish to retain their fertility.
Trial registration number: PEARL III – NCT01156857 and PEARL III extension – NCT01252069.
Trial registration date: 30th November 2010.

P-286 Frozen embryo transfer (fet) in the cycle immediately after IVF/cryoall with pgd results in higher implantation rate and decreased miscarriage rate compared to deferred fet

M. Rodriguez[1], L. Sekhon[2], M. Luna[3], A. Lee[4], M. Whitehouse[4], A. Copperman[4], B. Sandler[4]
[1]*Hospital, Reproductive Biology, Mexico DF, Mexico*
[2]*Icahn School of Medicine at Mount Sinai, Obstetrics, Gynecology and Reproductive Science, New York City, NY, USA*
[3]*Reproductive Medicine Associates of New York International Mexico, Reproductive Medicine Service, Mexico DF, Mexico*
[4]*Reproductive Medicine Associates of New York, Obstetrics, Gynecology and Reproductive Science, New York City, NY, USA*

Study question: Is there a benefit in allowing one menstrual cycle to occur before proceeding with a FET or to directly undergo FET the immediate subsequent cycle after undergoing an IVF/PGD/cryo-all cycle?
Summary answer: Results suggest that undergoing a FET the immediate subsequent month after a cryo-all cycle leads to greater implantation success than waiting one menstrual cycle in-between.
What is known already: Refined cryopreservation techniques have displayed improved cycle outcomes after a frozen embryo transfer (FET) as compared to fresh embryo transfer (ET). Recently, several practices counsel patients to undergo a two-cycle approach: a cryo-all cycle (all viable embryos are biopsied for genomic interpretation and cryopreserved) with a subsequent FET cycle. This strategy gives practitioners a greater opportunity to monitor, influence and enhance embryo/endometrium synchrony. Presently, there is no clinical data regarding whether there is benefit to allowing one menstrual cycle to occur before proceeding with a FET or to directly undergo an FET the immediate subsequent cycle.
Study design, size, duration: Retrospective cohort analysis from June 1st, 2011 to December 31st, 2015. The study had 80% power to detect 15% difference in between groups, with an alpha error of 0.05 ($n = 150$/group).
Participants/materials, setting, methods: Patients who underwent an IVF cycle with q-PCR-based CCS in which all embryos were cryopreserved after trophectoderm biopsy were included. Cohorts were segregated into groups according to the period between biopsy/cryopreservation to the first FET: A) Immediate subsequent FET (≤45 days); B) One month in-between IVF and FET (>45 days). The study was restricted to FETs performed <90 days after the cycle's retrieval. The outcome measure was IR.
Main results and the role of chance: A total of 638 cycles were included (Group A: 428 cycles; Group B: 210). IR was statistically higher when a FET was carried out in the immediate menstrual cycle as compared to waiting one menstrual cycle (63.4% vs 53.0%, $p < 0.05$), with an embryo being 1.5 times more likely to implant (OR 1.5, 95% CI 1.1 – 2.1). The early pregnancy loss rate was statistically lower when a FET was completed in the immediate menstrual cycle as compared to waiting one menstrual cycle (18.1 vs 25.0%, $p < 0.05$), with a 33% less probability of having a miscarriage when proceeding more quickly to a FET (OR 0.7, 95% CI 0.44 – 0.99).

	Immediate subsequent FET	One month in-between IVF and FET	Stats
Cycles	408	204	NS
Age at IVF	36.2 ± 4.1	36.9 ± 4.0	NS
Age at FET	36.3 ± 4.1	37.1 ± 4.0	
BMI at IVF	22.7 ± 4.0	22.7 ± 4.3	NS
BMI at FET	22.7 ± 4.0	22.8 ± 4.4	NS
Day 3 FSH	6.0 ± 3.2	6.1 ± 3.2	NS
AMH	3.9 ± 4.6	3.3 ± 2.9	NS
Endometrial Thickness at FET	8.9 ± 1.6	9.1 ± 1.5	NS
Retrieved	17.4 ± 10.4	16.6 ± 8.2	NS
2PN count	11.3 ± 7.3	9.9 ± 5.2	NS
Biopsy count	5.8 ± 4.2	5.0 ± 3.5	NS
ET count	1.1 ± 0.3	1.2 ± 0.4	NS
Clinical Pregnancy Rate	68.9% (281/408)	59.8% (122/204)	$p < 0.05$
Implantation Rate	63.4% (303/478)	53.0% (132/249)	$p < 0.05$
Early Pregnancy Loss Rate	18.1% (74/408)	25.0% (51/204)	$p < 0.05$

Limitations, reasons for caution: Retrospective nature.
Wider implications of the findings: The study's results suggest that undergoing a FET the immediate subsequent month after a cryo-all cycle leads to greater implantation success than waiting one menstrual cycle in-between. Patients who undergo an IVF cycle with PGS need not be discouraged from pursuing a FET attempt in their immediate subsequent menstrual cycle.
Trial registration number: Not required.

P-287 Endometrial scratching for pregnancy following sexual intercourse or intrauterine insemination (IUI): a cochrane systematic review and meta-analysis

S. Lensen[1], M. Manders[2], C. Nastri[3], A. Gibreel[4], W. Martins[3], G. Templer[1], C. Farquhar[1]
[1]*University of Auckland, Obstetrics and Gynaecology, Auckland, New Zealand*
[2]*Radboud University Medical Centre Nijmegen, Medical school, Nijmegen, The Netherlands*
[3]*University of Sao Paulo, Obstetrics and Gynecology, Sao Paulo, Brazil*
[4]*Mansoura University, Obstetrics and Gynecology, Mansoura, Egypt*

Study question: What is the effectiveness of endometrial scratching in subfertile women who are attempting to conceive naturally or with intrauterine insemination (IUI)?
Summary answer: Endometrial scratching appears to be beneficial in couples trying to conceive from intercourse or IUI, however the quality of the available evidence is low.
What is known already: Endometrial scratching, performed by pipelle biopsy or a similar device, has been reported to increase the probability of pregnancy in women undergoing in vitro fertilisation (IVF), specifically in women with recurrent implantation failure (RIF). The action of taking the endometrial biopsy is believed to elicit a favourable inflammation ('scratch') within the endometrium thereby making it more receptive to an implanting embryo.
Study design, size, duration: Meta-analysis and systematic review of randomised controlled trials (RCTs) evaluating endometrial scratching in women planning to undergo IUI or attempting to conceive spontaneously (with or without ovulation induction), compared to no intervention, a mock intervention, or endometrial scratching performed at a different time or to a higher/lower degree. The primary outcomes were live birth/ongoing pregnancy and pain. Last search performed October 2015.
Participants/materials, setting, methods: A thorough search for trials was performed including electronic searches in CENTRAL, MEDLINE, EMBASE, PsycINFO, CINAHL, Google, clinicaltrials.gov and hand searching of conference proceedings. Twenty one full-text articles were screened for eligibility and 8 were eligible and included in the review. Two authors independently screened the studies, extracted data and assessed study quality. Most participants in the trials had unexplained infertility and were attempting to conceive from stimulated IUI cycles.
Main results and the role of chance: Endometrial scratching increased the probability of live birth/ongoing pregnancy (RR 2.26, 95% CI 1.54 to 3.32) and clinical pregnancy (RR 1.92, 95% CI 1.44 to 2.55) compared to no procedure or a placebo procedure. This suggests that if the chance of live birth without endometrial injury is 10%, then the probability of a live birth following endometrial injury would be between 15% and 32%. However, the results must be treated with caution as most of the included RCTs were associated with a serious risk of bias. There was no evidence of an effect on miscarriage, ectopic pregnancy, or multiple pregnancy. Pain during the pipelle procedure was reported by one study as an average of 6/10.
Limitations, reasons for caution: This review only included evidence from the RCTs, however the available studies are associated with a very high risk of bias and the evidence remains at a low or very low quality.
Wider implications of the findings: High-quality RCTs which recruit sufficient numbers of women are needed to confirm or refute these findings. Although endometrial scratching is a cheap and simple procedure which can be conducted without analgesia during a short clinic visit, it does require an internal examination which is associated with pain/discomfort.
Trial registration number: N/A.

P-288 The balance between uterine CSF3/CSF3-receptor influences fertility

J. Evans[1], B. Vollenhoven[2], L.J. Rombauts[2], L.A. Salamonsen[1], T. Edgell[1]
[1]*The Hudson Institute of Medical Research, Centre for Reproductive Health, Clayton, VIC, Australia*
[2]*Monash University, Department of Obstetrics and Gynaecology, Melbourne, VIC, Australia*

Study question: Do concentrations of CSF3 and its receptor within the uterine cavity impact female fertility?
Summary answer: Elevated uterine CSF3 in and consequent reduction of endometrial CSF3 receptor levels are associated with poor receptivity, despite beneficial effects on trophoblast invasion/migration in vitro.
What is known already: CSF3 levels in follicular fluid are demonstrated to be positively associated with embryo quality. However, clinical studies of uterine CSF3 infusion as an adjuvant in ART cycles to promote endometrial growth and implantation have had mixed results. Critically, there are no scientific studies of CSF3 within the uterine microenvironment, its impact on the endometrium or how it may influence fertility.
Study design, size, duration: All samples were collected with informed consent. Uterine lavage and tissue curettage were collected from fertile (n = early secretory, n = 15 mid-secretory) and infertile (n = 18 early secretory, n = 18 mid-secretory) women during natural menstrual cycles. Lavage and/or serum were collected at the time of oocyte retrieval from 280 women (over an 18 month period) who underwent embryo transfer in the same cycle.
Participants/materials, setting, methods: CSF3 concentrations in lavage and serum assayed using Luminex. Primary epithelial cells stimulated with estrogen and progesterone; CSF3 in media measured by Luminex, receptor concentration within harvested cells determined by western blot. Immunohistochemical analysis performed on fertile/idiopathic infertile endometrium for CSF3 receptor. Response to chronic and acute exposure of ECC1 endometrial epithelial cells (adhesion and proliferation) and HTR-8/SVneo trophoblast cells (invasion and migration) to glycosylated and non-glycosylated CSF3 monitored using Xcelligence system.
Main results and the role of chance: CSF3 was elevated in lavage of natural-cycling idiopathic infertile women versus fertile women during early secretory (p = 0.019) and mid-secretory phases (p = 0.020) of the cycle. In ART cohort, elevated CSF3, in serum and lavage, evident among women who did not become pregnant; concentration was negatively correlated with endometrial thickness. Primary epithelial cells demonstrated increased secretion of CSF3 in response to progesterone; CSF3R was down-regulated under the same conditions, suggestive of negative feedback of CSF3 on its receptor. Immunohistochemistry showed reduced or absent epithelial CSF3R in tissue from secretory phase infertile women, compared with fertile controls. Acute exposure of ECC-1 to non-glycosylated (CSF3-NG) or glycosylated (CSF3-G) CSF3 increased ECC1 cell adhesion, a similar increase was evident after chronic exposure to CSF3-NG but not with CSF3-G. Acute treatment of ECC-1 with CSF3-G or CSF3-NG also enhanced proliferation ($*p < 0.05$), with a dose response evident upon treatment with CSF3-NG. However, chronic treatment with CSF3-G demonstrated an inhibitory effect on proliferation that was not evident with CSF3-NG. Treatment of HTR-8/SVneo (trophoblast) cells with CSF3-G and CSF3-NG enhanced their migration and invasion, with a significant impact on migration mediated by CSF3-NG ($*p < 0.05$) and a significant increase in invasion observed upon treatment with both CSF3-G and CSF3-NG ($*p < 0.05$).
Limitations, reasons for caution: Both CSF3-NG and CSF3-G are recombinant, therefore not a natural human form of the protein. The use of cancer derived cell lines as opposed to primary cells must be considered. Tissue from women undergoing ART was not examined. No women in whom CSF3 was used as an adjuvant were included.
Wider implications of the findings: Improved IVF treatment outcomes for many idiopathic infertile women may be achieved by inhibiting excess CSF3 and restoration of its receptor as opposed to exposure to adjuvant CSF3 which may decrease CSF3R further. Pre-screening of idiopathic infertile women to determine CSF3 and CSF3R may improve ART success.
Trial registration number: N/A.

P-289 Factors predicting improved success with use of Gcsf in thin endometrium

D. Rajeev Agarwal[1], P. Apoorva Reddy[2], D. Suparna Bhattacharya[1], R. Saroj Agarwal[1], D. Mukesh Sirohia[1], D. Khurshid Alam[1]
[1]*Care IVF, Reproductive Medicine, Kolkatta, India*
[2]*Sri Durga Hospital, Reproductive Medicine, Nellore, India*

Study question: If the cases with poor endometrial vascularity and thin endometrium benefit more from Gcsf than the ones with good endometrial vascularity?
Summary answer: Using Gcsf in poor endometrial vascularity cases has significantly increased pregnancy rates compared to ones with good vascularity despite non significant increase in endometrial thickness.
What is known already: The minimum measurement of the endometrium which results in acceptable pregnancy rates is still inconclusive. Literature shows data supporting values from as low as 6 mm to as high as 9 mm. on the other hand, in some investigations, there was no correlation between the IVF outcome and endometrium thickness. A wide range of therapies have been tried and tested for improvement of endometrial thickness with non definitive conclusions. The pilot study of Gleicher et al., showed the role of G-CSF on endometrial expansion in women with unresponsive endometrium, all though they failed to prove the same in subsequent publications.
Study design, size, duration: The current study is a prospective observational study conducted at Care IVF Kolkatta during the period between January 2015 and December 2015. A total of 38 cases fitting the inclusion criterion were evaluated for the effect of gcsf on the sub endometrial vascularity, endometrial expansion and pregnancy rates. The cases served as self controls from their previous failed or cancelled cycles.
Participants/materials, setting, methods: The inclusion criteria: women aged 18–45 years, previously cancelled at least one cycle because of thin unresponsive endometrium (<6 mm) during IVF programs, previously failed IVF due to poor endometrial measurement (6–9 mm), the lack of contraindications for G-CSF treatment, no genital tuberculosis, Asherman's, fibroids, and polyps. 1 ml of 300 mcg Gcsf (Endokine™ Intas) was instilled intrauterine using Cook's IUI catheter with start of Progesterone. The end points were increased endometrial vascularity and measurement and impact on clinical pregnancy rate.
Main results and the role of chance: 38 cases fulfilling the inclusion criterion were administered intrauterine Gcsf. In one of the 38 patients embryo transfer was cancelled as the ET didn't increase beyond 5 mm. Among the 37 patients in whom transfer was done, a sub group of 17 cases had poor vascularity apart from thin ET in the first cycle. Of these 17 cases 11(11/17 = 64.7%) showed improved vascularity to Zone III & Zone IV post Gcsf administration and 8 cases of these resulted in pregnancy.(8/11 = 72.7%)(mean ET = 7.35) Of the 6 remaining cases, 3 showed improvement in vascularity compared to previous cycle and 3 didn't show any improvement.(mean ET 6.76). But none of them resulted in pregnancy. 21 patients had higher grades of vascularity in the previous cycle despite poor endometrial thickness (mean ET = 6.96) Although the mean ET increased to 7.8 mm. Post gcsf only 4 cases resulted in pregnancy (4/21 = 19%). There was no significant difference in the mean endometrial thickeness between the groups that showed improved vascularity after Gcsf administration and the cases that had higher grades of vascularity before GCSF use. (7.35 vs 7.8 $p > 0.05$). But the pregnancy rates were significantly higher in the cases that had improved endometrial vasculature (64.7% vs 19% $p < 0.01$).
Limitations, reasons for caution: The number of cases in the study is small to draw any definitive conclusions. Randomized control studies are required to evaluate this further.
Wider implications of the findings: The findings can help in identifying the subgroup of patients who would benefit significantly from gcsf administration.
Trial registration number: not applicable.

P-290 HOXA-10 and E-cadherin expression in women with recurrent implantation failure (RIF) and recurrent miscarriage (RM)

Y. Yang[1], X. Chen[2], S. Saravelos[2], Y. Liu[2], J. Huang[2], J. Zhang[1], T.C. Li[2]
[1]*The Affiliated Hospital of Guilin Medical College, Center for Reproductive Medicine, Guilin, China*
[2]*The Chinese University of Hong Kong, Assisted Reproductive Technology Unit, Department of Obstetrics and Gynaecology, Hong Kong, China*

Study question: Is the expression of HOXA-10 and E-cadherin in women with unexplained RIF and RM different to that of fertile controls?
Summary answer: HOXA-10 and E-cadherin expression is reduced in women with unexplained RIF and RM compared with fertile controls.
What is known already: Both HOXA-10 and E-cadherin play crucial roles in endometrial receptivity and increased expression in endometrium during the implantation window. However, there have been limited studies on the expression of HOXA10 and E-cadherin in women with unexplained RIF and RM.
Study design, size, duration: This was part of a prospective study undertaken within a University ART unit between August 2014 and August 2015. In total 50 women were recruited, including 12 with unexplained RIF, 20 with RM, and 18 fertile controls.
Participants/materials, setting, methods: Timed endometrial biopsy samples were obtained from women 7 days after their LH surge. The expression of HOXA-10 and E-cadherin were examined by Immunofluorescence (IF) and Immunohistochemistry (IHC). The intensity of HOXA-10 and E-cadherin expression was graded and calculated according to an H-score equation: H score = ΣPi (i+1), where I was the intensity of staining (0 = negative;1 = weak; 2 = moderate; and 3 = strong), and Pi was the percentage of cells stained at each intensity (0%–100%).
Main results and the role of chance: HOXA-10 signal was mainly localized in nuclei of stromal cells and cytoplasm of glandular epithelium cells, while E-cadherin signal was only found in the nuclei of glandular epithelium cells. In the glandular epithelium, the HOXA-10 H-scores were significantly reduced in the RIF and RM compared with the fertile controls (205.00 ± 43.85 versus 270.28 ± 65.70; $p < 0.01$ and 177.75 ± 53.69 versus 270.28 ± 65.70; $p < 0.001$, respectively). In the stroma, the HOXA-10 H scores were also significantly reduced in the RIF and RM groups (218.33 ± 46.63 versus 263.89 ± 47.95; $p < 0.05$ and 201.75 ± 51.64 versus 263.89 ± 47.95; $p < 0.001$, respectively). However, the E-cadherin H-scores were significantly reduced in the RM group (243.25 ± 53.88 versus 308.06 ± 46.18; $p < 0.001$) but not in the RIF group (272.92 ± 59.29 versus 308.06 ± 46.18; $p = 0.08$). There was a trend for a reduced expression of all these markers in the RM group compared with the RIF group, although this did not reach statistical significance. Interestingly, there was a positive correlation of H-scores between both glandular and stromal HOXA-10 and E-cadherin in all women examined ($r = 0.552$, $p < 0.001$ and $r = 0.495$, $p < 0.001$ respectively).
Limitations, reasons for caution: Although this is the first study to examine the levels of HOXA-10 and E-cadherin expression in women with different types of reproductive failure, it was not designed to correlate these levels with specific clinical outcomes.
Wider implications of the findings: HOXA-10 and E-cadherin expression is significantly reduced in women with RIF and RM compared with fertile controls. Future studies should attempt to correlate the expression of these proteins to specific clinical reproductive outcomes.
Trial registration number: NA.

P-291 Conditioned medium of endometrial stromal cells from the implantation window, but not from proliferative phase, can enhance the proliferation and migration of trophoblast stem cells

H.Y. Li[1], C.Y. Liao[2], Y.J. Sung[2]
[1]*Taipei Veterans General Hospital and National Yang-Ming University School of Medicine, Department of Obstetrics and Gynecology, Taipei, Taiwan R.O.C*
[2]*National Yang-Ming university, Institute of Anatomy and Cell Biology, Taipei, Taiwan R.O.C.*

Study question: What's the effect of conditioned medium (CM) of endometrial stromal cells (ESC; implantation window vs proliferative phase) on trophoblast stem (TS) cell proliferation and migration?
Summary answer: CM of ESC from implantation window, but not proliferative phase, contained abundant growth factors and cytokines and could significantly enhance TS cell proliferation and migration.

What is known already: During embryo implantation, the endometrium becomes receptive for embryo after sequential actions of ovarian estrogen and progesterone. In response to hormones, cytokines and growth factors secreted by the endometrium during implantation window, the blastocyst becomes activated and acquires ability to adhere to the endometrium. Precise interactions between the blastocyst and the endometrium are critical for successful embryo implantation, but largely unknown. Understanding endometrium-embryo crosstalk will help increase implantation rate in assisted reproduction technology (ART).
Study design, size, duration: We first examined the effects of CM of ESC (implantation window vs proliferation phase) on trophoblast stem cell proliferation and migration. Then we analyzed growth factors and cytokines contained in CM of ESC (implantation window vs proliferation phase).
Participants/materials, setting, methods: ESC were isolated from uterine horns of female mice on d3.5 of pregnancy, which is the implantation window, and also from those of female mice in the proliferative phase. Collected CM of ESC from implantation window and proliferative phase, respectively. MTT assay was used to determine cell proliferation. Cell migration was determined by transwell assay. Protein array was performed to compare growth factors and cytokines in CM of ESC from implantation window vs proliferation phase.
Main results and the role of chance: We found that CM of ESC from implantation window can enhance the proliferation and migration of TS cells, as assayed by MTT metabolism and transwell analyses, respectively. By contrast, CM of ESC from proliferative phase had no effect on the proliferation and migration of TS cells. Growth factor and cytokine array analyses showed that CM of ESC from implantation window contained much more vascular endothelial growth factor, granulocyte macrophage colony-stimulating factor, heparin-binding epidermal growth factor, IL-1 and IL-6, as compared with that of ESC from proliferative phase. In conclusion, we demonstrated that CM of ESC from implantation window, but not from proliferative phase, are abundant in growth factors and cytokines and can enhance the proliferation and migration of TS cells.
Limitations, reasons for caution: For better understanding endometrium-embryo crosstalk in humans, human CM of ESC and TS cells may be performed after ethical issues are settled. Mouse model of recurrent miscarriage (CBA/J♀ X DBA/2♂) may be utilized to examine whether growth factors and cytokines contained in CM of ESC could prevent recurrent abortion.
Wider implications of the findings: This study supports the concept of endometrium-embryo crosstalk and may be applied to increase implantation rate in assisted reproductive technology (ART).
Trial registration number: Not applied.

P-292 Identification of human endometrial microRNAs associated with repeated implantation failures (RIF)

D. Haouzi[1], L. Drissennek[1], Y. Antoine[1], F. Entezami[2], A. Gala[3], T. Mullet[3], C. Vincens[3], S. Hamamah[3]
[1]*INSERM U1203, IRMB, Hôpital St-Eloi, CHRU Montpellier, Montpellier, France*
[2]*Laboratoire Eylau, UNILABS-La Muette, Clinique de La Muette-Ramsay-Générale de Santé, Paris, France*
[3]*Hôpital Arnaud de Villeneuve, CHRU Montpellier, Département de Médecine et Biologie de la Reproduction, Montpellier, France*

Study question: Can we identify microRNAs from endometrial biopsies involved in repeated implantation failures?
Summary answer: We identified six microRNAs differentially expressed between patients with a receptive endometrium achieving or not a pregnancy (bhCG+ versus bhCG-) after embryo replacement.
What is known already: After repeated implantation failures (RIF), it is estimated that about 1/3 of RIF are associated with abnormal endometrial receptivity. To date, the microRNAs have demonstrated their involvement in the regulation of endometrial cyclic changes during the menstrual cycle. However, only one study focused on the potential identification of microRNAs associated with RIF. Here, we reported the specific miRNAs expression profile during the implantation windows after evaluation of the endometrial receptivity status diagnosed as receptive by RT-qPCR transcriptomic approach in pregnant patients or not.
Study design, size, duration: Endometrial biopsies (n = 20) were collected during the implantation windows under hormone replacement therapy (6 to 9 days after progesterone administration). Then RNAs were extracted for mRNA and miRNA purification to perform RT-qPCR gene expression and the miRNA expression profile, respectively. The RT-qPCR gene expression consists of measuring the expression level of 13 transcripts associated to the endometrial receptivity (Window Implantation Test; Patent EP10305561.2). The miRNAs profile was evaluated with the *Affymetrix® miRNA 4.1 Array Strips*.
Participants/materials, setting, methods: Endometrial biopsies during the implantation windows were obtained from 20 patients with RIF (≥3) during IVF/ICSI cycles. At first, endometrial receptivity status was evaluated by the RT-qPCR gene expression. Then, miRNA expression profiles were evaluated in receptive patients (n = 15) with a bhCG- (n = 5) or bhCG+ (n = 10) after embryo replacement.
Main results and the role of chance: Using 3 distinct statistical analyses (Student's t test, Wilcoxon signed-rank test and ANOVA), we identified six microRNAs differentially expressed in receptive patients, with or without implantation failures. These six microRNAs were all over-expressed in receptive endometrium from patients with a negative bhCG [miR-1 (x2.5, FDR = 0.004), miR-2 (x5.9, FDR < 0.0001), miR-3 (x5.8, FDR < 0.0001), miR-4 (x6.5, FDR < 0.0001), miR-5 (x6.1, FDR < 0.0001) and miR-6 (x4.7, FDR < 0.0001)]. Two of them are members of the let-7 family that have been previously reported to play a crucial role in angiogenesis and maintain of pregnancy.
Limitations, reasons for caution: The number of samples used for miRNA analyses are low. However, the relevance of these biomarkers is being validated in independent large cohort of patients.
Wider implications of the findings: The identification of endometrial micro RNAs associated to implantation failures open new perspectives in RIF patient care management. As miRNAs can be found in the bloodstream, exploration of these biomarkers as potentially circulating miRNAs might provide non-invasive diagnostic tool, avoiding performing an endometrial biopsy, to diagnose the pregnancy outcome.
Trial registration number: Not applicable.

P-293 Day 3 embryo transfer improves clinical pregnancy rate in ART patients over 42 years of age

T. Yoshimura[1], H. Kitasaka[2], K. Nakayama[2], N. Hasegawa[1], E. Asano[1], S. Konogi[2], M. Kojima[1], N. Fukunaga[1,2,3], Y. Asada[1,2,3]
[1]*Asada Ladies Clinic Medical Corporation, Asada Ladies Kachigawa Clinic, Kasugai, Japan*
[2]*Asada Ladies Clinic Medical Corporation, Asada Ladies Nagoya Clinic, Nagoya, Japan*
[3]*Asada Ladies Clinic Medical Corporation, Asada Institute for Reproductive Medicine, Kasugai, Japan*

Study question: What is the optimal embryo transfer policy for ART patients 43 years of age and older?
Summary answer: The pregnancy rate in age classes ≥43 years was higher in cleavage stage (D3ET) compared to that of blastocyst stage (BT) transfer.
What is known already: It is frequently documented that a woman's age is inversely correlated with her fertility and the average age of infertility patients is rising because people marry later these days in Japan.

The Japan Society of Obstetrics and Gynecology (JSOG) reported that the percentage of women undergoing ART who were 40 years of age or older had increased from 31.2% in 2007 to 33.4% in 2009.
Study design, size, duration: We carried out a thorough review of 505 cycles (data from January 2013 to March 2015), from women undergoing ART who were 43 years and older which had undergone vitrified-thawed embryo transfers in a hormone replacement cycle.

Age categories were divided into 5 groups: 43, 44, 45, 46, and ≥47 years.
Participants/materials, setting, methods: All patients were treated with a clomiphene protocol. Retrieved oocytes were fertilized by ICSI. All embryos were vitrified at pronuclear stage and warmed using Kitazato protocols as described by the manufacturer. Hormone replacement treatment was used for all ET cycles.
Main results and the role of chance: The pregnancy rates (D3ET) of each age category was 14.8% (27/182), 11.9% (13/109), 10.0% (8/80), 3.0%

(1/33), and 0% (0/21), respectively. The respective pregnancy rates of BT were 7.5% (3/40), 4.2% (1/24), 0% (0/11), and 0% (0/5). The pregnancy rates of D3ET showed the higher tendency than that of BT. The rate of spontaneous abortion (D3ET) was 40.7% (11/27), 76.9% (10/13), 75.0% (6/8), and 100% (1/1), respectively. All the pregnancies resulting from BT resulted in a miscarriage.

Limitations, reasons for caution: This was an exploratory study with a limited sample size. Further research is necessary in detail.

Wider implications of the findings: Oocyte number and quality decrease with advanced maternal age reducing the chances of a viable pregnancy after ART. It is vital to make the general population aware of the high risk, and to allow them to make their own life plan concerning pregnancy and childbirth.

Trial registration number: N/A.

P-294 Human endometrial receptivity-associated miRNAs: beyond the genes

Y. Antoine[1], D. Haouzi[2], L. Drissennek[2], F. Entezami[3], L. Delaroche[4], C. Brunet[5], S. Hamamah[5]

[1]*Institut de Recherche en Biothérapie, Développement embryonnaire précoce humain et pluripotence, Montpellier Cedex 5, France*

[2]*Inserm U1203-IRMB, Hopital Saint Eloi CHRU Montpellier, Montpellier, France, France*

[3]*Laboratoire Eylau, UNILABS-La Muette, Clinique de La Muette-Ramsay-Générale de Santé, Paris, France*

[4]*Laboratoire Unilabs, Clinique Cherest, Neuilly, France*

[5]*Hopital Arnaud de Villeneuve CHRU Montpellier, Département de Biologie de la Reproduction, Montpellier, France*

Study question: Beyond the genes, do miRNAs are associated to endometrial receptivity status during the expected implantation windows?

Summary answer: We identified five specific miRNAs associated to a receptive endometrium compared with non-receptive endometrium during the implantation windows.

What is known already: To date, there are few studies on miRNA expression profile using Omics technologies according to the endometrial receptivity status. In addition, majority of them compared two phases of the menstrual phase (proliferative or early-secretory phase vs mid-secretory phase). Here, we reported the specific miRNAs expression profile according to the endometrial receptivity status diagnosed by the genomic approach Win-test' as receptive or non-receptive during the implantation windows in patients undergoing IVF/ICSI.

Study design, size, duration: Endometrial biopsies were collected during the implantation windows under hormone replacement therapy (6 to 9 days after progesterone administration). Then RNAs were extracted for mRNA and miRNA purification to perform the Win-Test and the miRNA expression profile, respectively. The Win-test consists of measuring the expression level of 13 transcripts associated to the endometrial receptivity by RT-qPCR (Window Implantation Test; Patent EP10305561.2). The miRNAs profile was evaluated with the *Affymetrix® miRNA 4.1 Array Strips.*

Participants/materials, setting, methods: Endometrial biopsies were obtained from 20 patients with repeated implantation failure (≥3) during IVF/ICSI cycles. The endometrial receptivity status was determined using the Win-Test allowing to classify endometrial samples as 'receptive' or 'non-receptive'. Then, miRNA expression profiles between the two groups of patients, receptive (n = 15) and non-receptive (n = 5), were performed.

Main results and the role of chance: Using 3 distinct statistical analyses (Student's t test, Wilcoxon signed-rank test and ANOVA), we identified five miRNAs differentially expressed between receptive and non-receptive endometrium [miR-1 (x-4.9, FDR < 0.0001; miR-2 (x-2.5, FDR < 0.0001), miR-3 (x-3.6, FDR < 0.001), miR-4 (x-3.9, FDR < 0.0001), miR-5 (x-2.1, FDR < 0.0001)]. All of them were down-regulated in receptive endometrium tissues and associated with the over-expression of the 13 specific genes biomarkers of the Win-Test. These 5 miRNAs target 165 over-expressed mRNAs during the implantation windows, including the 13 specific genes biomarkers of the implantation window, that were reached to several biological functions, including the granulocyte adhesion, the epithelial adherent junction signalling, the tight junction signalling and the ILK signalling playing a crucial role during implantation.

Limitations, reasons for caution: The relevance of these miRNAs biomarkers of the endometrial receptivity in endometrial tissues obtained during the implantation windows is being validated in independent cohort of patients.

Wider implications of the findings: The identification of miRNAs in endometrial tissues associated to endometrial receptivity opens new perspectives in poor implanted patient. As miRNAs can be found in the bloodstream, exploration of these biomarkers as potentially circulating miRNAs might provide non-invasive diagnostic tool to appreciate the endometrial receptivity, and consequently, to increase pregnancy rate.

Trial registration number: Not applicable.

P-295 Endometrial thickness does not predict endometrial receptivity

D. Valbuena Perilla[1], M. Ruiz-Alonso[2], C. Marín[2], J. Soria[2], C. Simón[3], J.A. García Velasco[4]

[1]*Igenomix, Research and Development, Paterna, Valencia, Spain*

[2]*Igenomix, ERA, Paterna, Spain*

[3]*Igenomix, IVI Valencia, Fundación Instituto Valenciano de Infertilidad FIVI. Instituto Universitario IVI/INCLIVA, Valencia University, Department of Obstetrics and Gynecology, School of Medicine. Stanford University, Research and Development, Palo alto, CA, USA*

[4]*IVI Madrid, Infertility, Madrid, Spain*

Study question: Does the endometrial thickness measured by ultrasound before progesterone administration predicts endometrial receptivity assessed by molecular analysis?

Summary answer: Endometrial thickness (ETh) before progesterone administration does not predict endometrial receptivity analyzed by molecular endometrial receptivity array (ERA) at the window of implantation (WOI).

What is known already: A number of studies have investigated the association between endometrial thickness by 2D ultrasound with endometrial receptivity in patients undergoing ART procedures, but no clear conclusions have been obtained except that an endometrial thickness between 6 and 12 mm at the day of hCG administration or prior to progesterone administration in a hormonal replacement therapy (HRT) cycle is considered as receptive.

Study design, size, duration: Retrospective study including 482 patients analyzing the association between endometrial thickness (ETh) and endometrial receptivity status assessed by ERA. ETh was measured by 2D ultrasound the day before progesterone supplementation in HRT cycles prior to ovum donation or frozen embryo transfers, ERA was performed during the WOI after 5 days of progesterone administration. Patients were classified as Eth <6 mm, 6–12 mm, or >12 mm; ERA results were considered as Receptive (R) or Non-receptive (NR).

Participants/materials, setting, methods: ETh was measured as the sum of the two endometrial layers on a longitudinal transvaginal US scan at the site of maximum thickness. For ERA analysis RNA was extracted and those with RNA integrity >7 were assessed. Hybridized microarrays were scanned and the data was extracted and presented in a GPR file analyzed by the ERA computational predictor obtaining the diagnosis as Receptive or Non-receptive (Diaz-Gimeno, et al., 2011).

Main results and the role of chance: The analysis of ERA during the WOI reveals that in endometria with ETh considered as receptive (between 6–12 mm) the ratio of R vs NR was 77.26/22.73 respectively, whereas in atrophic endometrium (<6 mm) the ratio was 42.85/57.14 (*p = 0.003 by Chi-square test). In hypertrophic endometria, the ratio was 64.86/35.13 not showing differences with the other groups.

Endometrial thickness (mm)	Receptive %	Non Receptive %	Total
<6	6/14 (42.85%)*	8/14 (57.14%)*	14
6–12	333/431 (77.26%)*	98/431 (22.73%)*	431
>12	24/37 (64.86%)	13/37 (35.13%)	37
Total	363	119	482

* p = 0.003 by Chi-square test.

Limitations, reasons for caution: The retrospective nature of the study limits the validity of the results.

Wider implications of the findings: For clinicians is interesting to know that endometrial thickness between 6–12 mm does not preclude the existence of a receptivity status, that is in the range of (75% R/25% NR). In atrophic endometrium, NR cases increase significantly, whereas hypertrophic endometrium is similar to normal endometrium in receptivity terms.
Trial registration number: Not apply.

P-296 Intrafollicular PTX3 level and CCs apoptosis rate in endometriosis IVF patients

S. Cesarano[1], M.D. D'Eufemia[1], F. Caprio[1], C. Trotta[1], M. Santonastaso[1], N. Colacurci[1]
[1]Second University of Naples, Department of Woman, Children and General and Specialized Surgery, Naples, Italy

Study question: To determinate the association between follicular fluid (FF) pentraxin3 (PXT3) levels, cumulus cells (CCs) apoptosis rates and in vitro fertilization (IVF) outcome in endometriosis-IVF patients.
Summary answer: High levels of PXT3 have been detected in severe endometriosis and are associated to CCs apoptosis and reduction of fertilization rates and embryo development.
What is known already: Pathogenesis of endometriosis, a women disease during reproductive age, is related to complex mechanisms that involve estrogen and progesterone activity, angiogenesis, apoptosis and inflammation, but it remains still unclear. Endometriosis influences negatively oocyte quality and IVF success. PTX3 is a long pentraxin that plays a key role in female fertility as an essential structural constituent of the cumulus oophorus extracellular matrix and elevated levels of soluble PTX3 can be found in human follicular fluid. Infertility of PTX3 deficient mice is due to defects in ovulation and oocyte fertilization. The relationship between endometriosis stage and PTX3 levels is unknown.
Study design, size, duration: In this prospective study 73 women undergoing to ICSI-ET cycle were enrolled from March to October 2015. The two study groups consisted of mild endometriosis cases (n = 24; A Group) and severe endometriosis cases (n = 24; B Group) (ESHRE criteria). The control group was ICSI cases with mild/moderate male infertility (n = 25; C Group).
Participants/materials, setting, methods: Exclusion criteria: age>35 years, BMI > 27 kg/m^2, smoking status, basal FSH > 9 IU/mL, PCOS, diabetes and severe oligoasthenoteratozoospermia. The controlled ovarian hyperstimulation was performed with a long protocol and recombinant FSH. At the time of pick-up were retrieved follicular fluid and isolated CCs. The apoptotic index was performed by TUNEL TEST. The Enzywell PTX3 kit was used for PXT-3 determination. Oocyte quality, fertilization rate, embryo quality were assessed. Data were analyzed using the unpaired Student's t-test (p-value ≤ 0.05).
Main results and the role of chance: No statistically significant differences in PTX-3 level and apoptosis were observed in patient with mild endometriosis respect to control group (PTX-3:15.5 ± 10.5 vs 10.7 ± 6.4; %DFI: 18.3 ± 5.5 vs 12.7 ± 4). The PTX-3 level and CCs apoptosis was higher in severe endometriosis cases compared to control group (PTX-3: 22 ± 9.1 vs 10.7 ± 6.4;%DFI: 32.5 ± 5.5 vs 12.7 ± 4). The IVF outoumes (MII retrieved oocytes number, fertilization rate and embryo quality) were statistically significant lower in endometriosis patient compared to control group.
Limitations, reasons for caution: No evaluation of serum PTX3 level.
Wider implications of the findings: This research showed an increased PTX3 levels in follicular fluid and apoptosis rate in CCs of severe endometriosis patients. These results suggest a possible mechanism responsible of reduced oocyte competence and IVF outcome in endometriosis.
Trial registration number: No requested.

P-297 Changes in spontaneous behavior in rats with surgically induced endometriosis during different phases of the estrous cycle

A.W. Nap[1], M. van Aken[2], P. Groothuis[3], M. van Duin[4], T. Van Rijn[5], A. Peeters[6]
[1]Ziekenhuis Rijnstate, Department of Gynaecology and Obstetrics, Arnhem, The Netherlands
[2]Rijnstate, Obstetrics and Gynaecology, Arnhem, The Netherlands
[3]Synthon Biopharmaceuticals B.V., Preclinical department, Nijmegen, The Netherlands
[4]Ferring Pharmaceuticals, Research Institute, San Diego, CA, USA
[5]Radboud University, Department of Biological Psychology, Nijmegen, The Netherlands
[6]Radboud University, Department of Anatomy, Nijmegen, The Netherlands

Study question: How can we measure pain in rats with surgically induced endometriosis?
Summary answer: We can measure pain by measuring active behavior, which is lost due to pain or discomfort in the rat.
What is known already: Women with endometriosis suffer from pain which may negatively influence physical activity. In rats, it is possible to surgically induce endometriosis. Surgical induction of endometriosis has been shown to cause hyperalgesia and allodynia as demonstrated by increased escape behavior during vaginal distention and reduced response latency in the hot plate test.
Study design, size, duration: Design: control versus treatment study; number of treated/controls: three groups: 7 controls, 9 sham operated rats, 14 rats in whom endometriosis was surgically induced; treatment duration: 7 days of observation (during one estrous cycle) after induction of endometriosis and recovery time after surgery; sampling procedures: continuous monitoring of behavior in a home cage observation system called the Phenotyper®. The locomotor activity and explorative behaviors are recorded on a continuous basis with an infrared sensitive camera.
Participants/materials, setting, methods: General approach: animal treatment model. Species: Female Wistar rats of 6–8 weeks of age. Methods and endpoints: surgical induction of endometriosis by autotransplantation of one uterine horne, which was cut into four pieces and transplanted to the abdominal wall and mesentery. Endpoints: Mobility (duration of active moving (in average seconds) of the rat) and rearing (the number of times a rat stands upright on its hind legs), recorded in the first hour after dark.
Main results and the role of chance: We did not observe a difference in overall mobility and rearing between animals with and without an estrous cycle. However, we did observe cycle-related differences.

With regard to mobility: In control rats, no differences were seen between the estrous and the non-estrous phase of the cycle regarding the number of seconds that the rat was actively moving. In the sham operated group, the rats were significantly more active in the estrous phase as compared to the non-estrous phase ($p < 0.05$), in contrast, in the endometriosis group the rats were significantly more active during the non-estrous phase ($p < 0.05$).

With regard to rearing: In the control group, the rats significantly reared more during the non-estrous phase compared to the estrous phase ($p < 0.05$). In the endometriosis group, we saw the same effect ($p < 0.01$). In the sham operated group, no difference in number of rearings was observed between the different phases.
Limitations, reasons for caution: A woman with endometriosis has a higher volume of endometrium in her abdominal cavity due to retrograde menstruation. In our model, endometrial autotransplantion did not result in a higher volume of endometrium but only in transplantation to an other site in the abdomen. This does not mimic the human situation.
Wider implications of the findings: We speculate that the loss of active behavior during the estrous phase in endometriosis rats is caused by pain or discomfort as a consequence of the presence of ectopic endometrial tissue in the abdominal cavity.

Our data provide the basis to develop a new non-invasive animal model for pain in endometriosis.
Trial registration number: none.

P-298 Recurrent implantation failure: association with single nucleotide polymorphisms

A. Renzi[1], C.G. Petersen[1,2], L.D. Vagnini[1], G.R. Oliveira-Pelegrin[1], I.T. da Silva[3], R. Valieris[3], A.L. Mauri[1], J. Ricci[2], F. Dieamant[1,2], M. Cavagna[1,2,4], J.B.A. Oliveira[1,2], R.L. Baruffi[1,2], J.G. Franco Jr[1,2]
[1]Paulista Centre for Diagnosis, Research and Training, Research, Ribeirao Preto, Brazil
[2]Centre for Human Reproduction Prof. Franco Jr, Research, Ribeirão Preto, Brazil

[3]Laboratory of Bioinformatics and Computational Biology, AC Camargo Cancer Center, Research, Sao Paulo, Brazil
[4]Women's Health Reference Center, Perola Byington Hospital, Research, Sao Paulo, Brazil

Study question: Is there any genetic polymorphism involved in recurrent implantation failure (RIF) that could be used as molecular biomarker helping in diagnosis and treatment?
Summary answer: Next generation sequencing (NGS) of different genes has identified some single nucleotide polymorphisms that can be involved with implantation failure.
What is known already: It has been suggested that single gene disorders could be associated with regulation of invasion and angiogenesis in embryo implantation process. Polymorphisms in these genes could increase the susceptibility of implantation failure. Next generation sequencing allowed the identification of mutations in several hundred genes which can potentially lead to infertility. The use of this tool could help in the discovery of SNPs involved in implantation failure allowing a precise diagnosis.
Study design, size, duration: A cross-sectional study was conducted with blood samples of 48 women presenting RIF, subjected to IVF/ICSI protocols and 46 fertile women (control group).
RIF group: inclusion criteria: ≥2 failed IVF/ICSI attempts/≥ 5embryos transferred, age ≤39 years and normal karyotype; exclusion criteria: uterine defects, ultrasonographic evidence of hydrosalpinx, infections, endocrine problems, coagulation defects or thrombophilia and autoimmune defects.
Control group: volunteers with at least 1 live birth, without treatment and no history of miscarriage.
Participants/materials, setting, methods: Genomic DNA was extracted from the peripheral blood of RIF and control groups. The coding regions (exons), no translated variants in both 3′/5′ UTRs and intronic regions of selected genes were analyzed by NGS using TruSeq Custom Amplicon/ MiSeq-Systems. Raw paired-end reads were aligned to human reference genome GRCh37 using BWA v0.7.12. Reads were re-aligned around indels and quality scores re-calibrated using GATK–(v3.5-0-g36282e4). GATK's UnifiedGenotyper was used as a variant caller to detect SNVs on the full alignments.
Main results and the role of chance: Following the best practices of GATK for amplicon sequencing we found prevalent genetic variants in 8 of 36 genes studied (FSHR, ESR1, ESR2, CYP19A1, BMP15, TP63, TP73, LIF, TP53, USP7, IL6ST, VEGFA, AMH, AMHR2, IL6, INHIBIN B, FMR1, IgF1, GDF9, CYP17A1, IL13, APOE, LEP, LEPR, LHB, LHCGR, AR, IgF1R, CYP11A1, PGR, MMP9, MMP2, IL1B, MTHFR, FSHB, TNF) in RIF group and their frequencies are shown in Table 1.

Table 1 | Variants frequencies

Gene	rs	allele	Control	Control	RIF	RIF
			n	Minor allele frequency	n	Minor allele frequency
AMHR2	rs2071558	C>T	11	0.094	16	0.178
AMHR2	rs2272002	T>A	8	0.068	10	0.131
ESR1	rs9341077	T>C	5	0.059	8	0.102
ESR1	rs6914438	C>T	7	0.037	11	0.099
ESR2	rs1152580	T>G	6	0.049	10	0.130
IGF1R	rs3743262	C>T	4	0.040	9	0.092
MTHFR	rs1537514	G>C	4	0.054	9	0.097
PGR	rs11224558	C>T	7	0.062	12	0.184
PGR	rs10895053	C>T	7	0.058	12	0.173
PGR	rs11224560	C>T	7	0.060	12	0.169
PGR	rs11224561	C>T	8	0.062	16	0.221
PGR	rs11224563	C>T	8	0.094	15	0.176
PGR	rs1042838	C>A	8	0.092	15	0.173
PGR	rs1824128	G>T	9	0.073	18	0.236
TP73	rs3753211	T>C	6	0.065	14	0.159
VEGFA	rs3025040	C>T	10	0.072	14	0.162

Limitations, reasons for caution: More studies are necessary to confirm this data considering variations in different ethnic population.
Wider implications of the findings: Taking into account that these SNPs could be involved with recurrent implantation failure, the expansion of this research should be considered.
Trial registration number: Not applicable. The local ethics committee authorized this study.

P-299 Endometrial thickness is not an independent predictor of live birth in IVF: should we stop measuring it during monitoring of the cycle?

G. Griesinger[1], S. Trevisan[2], B. Cometti[2]
[1]Universitaetsklinikum Schleswig-Holstein, Campus Lübeck, Department of Gynecological Endocrinology and Reproductive Medicine, Lübeck, Germany
[2]IBSA Institut Biochimique SA, Department. of Statistics and Research, Pambio-Noranco, Switzerland

Study question: To determine if endometrial thickness (EMT) is an independent predictor of pregnancy and live birth.
Summary answer: Though EMT is associated with live birth likelihood in uni-variate analyses, EMT is not an independent predictor, when controlling for confounders (e.g., age, ovarian response).
What is known already: A large number of studies have established an association of EMT with pregnancy likelihood, however, the majority of studies failed to test the impact of EMT among other important confounders. A large systematic review of 22 studies recently reported that a thin endometrium is related to a lower chance of pregnancy: the clinical pregnancy rate for an EMT ≤7 mm was significantly lower compared with cases with EMT > 7 mm [23.3% versus 48.1%, OR 0.42 (95% CI 0.27 –0.67)] (Kasius et al., Hum Reprod Update 2014). The systematic review called for further research to determine the real independent significance of EMT in IVF.
Study design, size, duration: This analysis collates data from two, large, randomized, GCP-standard, phase III trials (07EU/Prg06, NCT00827983; 07USA/Prg05, NCT00828191) on luteal phase support in IVF (Lockwood et al., Fertil Steril 2013; Baker et al., Hum Reprod 2014). Total sample size is 1,401 patients with complete data sets. Outcomes of interest: ongoing pregnancy rate (PR) and live birth rate (LBR) in relation to EMT on day of hCG Administration.
Participants/materials, setting, methods: Patients: 18 to 42 years, BMI <30 kg/m^2, <3 prior ART-cycles, baseline FSH <15 IU/L and E_2 <80 pg/mL, normal uterine cavity as per recent hysterosalpingogram, sonohysterogram or hysteroscopic exam and at least 3 retrieved oocytes. In the absence of statistical heterogeneity between studies, data were pooled and analysed on individual patient level, accounting for clustering of patients within trials. Uni-variate and multivariate analyses were performed. EMT was studied by percentile analysis and cut-offs in 1 mm steps.
Main results and the role of chance: The pregnancy rate was significantly lower in patient with low (25th percentile ≤9.5 mm; PR = 22.03%) and high (75th percentile > 12.04 mm; PR = 27.20%) EMT as compared to intermediate EMT (25th–75th percentile > 9.5 to ≤12.04 mm; PR = 50.77%; Cochran-Mantel- Haenszel test p = 0.021). A threshold of <9 mm EMT discriminates patients with or without ongoing pregnancy (odds ratio [<9 mm vs ≥9 mm] = 1.699, 95% CI = 1.23–2.35, p = 0.001; sensitivity = 88.9%; specificity = 17.5%; PPV = 39.0%; NPV = 72.6%). Patients with low EMT (5th percentile approx. ≤8 mm) had significantly less oocytes retrieved, while female age, cause of infertility and type of stimulation protocol did not differ between groups of EMT. In multivariate analyses, in which treatment arm and trial were considered as fixed effects and other predictors of pregnancy and live birth, respectively, were selected by a stepwise logistic regression, it was found that EMT is not an independent predictor of ongoing pregnancy and live birth, when adjusting for female age, number of oocytes retrieved and transfer difficulty (easy; moderately difficult; extremely difficult).
Limitations, reasons for caution: Women with thin endometrium are not underrepresented herein despite the patient selection in a phase III trial, since thin endometrium, defined as ≤7 mm, was present in 4.8% cases compared to 2.4% in the review of Kasius et al. (Hum Reprod Update 2014).
Wider implications of the findings: Extremes of EMT require further diagnostic work-up before IVF treatment, while EMT should be ignored in the majority of cases during routine cycle monitoring in IVF patients undergoing controlled ovarian stimulation and fresh embryo transfer.
Trial registration number: NCT00827983; NCT00828191.

P-300 The hormonal environment of endometrium is a primary factor, which increases the birthweight of singletons born after frozen-thawed embryo transfer

Y. Tsuji[1], J. Otsuki[1], T. Iwasaki[1], K. Furuhashi[1], Y. Matsumoto[1], S. Kokeguchi[1], M. Shiotani[1]
[1]*Hanabusa Women's Clinic, Reproductive Medicine, Kobe, Hyogo, Japan*

Study question: Why does frozen-thawed embryo transfer (FET) lead to greater birthweights than fresh embryo transfer (fresh-ET)?
Summary answer: The primary factor affecting the birthweight was the pre-/post-ET hormonal environment of endometrium, not the stage of transferred embryos nor the frozen-thawed procedure itself.
What is known already: Several studies have shown that FET decreased the risk of low birth-weight in comparison with fresh embryo transfer. Furthermore, these studies indicate the cause of the increased birth-weight may be associated with the frozen-thawed procedure, suggesting the possibility of epigenetic errors in the embryos. It has also been reported that the birth weight of boys derived from frozen-thawed embryo transfers was significantly greater than that of girls.
Study design, size, duration: This retrospective study was conducted over the period from January 2011 to December 2014, on 2,281 singletons born at 36–41 weeks of gestation, following assisted reproductive technologies (ART) in a single facility. These singletons were born after 249 fresh-ET and 2,032 FET (ovulatory cycles: $n = 204$, and HRT cycles: $n = 1,828$). Meanwhile, during the HRT cycles, endometrium was prepared by estrogen and progesterone administration.
Participants/materials, setting, methods: In this study, all pregnancies were assisted with hormonal supplementation for luteal support. The mean birth-weight of singletons born after fresh-ET were compared with singletons born after FET. Furthermore, in FET cycles, the mean birth-weight of singletons was compared between ovulatory cycles and HRT cycles. Additionally, the duration of embryonic culture until embryo transfer and the quality of embryos were categorized into cleavage stage/blastocyst stage and high quality/low quality, respectively.
Main results and the role of chance: The mean birth-weight of singletons after FET was significantly higher when compared with fresh-ET (3108 g ± 384 g vs 3047 g ± 399 g; $p = 0.023$). In FET cycles, the birthweight in HRT cycles was significantly higher than that in ovulatory cycles (3119 g ± 391 g vs 3002 g ± 374 g; $p = 0.000046$). The ratios of male neonate were similar in each ET group and each cycle in FET (52.1% vs 55.4%; $p = 0.32$, and 51.6% vs 56.4%; $p = 0.20$, respectively). In HRT cycles, there were no differences between the birthweight of singletons born from blastocyst transfers and that from cleavage stage embryo transfers (3119 g ± 386 g vs 3120 g ± 352 g; $p = 0.99$). Similarly, the mean birthweight of singletons born from high quality cleavage stage embryos showed no marked difference from the mean birthweight of low quality cleavage stage embryos (3115 g ± 359 g vs 3125 ± 346 g; $p = 0.24$). Likewise there was no detectable difference in birthweight between high quality blastocysts and low quality blastocysts (3110 g ± 381 g vs 3134 g ± 395 g; $p = 0.86$ respectively).
Limitations, reasons for caution: As our study only focused on the point of birth, long-term study is required to assess the effect of freezing and thawing procedures and the influence of HRT on birthweight in each cycle.
Wider implications of the findings: The mean birthweight of singletons born after HRT cycles was significantly higher than that of FET ovulatory cycles, indicating that the hormonal environment of endometrium may be a primary factor in increasing the birthweight in HRT cycles, rather than the stage of the transferred embryos or the frozen-thawed procedure itself.
Trial registration number: Not applicable.

P-301 Initial trial of a uterine lavage diagnostic profile to predict outcome of embryo transfer

L.A. Salamonsen[1], B.J. Vollenhoven[2], L.J.F. Rombauts[2], T.A. Edgell[1]
[1]*Hudson Institute of Medical Research, Centre for Reproductive Health, Melbourne, VIC, Australia*
[2]*Monash University, Department of Obstetrics and Gynaecology, Clayton, VIC, Australia*

Study question: Can a uterine lavage (hCG+2) biomarker diagnostic profile predict the outcome of a same cycle embryo transfer?
Summary answer: A uterine lavage biomarker panel combined to produce a prognostic algorithm correctly predicting the result of embryo transfer for 95.1% of women.
What is known already: Successful IVF requires both a quality embryo and a receptive endometrium. Currently there is no diagnostic test available to assess the quality of the maternal endometrium during an embryo transfer cycle. Previously we have identified a cohort of 6 biomarkers secreted by the endometrium into the uterine cavity at the time of receptivity. These markers had shown significant discrimination of fertile and primary idiopathic infertile women during natural cycles.
Study design, size, duration: All lavage was collected with informed consent over a 1 year period. Uterine lavage was collected at the time of oocyte retrieval from 85 women having a same cycle embryo transfer. Of these women (aged 25–45 years) 15 became pregnant (confirmed by ultrasound), with 10 resulting in a live birth. Individual biomarkers and ratios of biomarkers were analysed for discrimination of transfer outcomes. Logistic modelling was performed and performance assessed by ROC analysis.
Participants/materials, setting, methods: Lavage was assayed for Colony Stimulating factor-3 (CSF3), Interleukin-8 (IL8), Interleukin-6 (IL6), vascular endothelial growth factor (VEGF) and Interleukin-17A (IL17A) using Milliplex bead-based ELISA. C-reactive protein (CRP) was determined using Randox high sensitivity assay. Additional parameters, e.g., peak estradiol, progesterone, embryo quality, age, BMI, etiology, endometrial thickness etc. was collected. Pregnancy was confirmed by ultrasound; biochemical pregnancies ($n = 3$) are excluded from analysis.
Main results and the role of chance: Individually, Il6, IL8, VEGF and IL17A showed significant ($p < 0.05$) discrimination of embryo transfer outcome being elevated among women for whom transfer was unsuccessful. These were significantly ($p < 0.05$) positively correlated with progesterone concentration but not peak estradiol. Ratios of Il17A/CRP ($p = 0.067$) and VEGF/CRP ($p = 0.084$) and CSF3/IL17A ($p = 0.078$) showed a non-significant trend ($p = 0.078$) to be lower among the pregnancy group. None of the 6 biomarker levels were related to age, BMI parity, cycle number, aetiology or treatment type. CSF3 was significantly negatively correlated with endometrial thickness ($p = 0.023$).

In logistic regression modelling, the most significant factors in creating the prognostic algorithm were; age, P4, Il17A/CRP, endometrial thickness, BMI, peak E2, and Il6/VEGF. The algorithm correctly predicted outcome of embryo transfer in 95.1% of women, with an Area under the ROC curve of 0.996 with a significance level of $p < 0.0001$. Using a threshold of 0.378, a sensitivity of 100% (i.e., all actual pregnancies were predicted as pregnancy) with a specificity of 94% (i.e., 64/67 of women who failed to become pregnant correctly predicted as no pregnancy) is achieved, thus a PPV of 83.3 and NPV of 100 is obtained.
Limitations, reasons for caution: This is a single site study. Numbers are limited particularly with regard to successful pregnancies. A larger second test data set to evaluate the true diagnostic performance is required.
Wider implications of the findings: Potential identification of further biomarkers including those to identify specific risk factors, best therapy options and combination with embryo quality testing may provide a path to cycle monitoring and individualised therapy.
Trial registration number: Not applicable.

P-302 The effects of endometrial preparation regimen on pregnancy and neonatal outcomes following single vitrified warmed blastocyst transfer

K. Kato[1], M. Ito[1], T. Okuno[1], T. Kobayashi[1]
[1]*Kato Ladies Clinic, Advanced Medical Research Institute of Fertility, Tokyo, Japan*

Study question: Does the difference in endometrial preparation regimen influence the pregnancy and neonatal outcomes following single vitrified warmed blastocyst transfer (SVBT)?
Summary answer: Endometrial preparation using letrozole improved live birth rate following SVBT, although the incidence of adverse neonatal outcomes was not increased in any endometrial preparation regimens.

What is known already: Different cycle modalities with regard to endometrial preparation for frozen-thawed embryo transfer (FET) are used: natural cycles, hormone replacement (HR) cycles and cycles stimulated with gonadotropin, clomiphene citrate or aromatase inhibitor such as letrozole. Currently, there is a little consensus on the most effective endometrial preparation regimen aiming to improve success rates following FET. In addition, there are few large-scale cohort studies on the relationship between the difference in endometrial preparation regimen and pregnancy and neonatal outcomes.

Study design, size, duration: The retrospective study period was from January 2010 to December 2013, including 13450 of SVBT cycles (8789 women, age: 36.1 ± 0.1) performed in Kato Ladies Clinic, Tokyo, Japan. Pregnancy and neonatal outcomes after SVBT in three endometrial preparation regimen: natural cycles (NC: n = 11208, 7264 women, age: 36.2 ± 0.02), HR cycles (HR: n = 876, 546 women, age: 35.7 ± 0.1) or cycles stimulated with letrozole (LET: n = 1366, 979 women, age: 35.3 ± 0.1) were compared.

Participants/materials, setting, methods: In SVBT cycles, blastocysts were vitrified and warmed using Cryotop safety kit. The primary outcomes were clinical pregnancy rate (CPR) with gestational sac at 6–7 weeks of pregnancy, ongoing pregnancy rate (OPR) with heart beat at 9 weeks of pregnancy and live birth rate (LBR) at 22 weeks of pregnancy over. Secondary outcomes were perinatal mortality and major birth defects of singleton delivered by SVBT.

Main results and the role of chance: CPR per SVBT cycles was 56.7% (6352/11208) in NC group, 57.0% (499/876) in HR group and 58.6% (801/1366) in LET group. OPR in NC, HR and LET groups were 50.3% (5641/11208), 51.0% (447/876) and 53.6% (732/1366), respectively. LBR was 44.6% (5000/11208) in NC group, 43.2% (378/876) in HR group and 48.3% (660/1366) in LET group. Significant difference was observed between NC and LET groups in CPR. LBR was significantly higher in LET group compared with NC and HR groups ($P < 0.05$). Perinatal mortality and major birth defect rates were comparable between NC, HR and LET groups (Perinatal mortality rates: 0.2% (4/4932), 0% (0/376) and 0.3% (2/650), major birth defect rates: 2.8% (139/4932), 3.2% (12/376) and 3.8% (25/650), respectively).

Limitations, reasons for caution: Despite the large number of SVBT cycles were included, this study is limited by its retrospective design. Further randomized controlled trials are required to clarify the effect of endometrial preparation methods on pregnancy and neonatal outcomes.

Wider implications of the findings: Our observation that LBR per SVBT cycles is significantly higher in LET group suggests that cycles stimulated with letrozole for endometrial preparation prior to SVBT would improve the pregnancy outcomes. Additionally, endometrial preparation regimen would not influence the incidence of adverse neonatal outcomes following SVBT.

Trial registration number: Not applicable.

P-303 The expression of angiotensin II receptors mRNA in granulosa-lutein cells in endometriosis patients

C. Hayashi[1], K. Matsumoto[1], E. Kato[1], T. Nakao[1], T. Nakajima[1], F. Chishima[1], T. Yamamoto[1]
[1]*Nihon University, Department of Obstetrics and Gynecology, Tokyo, Japan*

Study question: Is the expression of angiotensin II receptors in granulosa-lutein (GL) cells altered in endometriosis patients?

Summary answer: The expression levels of angiotensin II receptors in GL cells were lower in endometriosis patients than non-endometriosis patients.

What is known already: Rennin-angiotensin system plays a key role in the regulation of blood pressure and the hydro-electrolytic balance. There were several reports that angiotensin II is present in high concentrations in follicular furuid (FF). Angiotensin II receptors can be classified angiotensin II type 1 receptor (AT1) and angiotensin II type 2 receptor (AT2) and others. AT1 has these functions such as vasoconstriction, angiogenesis and proliferation of cells. AT2 has these functions such as vasodilation, and apoptosis. AT1 and AT2 have been identified in human ovarian follicular cells.

Study design, size, duration: We investigate the concentration of angiotensin II in FF and the expression of AT1 mRNA and AT2 mRNA in granulosa-lutein (GL) cells in endometriosis patients with controlled ovarian stimulation (COS) for ART. FF samples were obtained from 50 IVF cycles (40 without endometriosis for control, and 10 with endometriosis). GL cells were obtained from 16 IVF cycles (10 without endometriosis, 6 with endometriosis). The patients with endometriosis were diagnosed by ultrasound and/or surgery.

Participants/materials, setting, methods: FF samples were obtained from 50 IVF cycles at the day of oocyte pick up. We examined the level of angiotensin II in FF by ELISA. GL cells were collected from FF. GL cells lightly centrifuged after removal of the oocyte. Cells washed in isolation medium twice, and separated from red blood cells using a 50% Percoll gradient. We examined the expression of AT1 mRNA and AT2 mRNA by RT-PCR.

Main results and the role of chance: The levels of angiotensin II were no significant difference between control and endometriosis group. The expression levels of AT1 mRNA in endometriosis was significant lower than control (p-0.0075). The expression levels of AT2 mRNA in endometriosis was significant lower than control (p-0.0075). There were positive relationship between AT1 mRNA and AT2 mRNA in all cases. We counted the number of oocytes retrieved. In control group (n = 10), total 40 oocytes were obtained including one immature oocyte (2.5%). In endometriosis group (n = 6), total 13 oocytes were obtained including 3 immature oocytes (23%).

Limitations, reasons for caution: The number of samples was small.

Wider implications of the findings: There was a report that the existence of a proper balance between proliferation and apoptosis in GL cells is indispensable to obtaining a fully competent oocyte. Thus we considered that lower expression levels of angiotensin II receptors mRNA in GL cells with endometriosis may affect decreased number of mature oocytes.

Trial registration number: Institutional Review Board (IRB) approval was obtained. Trial registration number is RK-140411-3.

P-304 The effects of integrin β3 on enzymes of the endocannabinoid system and endometrial receptivity

S. Melford[1], A. Taylor[1,2], J. Konje[1]
[1]*University of Leicester, Reproductive Medicine, Leicester, UK*
[2]*Nottingham Trent University, Bioscience, Nottingham, UK*

Study question: What effect does integrin β3 have on the enzymes of the endocannabinoid system (NAPE-PLD and FAAH) and are any differences linked to endometrial receptivity?

Summary answer: Receptive endometrial cells increased FAAH and decreased NAPE-PLD transcript levels in response to an increase in integrin β3 activity. Non-receptive endometrium cells showed no change.

What is known already: Endogenous cannabinoid (endocannabinoid) concentrations need to be carefully titrated to ensure uterine receptivity, and this "anandamide tone" is vital for successful embryo implantation. Anandamide tone is achieved by a careful balance between the activity NAPE-PLD and FAAH. Furthermore, the expression ratio of NAPE-PLD: FAAH differs at the implantation zone and the inter-implantation zone.

Integrin β3 expression coincides with the window of implantation, and aberrant expression of integrin β3 has been linked to infertility. Integrin β3 expression has also been linked to pinopode expression, suggesting that integrin β3 might be involved in producing the preferred site of embryo-endometrial interaction.

Study design, size, duration: Human endometrial cell lines were examined: Ishikawa cells were used as a receptive endometrium model; HEC1A cells were used as a non-receptive endometrium model. *S*-nitroso-*N*-acetylpenicillamine (SNAP: a nitric oxide donor) was used to up-regulate the expression of the integrin β3 (in a dose-dependent manner). SNAP (0–2000 μM) was used for 48 h and each concentration was added to 6 wells of cells. RT-PCR for the enzyme genes measured and corrected for GAPDH.

Participants/materials, setting, methods: Ishikawa and HEC1A cells (5×10^5) were seeded into a 6-well plate and cultured in 2 ml of culture medium (37°C, 5% CO_2) for 24 h. Following this, culture medium was replaced with medium augmented with *S*-nitroso-*N*-acetylpenicillamine (SNAP, 0–2000 μM) and the cells were cultured for a further 48 h. Following this, the total cellular

RNA extracted and quantified (Taqman PCR) and the relative levels of NAPE-PLD and FAAH transcripts measured.

Main results and the role of chance: The experiments with the Ishikawa cells (receptive endometrium) showed a clear inverse and statistically significant correlation between the concentration of SNAP and the expression of NAPE-PLD when compared against the control ($p < 0.01$ for 500 and 1000 μM, $p < 0.05$ for 2000 μM; Tukey's multiple comparison test). It also showed positive correlation between the concentration of SNAP and the relative expression of FAAH expression. Cells treated with 2000 μM SNAP showed a statistically significant difference in the relative FAAH expression when compared against the control (p-0.001). In addition, cells treated with 50–500 μM of SNAP showed a statistically significant difference when compared against 2000 μM of SNAP ($p < 0.001$ for 50 μM, $p < 0.01$ for 100 and 500 μM SNAP; One-way ANOVA with Tukey's multiple comparison test).

In contrast, the experiments with the HEC1A cells (non-receptive endometrium) treated with increasing concentrations of SNAP did not show any significant relationship between in their expression of either NAPE-PLD or FAAH (One-way ANOVA; NAPE-PLD $p = 0.1862$, FAAH $p = 0.2170$).

Furthermore, the relative expression of NAPE-PLD in Ishikawa cells was twice that of HEC1A cells, and the relative expression of FAAH in Ishikawa cells was 100 times that of HEC1A cells, suggesting FAAH expression is a key regulator of implantation in the human endometrium.

Limitations, reasons for caution: The small sample size ($n = 6$ for each concentration) means further work is necessary before decisive conclusions can be made, however, the strong statistical significance is promising. Also, we have only shown relative expression of NAPE-PLD and FAAH rather than exploring their functionality.

Wider implications of the findings: This study supports the existing literature showing that integrin β3 and the endocannabinoid system have individually been implicated in human and animal endometrial receptivity, however, this is the first study that brings these two factors together and links them. This provides a new therapeutic target for improving fertility rates.

Trial registration number: N/A.

P-305 The window of endometrial receptivity might be displaced under different protocols for endometrial preparation

M. Cerrillo Martínez[1], M. Ruiz[2], A. Bermejo[3], D. Blesa[2], M. Mayoral[1], J.A. García Velasco[4], C. Simón[5]
[1]*IVI Madrid, Reproductiva Medicine, Madrid, Spain*
[2]*Igenomix, Genetic, Valencia, Spain*
[3]*Minifiv, Director, Madrid, Spain*
[4]*IVI Madrid, Director of IVI Madrid, Madrid, Spain*
[5]*IVI and Igenomix, Scientific Director, Valencia, Spain*

Study question: Does the window of endometrial receptivity (WOI) change in the same patient under different protocols for endometrial preparation?

Summary answer: WOI might vary within the same patient under different protocols for endometrial preparation being hormone replacement therapy, and natural cycle with hCG the most consistent.

What is known already: The most used protocols to prepare the endometrium for embryo transfer are the controlled ovarian stimulated (COS) for fresh transfers, hormone replacement therapy (HRT), natural modified cycle with hCG triggering (NC-hCG), or natural cycle (NC) following spontaneous LH peak. Controversy exist regarding the superiority of each of them to optimize the WOI.

Study design, size, duration: Prospective study in which with 5 healthy volunteers with proven fertility between January 2014 and March 2015 in IVI Madrid that consecutively underwent COS, HRT, NC-hCG, or NC. Endometrial biopsy was obtained in COS 5 days after OPU day with 4 days with 200 mg/12 h vaginal progesterone, HRT after 5 days of added 400 mg/12 h of P4, NC-hCG, 7 days after hCG with 4 days of 200 mg/12 h of P4 and in NC 7 days after LH peak.

Participants/materials, setting, methods: A total of 20 endometrial biopsies were analyzed. RNA was extracted and those with RNA integrity >7 were assessed. Hybridized microarrays were scanned and the data was extracted and presented in a GPR file analyzed by the ERA computational predictor obtaining the diagnosis as Receptive or Non-receptive (Diaz-Gimeno et al., 2011). The level of progesterone in ng/ml was assessed at the day that endometrial biopsy was taken.

Main results and the role of chance: All the patients analyzed showed consistent WOI obtained by ERA diagnosis in HRT and NC-hCG cycles, being receptive in all of them at the time were endometrial biopsy was obtained. However, the WOI was displaced in 1 out of 5 patients undergoing COS cycles, and in 2 out of 5 patients in NC. Only 2 out of the 5 patients analyzed maintained the same WOI regardless of protocol used. No correlation was found between the levels of progesterone at the day of endometrial biopsy and the displacement of the WOI found under different endometrial preparation.

Limitations, reasons for caution: The size of study is limited, all of the volunteers had proven fertility, we do not know if infertile patients could have different results.

Wider implications of the findings: For clinicians is interesting to know that HRT and NC-hCG protocols are more predictable whereas COS or NC might induce a displacement of the WOI in the same patient. Embryo transfer must be performed always with the same type of endometrial preparation used for the ERA test.

Trial registration number: NCT02280798 in Clinical Trials.

P-306 Endometrial mesenchymal stem cells (E-MSC) can differentiate into endothelial cells in a direct co-culture-based *in vitro* model of ovarian endometriosis

S. Canosa[1], A. Moggio[2], A. Brossa[2], G. Pittatore[1], G.L. Marchino[3], S. Leoncini[1], C. Benedetto[3], A. Revelli[1], B. Bussolati[2]
[1]*S. Anna Hospital, Physiopathology of Reproduction and IVF Unit, Department of Surgical Sciences, Turin, Italy*
[2]*Molecular Biotechnology Center, Department of Molecular Biotechnology and Health Sciences, Turin, Italy*
[3]*S. Anna Hospital, Department of Surgical Sciences, Turin, Italy*

Study question: Are endometrial mesenchymal stem cells (E-MSC) directly involved in the angiogenic process supporting ovarian endometriotic implants?

Summary answer: The angiogenic potential of E-MSC can be observed as the acquisition of CD31 marker in a direct co-culture system with endothelial cells.

What is known already: Previous studies demonstrated that cells with properties of mesenchymal stem cells are present both in the human endometrium and in culture cells from ovarian endometriotic lesions. An attractive hypothesis is that endometrial stem cells may migrate into the peritoneal cavity and participate in the generation of endometriotic implants. This process is strictly supported by the formation of new blood vessels, which provide oxygen and nutrient supply to the ectopic tissue, suggesting the need of a proangiogenic microenvironment for the development of the endometriotic lesion.

Study design, size, duration: For this *in vitro* study E-MSC were obtained from seven patients receiving surgery for treatment of ovarian endometriosis at S. Anna Hospital in Turin from November 2013 to February 2015.

Participants/materials, setting, methods: *In vitro* formation of capillary-like structures was studied on growth factor-reduced Matrigel and compared with HUVEC cells. A co-culture system was established seeding HUVEC (GFP^+) and E-MSC (ratio of 1:1–3 × 10^5 cells/line) for 48 h. The acquisition of endothelial markers, including CD31, was evaluated by FACS analysis and immunofluorescence. In same culture conditions the population of E-MSC-$CD31^+$ was sorted and analyzed by Real-Time PCR.

Main results and the role of chance: E-MSC expressed mesenchymal markers (CD44, CD73, CD105, CD29 and CD90) at basal level, whereas endothelial markers (CD31, VEGFR1, VEGFR2, VEGFR3 and Tie2) were not expressed. In the tubes forming assay, E-MSC were equally able to create interconnections as well as HUVEC (control cell line). In the co-culture system, the interactions between HUVEC (GFP^+) and E-MSC induced an increase of +10% in CD31 expression in the GFP^- cell population observed by FACS analysis. Furthermore, immunofluorescence images showed that E-MSC, directly in contact with HUVECs, acquire the expression of CD31. Using a cell sorter we isolated $GFP^-/CD31^+$ (post co-culture) and Real-Time PCR confirmed the significant increase of CD31, VEGFA, VEGFR2 and

TIE2 gene expression ($p < 0.05$). On the other hand, the expression of mesenchymal genes such as Vimentin and N-Cadherin significantly decreased ($p < 0.05$).
Limitations, reasons for caution: Further studies have to be performed to prove the relevance of this biological phenomenon. An *in vivo* model of endometriosis could mimic the histological complexity of endometriotic tissues, giving more information about the interaction between E-MSC and endothelium.
Wider implications of the findings: E-MSC undergo endothelial differentiation, showing a clear angiogenic potential, due to a direct interaction with endothelial cells. It can be hypotesized that the formation of vessels during the early stages of the development of endometriotic implants could involve E-MSC.
Trial registration number: None.

P-307 VEGFA mRNA: a new biomarker allowing to detect chronic endometritis during the window of implantation?

V. Tabolova[1], I. Korneeva[1], A. Donnikov[2], O. Bourmenskaya[2], N. Mishieva[1], A. Gavisova[1], D. Trofimov[2]
[1]*Research Center for Obstetrics, Gynecology and Perinatology Ministry of Healthcare of the Russian Federation, Department of Preservation and Restoration of Reproductive Function, Moscow, Russia C.I.S.*
[2]*Research Center for Obstetrics, Gynecology and Perinatology Ministry of Healthcare of the Russian Federation, Laboratory of Molecular genetic Methods, Moscow, Russia C.I.S.*

Study question: Can chronic endometritis (CE) be diagnosed based on the endometrial mRNA expression profiles during the window of implantation and what are the diagnostic criteria?
Summary answer: *VEGFA* mRNA expression (>0.250) in the mid-luteal phase is associated with CE (sensitivity 64%, specificity 89%).
What is known already: Endometrial morphology and function plays an important role in IVF. Prevalence of CE in patients with recurrent IVF failures ranges between 30% and 60%. Diagnosis of CE is based on the histological evaluation of endometrial biopsies on Day 7–10 of the menstrual cycle. The critical marker of CE is presence of plasmatic cells. At the same time, endometrial receptivity is assessed in the mid-luteal phase, and the possibility to combine these two tests would facilitate management of IVF patients. A universal marker of endometrial inflammation and receptivity, which could be used for tailored pre-conception management, has not yet been identified.
Study design, size, duration: The study had a case-control design and included 33 patients with tubal infertility. All patients underwent hysteroscopy and diagnostic curettage in the first phase of the menstrual cycle. Group 1 ($n = 15$) consisted of patients in whom plasmatic cells were identified in the endometrial tissue. Group 2 ($n = 18$) included women in whom no plasmatic cells were found. In the subsequent menstrual cycle, all women underwent endometrial biopsy during the window of implantation.
Participants/materials, setting, methods: Inclusion criteria: age <37 years; spontaneous ovulation; history of 2 unsuccessful IVF cycles. Exclusion criteria: endometrial thickness <8 mm during the window of implantation, contraindications to IVF, gynaecological conditions: uterine fibroids, endometriosis, PCOS. Expression of 39 genes in mid-luteal endometrial biopsies was assessed using RT-qPCR mRNA quantification. The genes studies belonged to the families of growth factor markers, cytokines, surface immune markers, matrix metalloproteinases, homeobox genes, cycloxygenase, estrogen and progesterone receptors, and apoptotic markers.
Main results and the role of chance: Only 4 genes showed significantly different expression levels in Group 1 and Group 2 (*VEGFA, VEGFA*$_{189}$, *IGFBP1*, *IL2*). Specifically, *VEGF*pmRNA levels in Group 1 [Me: 0.392 (0.228–0.548)] were almost 1.7-fold higher than in Group 2 ($p = 0.008$). *VEGFA*$_{189}$ mRNA levels in Group 1 [Me: 0.240 (0.196–0.430)] were 2.4-fold higher than in Group 2 ($p = 0.011$). *IGFBP1* mRNA levels [Me = 0.0003634 (0.0000245–0.0010467)] in Group 1 were 16.6-times higher than in Group 2 ($p = 0.032$). Multifactorial regression analysis allowed to select a single independent informative marker, *VEGFA,* which allowed to diagnose CE in the luteal phase. According to ROC-analysis, high levels of *VEGFA* mRNA expression were associated with presence of plasmatic cells in the first phase of the menstrual cycle. For the baseline level of expression set at 0.250, the area under curve was estimated to be 0.778 (0.612–0.943). The model sensitivity and specificity at the baseline level were 64% and 89%, respectively.
Limitations, reasons for caution: Our study was carried out in a relatively small subset of women with tubal infertility and normal ovulation. Therefore, the results obtained cannot be readily extrapolated on other groups of patients and need to be confirmed in larger trials.
Wider implications of the findings: This study opens new possibilities for simultaneous assessment of endometrial receptivity and detection of CE in the mid-luteal phase of the menstrual cycle in women starting IVF.
Trial registration number: N/A.

P-308 Role of STAT3 in endometrial regeneration in the mouse model of decellularized uterine matrix transplantation

T. Hiraoka[1], Y. Hirota[1], T. Saito-Fujita[1], K.S. Furukawa[2], T. Fujii[1], Y. Osuga[1]
[1]*The University of Tokyo, Department of Obstetrics and Gynecology, Graduate School of Medicine, Tokyo, Japan*
[2]*The University of Tokyo, Department of Bioengineering, School of Engineering, Tokyo, Japan*

Study question: Are there any useful experimental models to study the process of uterine regeneration? What are fundamental mechanisms of endometrial regeneration?
Summary answer: We established a model of decellularized uterine matrix (DUM) transplantation to analyze uterine regeneration and revealed a significant role of STAT3 in endometrial epithelial regeneration.
What is known already: Human endometrium exhibits high capacity of regeneration, which renews every menstrual cycle to prepare for pregnancy. Mouse endometrium also shows rapid reconstruction after parturition to prepare for next pregnancy. The previous studies reported that a limited population of endometrial cells presents particularly high regeneration capacity, and however, the detailed mechanism of endometrial regeneration remains unknown.
Study design, size, duration: A mouse model of DUM transplantation, in which an artificial defect of a living recipient uterus was surgically complemented with a portion of DUM, a scaffold of extracellular matrix proteins containing no intact cells, was used in this study. Sites of DUM transplantation were histologically examined.
Participants/materials, setting, methods: Wild-type (WT) mice and uterine *Stat3* knockout mice (*Stat3-floxed/Pgr-Cre* mice) were used in this study. Resected donor mouse uteri were processed with sodium dodecyl sulfate to make them only extracellular matrices without any intact cells. The decellularized matrices were transplanted into artificial defects of recipient mouse uteri, and the sites of transplantation were examined by H&E staining, immunostaining, and fluorescence assay.
Main results and the role of chance: In the transplanted DUM of WT recipient mice, all the uterine layers were histologically recovered by post-transplantation day 28 (Day 28). In the regenerated uterus, normal hormone responsiveness in the periimplantation period were observed during pregnancy. Time-series observation of the regeneration process revealed that flat cells rapidly migrated onto the DUM and formed a new epithelial layer as early as on Day 1, and the layer became a normal columnar epithelium on Day 7, indicating prominent regeneration capacity in the endometrial epithelium. Stromal and myometrial regeneration occurred following epithelial regeneration. In the DUM transplantation model using ovariectomized WT mice, uterine regeneration was similarly observed, suggesting that ovarian hormones are not essential for this regeneration process. The prominent immunoreactivity of phosphorylated STAT3 (pSTAT3) was observed in the epithelium of WT recipients around the DUM on Day 1. Interestingly, cell proliferation and reconstruction of the epithelium at the DUM on Day 1 were markedly suppressed in uterine *Stat3* knockout mice. In addition, the human endometrium showed the heightened immunoreactivity of pSTAT3 at the menstrual period when endometrial regeneration remarkably occurs. These findings suggest a key role of STAT3 in endometrial epithelial regeneration as the initial step of the uterine/endometrial regeneration process.
Limitations, reasons for caution: We performed all the analyses using a mouse *in-vivo* model. Further investigations are required for the

establishment of an *in-vitro* uterine regeneration model using human DUM and cells.
Wider implications of the findings: DUM transplantation can be a novel approach for uterine regenerative research and medicine. This technology may clarify molecular mechanisms of uterine regeneration including STAT3 signaling, and lead to clinical application against uterine diseases such as implantation failure in the future.
Trial registration number: N/A.

P-309 Elevated nerve growth factor and its receptors levels in endometriotic tissues are associated with deep dyspareunia

Abstract withdrawn by the authors

P-310 Interval double transfer undergoing frozen-thawed transfer cycle improves treatment success in patients with over twice consecutive IVF failures

G. Hui[1]
[1]*Citic-Xiangya Reproductive& Genetic Hospital, IVF Centre, Changsha, China*

Study question: This prospective control study was to examine whether sequential embryo transfer improves IVF/ET success rates in patients which over twice consecutive IVF failures.
Summary answer: Interval double transfer undergoing frozen-thawed transfer cycle improves treatment success in patients with over twice consecutive IVF failures.
What is known already: It is supposed that improvement of IVF/ET outcome in women who underment endometrial biopsy prior to the recent cycle and blastocyst transfer.
Study design, size, duration: Women undergoing frozen-thawed embryo transfer with minimum of two IVF/ET failures (n = 150) were selected for our analysis. The patient selection criteria in the study were: (i) age ǧ40, (ii) normal thrombophilia screening, (iii) normal karyotype, (iv) normal endometrial by hysteroscopy investigation, (v) at least three good-quality embryos that were frozen on day 3 of culture. The study was carried out from April 2013 to November 2014.
Participants/materials, setting, methods: Patients undergoing frozen-thawed embryo transfer were prospective by randomized to one of three groups according to a randomized controlled table. Group A sequential transfer on one day 3 embryo followed by a 5 day blastocyst. Group B underwent mock transfer on day 3 and two blastocyst on day 5. Group C just transfer two embryos which had developed to blastocysts after being preserved in liquid nitogen and thawed. Clinic pregnancy rate (PR) was measured.
Main results and the role of chance: The clinical pregnancy rate of Group A was highest of three groups (77.5% vs. 58.7% vs. 59.6% p = 0.03) while the clinical pregnancy rates of Group B and Group C were not significantly different (58.7% vs. 59.6%).
Limitations, reasons for caution: A statistic difference may be reached only after we increase the sample size.
Wider implications of the findings: interval double transfer may improve the clinical pregnancy rates for patients with consecutive IVF/ET failures compared with regular 5 day blastocyst transfer. This study has shown that co-culture of early-stage embryos with endometrial epithelium may increase success rate of IVF/ET, mechanical stimulation of the endometrial dose not play a role.
Trial registration number: Guo H, Li Y, Luo K, Gong F.

P-311 The aerobic glycolysis induced by HIF1α-prohibitin pathway in Endometriosis

Y. Zhu[1], X. Wu[1], J. Qu[1], Y. Mao[1]
[1]*Jiangsu Province Hospital, Clinical Center of Reproductive Medicine, Nanjing, China*

Study question: Whether HIF-1a can regulate the expression of PHB in EMs.
Summary answer: HIF-1α may combine with the HER in PHB to down regulate the expression of PHB in EMs.
What is known already: Prohibitin (PHB) combined with hypoxia inducible factor-1α (HIF-1α) has been confirmed to induce the aerobic glycolysis in Endometriosis (EMs) by our group. Under hypoxic condition, HIF-1α translocates to the nucleus, creates a dimeric complex with its partner HIF-1β subunit, and combines with the hypoxia response element (HRE), which eventually triggers the expressions of target genes. It has been confirmed that there was HRE (s) in PHB gene.
Study design, size, duration: The cultured Endometrial stromal cells were transfected with HIF-1α -siRNA. The relationship between HIF-1α and PHB were investigated by the chromatin immunoprecipitation (CHIP).
Participants/materials, setting, methods: Endometrial stromal cells (ESCs), from women with and without endometriosis, were cultured *in vitro* under normoxic and hypoxic conditions. siRNA transfection was used to down-regulate the expression of HIF-1a. Expression of PHB in those cells was quantified by Western blot. The combination between HIF-1a and PHB was explored by the chromatin immunoprecipitation (CHIP).
Main results and the role of chance: PHB level was significantly decreased in the ESCs from EMs women when compared with women without EMs (P < 0.05). In the cells from women with EMS, PHB level was decreased in the ectopic stomal cells compared with eutopic stomal cells (P < 0.05). PHB level was significantly decreased in ESCs cultured in hypoxic condition when compared with those cultured in normoxic condition (P < 0.05). Expression level of PHB was significantly increased in the ESCs when down regulated HIF-1a (P < 0.05). ChIP assays show that HIF-1α binds to PHB.
Limitations, reasons for caution: More further experiments, like luciferase reporter assays and real-time PCR, are needed to support our study. And our research is only in view of the aerobic glycolysis in EMs.
Wider implications of the findings: This finding may be a potential therapeutic target in Endometriosis for future clinical application.
Trial registration number: We do not have it.

P-312 A comparison of the changing pattern of 4 different endometrial markers of receptivity across the window of implantation in artificial cycles

L. Liu[1], L.J. Zhao[1], D.H. Luo[1], T.C. Li[2], X.M. Tong[1], S.Y. Zhang[1], X. Lin[1], C. Wei[1], X.X. Hu[1], P. Zhou[1], L.M. Zheng[1], F. Hong[1], Y.Y. Jin[1]
[1]*Sir Run Run Shaw Hospital, College of Medicine, Zhejiang University, Reproductive Center, Hangzhou, China*
[2]*Chinese University of Hong Kong, Obstetrics & Gynecology, Hong Kong, China*

Study question: Does the 4 known markers of endometrial receptivity, pinopode, integrim αvβ3, HOXA10 and LIF change in the same pattern across the implantation window in women underwent artificial cycle?
Summary answer: The expression of all 4 markers reached a peak on the sixth days of progesterone administration.
What is known already: Interim αvβ3, HOXA10, and LIF are universal accepted implantation markers, but the clinical value of pinopode measurement in human beings remained elusive.
Study design, size, duration: This was a single-center, prospective observational study carried out in a university-affiliated reproductive center between September 2013 and October 2014. Endometrial biopsy was obtained from 39 subjects.
Participants/materials, setting, methods: Women underwent mock hormone replacement treatment cycle which had been proven capable of supporting success implantation. Endometrial samples were obtained 3 to 7 days after the initiation of progesterone therapy (P3 to P7): P3, n = 6; P4, n = 6; P5, n = 7, P6, n = 13, and P7, n = 7. The expression of pinopodes was determined by morphometric techniques, and the expression of integrin αvβ3, HOXA10 and LIF was measured with the use of semi-quantitative western blot methods.
Main results and the role of chance: (1) Although fully developed pinopodes could be observed across P3 to P7, clustered area with >50% of fully developed pinopodes could be observed from P5 to P7, the peak percentage of fully developed pinopode occurred on P6 in all cases. (2) The changing pattern of interim αvβ3, HOXA10, and LIF expression exhibited a similar trend, with a

peak on P6. (3) The expression of fully developed pinopode showed significant ($p < 0.05$) correlation with the other three markers.
Limitations, reasons for caution: None.
Wider implications of the findings: The expression of pinopodes as determined by morphometric techniques correlated well with other implantation markers. The expression of all 4 markers reached a peak 6 days after the initiation of progesterone therapy. It remains to be seen if the use of multiple markers could improve the assessment of endometrial receptivity.
Trial registration number: None.

P-313 Unique mRNA/miRNA/LncRNA signature of the endometrium during the window of implantation in patients with repeated implantation failure

C. Shi[1], H. Hongjing[1], F. Lijuan[1], Z. Xingbang[1], C. Xi[1], L. Rong[1], S. Huan[1]
[1]People's Hospital-Peking University, Reproductive Center, Beijing, China

Study question: Is the mRNA/miRNA/LncRNA signature of the endometrium during the window of implantation of women with impaired endometrial receptivity different from those having normal endometrial receptivity?
Summary answer: The mRNA/miRNA/LncRNA signature of the endometrium during the window of implantation was altered in patients with RIF.
What is known already: High endometrial receptivity in the window of implantation (WOI) is essential in successful implantation. Therefore, appropriate endometrial receptivity evaluation for embryo transfer is critical for pregnancy, especially for treating patients with repeated implantation failure (RIF). However, a diagnosing tool with high specificity for impaired endometrial receptivity remains to be developed.
Study design, size, duration: Study design: A cohort of endometrial samples during the WOI was used to analysis the mRNA/miRNA/LncRNA signature of impaired and normal endometrium.
Size: 22.
Duration: 12 months.
Participants/materials, setting, methods: Participants: Patients with a history of RIF (12) and those who conceived after the first attempt of IVF/ICSI (10) were recruited as the study and control group respectively.
Setting: IVF center.
Methods: We collected endometrium specimen in WOI from all the participants. 7 and 5 samples from the study and control group respectively were conducted mRNA, miRNA and LncRNA microarray. The other samples were used for real-time PCR validation. Relevant comparative and functional analyses were performed.
Main results and the role of chance: Microarray analysis revealed 357 mRNAs, 105 miRNAs and 197 LncRNAs exhibiting modified expression between the two groups. The major function biological pathways for down-regulated mRNAs were the cytokine-cytokine receptor interaction, the p53 signaling pathway and the complement and coagulation cascades. Up-regulated mRNAs were found to mainly participate pathways such as the PPAR signaling pathway, the hematopoietic cell lineage, the phosphatidylinositol signaling system, the ECM-receptor interaction and the notch signaling pathway. A total of 176 regulations between the dysregulated miRNAs and mRNAs were found by regulatory network analysis.
Limitations, reasons for caution: The sample size is small. No less than 10 samples per group were used for the microarray analysis in our study. Considerable individual differences may exist and more samples were needed to do validation.
Wider implications of the findings: The unique profile we got can be used to develop an array, which will help to improve diagnosing the endometrial receptivity of patients with RIF.
Trial registration number: No.

P-314 Spontaneous fertility after expectant or surgical management of rectovaginal endometriosis with/without ovarian endometrioma: a 7-year retrospective analysis

U. Leone Roberti Maggiore[1], E. Tafi[1], A. Racca[1], C. Bondi[1], F. Laraud[1], P.L. Venturini[1], S. Ferrero[1]
[1]IRCCS AOU San Martino – IST, Academic Unit of Obstetrics and Gynecology, Genoa, Italy

Study question: Which is the spontaneous pregnancy rate (SPR) in women with rectovaginal endometriosis (RV) with/without ovarian endometrioma (OMA) treated by expectant or surgical management?
Summary answer: Crude SPRs (cSPRs) are significantly lower in women treated by expectant versus surgical management, while adjusted SPRs (aSPRs) are similar in the two study groups.
What is known already: No evidence is available on the SPRs of women with RV with/without OMA. This lack of knowledge prevents the physician to offer these patients a proper counselling on the possibility to achieve a spontaneous conception.
Study design, size, duration: This was a retrospective analysis of a prospectively collected database (January 2009–December 2015). The study included patients with RV without OMA who either directly tried to conceive (group eRV; $n = 121$) or tried to conceive after surgery (group sRV; $n = 96$), and patients with RV with OMA who either directly tried to conceive (group eOMA; $n = 163$) or tried to conceive after surgery (group sOMA; $n = 125$).
Participants/materials, setting, methods: The study included patients with RV with/without OMA, without history of infertility and with partners with normal semen analysis. Patients tried to conceive spontaneously for one year either without undergoing surgery or after surgery. cSPRs (calculated according to intention-to-treat analysis), aSPRs (calculated considering only patients who tried to conceive consecutively for one year), time to conception, and pregnancy outcomes were compared between the study groups.
Main results and the role of chance: At one year, cSPRs was lower in group eRV (24.8%) than in group sRV (42.7%; $p = 0.004$). Similarly, cSPRs was inferior in group eOMA (11.7%) than in group sOMA (30.4%; $p < 0.001$). 57.9% (group 1; 70/121 patients), 22.9% (group 2; 22/96 patients), 70.6% (group 3; 115/163 patients), and 24.8% (group 4; 21/125 patients) gave up trying to conceive spontaneously before 1-year follow-up. At one year, no significant difference was observed in aSPRs between group eRV (58.8%) and group sRV (55.4%; $p = 0.423$), and between group eOMA (39.6%) and group sOMA (40.4%; $p = 0.535$). Furthermore, at 1-year follow-up, cSPRs was significantly higher in group eRV (24.8%) than in group eOMA (11.7%; $p = 0.003$), and in group sRV (42.7%) than in group sOMA (30.4%; $p = 0.040$). At the same follow-up, aSPRs was significantly higher in group eRV (58.8%) than in group eOMA (39.6%; $p = 0.043$), and in group sRV (55.4%) than in group sOMA (40.4%; $p = 0.038$).
Limitations, reasons for caution: This research is limited by the retrospective study design. Furthermore, the SPRs reported in this study were observed in selected populations of women without history of infertility and with partners with normal semen analysis. Therefore, these data cannot be extrapolated to the general population of women with endometriosis.
Wider implications of the findings: If further studies will confirm the results of this research, patients with RV with/without OMA might be advised that surgery improves cSPRs. The presence of OMA decreases cSPRs independently from expectant or surgical management.
Trial registration number: Not applicable.

P-315 Morpho-functional endometrium peculiarities after uterine artery embolisation in leiomyoma patients with reproductive plans

I. Gyulmamedova[1], T. Tatarchuk[2], T. Zadorozhna[3], F. Dakhno[1], N. Redko[2], A. Kutsenko[1], O. Giulmamedova[2], I. Mogilevkina[4]
[1]Institute of Reproductive Medicine, IVF, Kyiv, Ukraine
[2]Institution of Pediatrics, Obstetrics and Gynecology Academy of Medical Science, Endocrine Gynecology, Kiev, Ukraine
[3]Institution of Pediatrics, Obstetrics and Gynecology Academy of Medical Science, Pathomorphology Laboratory, Kiev, Ukraine
[4]P.L. Shupik National Medical Academy of Post-Graduate Education, Science Department, Kiev, Ukraine

Study question: Are there morphological and functional changes in endometrium in leiomyoma patients after uterine artery embolisation (UAE) without myoma node expultion reducing fertility?
Summary answer: UAE more often leads to chronic endometritis, hypoplasia and dyshronosis of endometrium, decrease in expression of nuclear estrogen receptor and Ki-67 in glands and stroma.
What is known already: UAE for leiomyoma is becoming accepted as an alternative to surgical treatment but still to be controversial issue for women with incomplete reproductive plans. Ovarian failure and uterine infection are the most

dreaded complications of this procedure. The frequency of abnormal hysteroscopic findings after embolization is surprisingly high. In experiment UAE was associated with a decrease in endometrial integrin αvβ3 levels, which would negatively affect endometrial receptivity, but might be transient and reversible. Conflicting results varying from completely well tolerated to negative effect on endometrium and ovary function have been reported. Nevertheless, pregnancies after this procedure have been described.

Study design, size, duration: Prospective study of 125 patients of Reproductive Health Institution during 2012–2015. Among them 91 leiomyoma patients 20 to 45 years old admitted for organ-safe surgery: 48 patients with multi-nodes leiomyoma of big size with advanced blood flow where EUA was performed (Gr1); 43 patients with laparotomy conservative myomectomy (Gr2). Exclusion criteria: suspicion of oncology, PID or node expulsion after UAE, entry into the uterus during myomectomy. 34 IVF patients without leiomyoma served as control (CGr).

Participants/materials, setting, methods: Hysteroscopy with biopsy of uterus and cervix was performed for all patients (as part of IVF protocol). In 6 months after surgery "second look" biopsy was performed. Morphology; immunohystochemestry of endometrium: CD-138, nuclear estrogen (ER) and progesterone (PR) receptors in glands and stroma, Ki-67; scan electronic microscopy (SEM) were studied. Descriptive statistics was used.

Main results and the role of chance: Before surgery: endometrium structure corresponds to the phase of the menstrual cycle – 9 (18.75%)- Gr 1; 8 (18.6%)- Gr 2; 29 (85.29%)- CGr (pGrI-CGr < 0.05: pGr2-CGr < 0.05); polyps – 11 (22.91%); 11 (25.58%) and 1 (2.94%) respectively (pGrI-CGr < 0.05: pGr2-CGr < 0.05); simple hyperplasia- 4 (29.16%) in Gr1 and 12 (27.9%) in Gr2 (pGr1-Gr2 > 0.05); complex hyperplasia in 4 (8.33%) and 4 (9.3%), respectively, no cases in CGr.

6 months after surgery: endometrium polyps – 5 (10.41%) in Gr1 and 1 (2.35%) in Gr2, ($p > 0.05$); dischronosis of endometrium in 9 (18.75%) and 1 (2.35%) patients respectively ($p < 0.05$).

After UAE there was endometrium hypoplasia in 3 (6, 25%) patients, morphological signs of chronic endometritis in 12 (25%), positive expression of CD 138 in stroma in 15 (31, 25%). No cases of hypoplasia and chronic endometrities after conservative myomectomy.

There was increase CD16 and CD56 in stroma expression and decrease in RE and Ki-67 expression in glands and stroma in Gr1 ($p < 0.05$) and decrease in expression of nuclear steroid receptors. CD 138, CD 16, CD 56, Ki-67 in gland and stroma in Gr2 comparing to CGr ($p > 0.05$).

Rare pinopodii reduced dimensions on SEM, implantation window displaced more than 3 days were found in Gr1.

Limitations, reasons for caution: Not the same indications were considered for UAE and conservative myomectomy. UAE is admitted to women with reproductive intentions only in case it is the only possible way to save uterus.

No difference in endometrium status before the surgery in two groups (Gr1 and Gr2) make comparison after surgery possible.

Wider implications of the findings: UAE can be considered as the only option to preserve uterus in women with reproductive plans in big size multiple fibroids with advanced blood flow. High frequency of dangerous endometrium pathology after UAE requires hysteroscopy in 6 months. Future investigation is needed for in-time diagnosis and correction of endometrium receptivity.

Trial registration number: No trial; this prospective study was approved by Ethics Committee.

P-316 Magnetic resonance enema versus computed tomographic colonography in the diagnosis of bowel endometriosis

R. Annalisa[1], E. Biscaldi[2], U. Leone Roberti Maggiore[1], V.G. Vellone[3], E. Tafi[1], N. Aiello[1], P.L. Venturini[1], S. Ferrero[1]
[1]*IRCCS AOU San Martino – IST, Academic Unit of Obstetrics and Gynecology, Genoa, Italy*
[2]*Galliera Hospital, Unit of Radiology, Genoa, Italy*
[3]*IRCCS AOU San Martino – IST, Department of Surgical and Diagnostic Science, Genoa, Italy*

Study question: Which is the performance of magnetic resonance enema (MRe) and computed tomographic colonography (CTC) in the diagnosis of bowel endometriosis?

Summary answer: Both MRe and CTC have high accuracy in the diagnosis of intestinal endometriosis without significant difference between the two techniques.

What is known already: Several radiological techniques have been proposed for the diagnosis of intestinal endometriosis. Transvaginal ultrasonography is now considered the first line investigation in the study of rectosigmoid endometriosis; however, it cannot assess the presence of intestinal nodules located proximally to the sigmoid because these lesions are beyond the field of transvaginal ultrasonography. It remains to be established which is the best radiological technique to study the large intestine.

Study design, size, duration: This double-centre prospective study included 105 women with suspicion of intestinal endometriosis who underwent laparoscopy. Patients were examined and underwent surgery between October 2013 and January 2016.

Participants/materials, setting, methods: This study included women of reproductive age scheduled for laparoscopy with suspicion of intestinal endometriosis. Patients were excluded from the study if they had previous surgical diagnosis of intestinal endometriosis, previous radiological diagnosis of intestinal endometriosis, history of colorectal surgery (except appendectomy), previous bilateral ovariectomy and contraindications to bowel preparation or CTC. CTC and MRe results were compared with surgical and pathologic findings. Different radiologists independently and blindly performed CTC and MRe.

Main results and the role of chance: The mean (±SD) age of the study population was 34.9 (±5.5) years. At the time of the study, 69 patients (65.7%) were under hormonal therapy. 59 patients (56.2%) had surgical diagnosis of intestinal endometriosis. The accuracy, sensitivity, specificity, positive likelihood ratio, negative likelihood ratio, positive predictive value and negative predictive value for CTC and MRe were, respectively, 90.1%, 89.8% (79.2%–96.2%), 92.2% (81.1%–97.8%), 11.5 (4.5–29.5), 0.1 (0.1–0.2), 93.0% (83.0%–98.1%), 88.7% (77.0%–95.7%) and 92.8%, 91.5% (81.3%–97.2%), 96.1% (86.5%–99.5%), 23.3 (6.0–91), 0.1 (0.0–0.2), 96.4% (87.7%–99.6%), 90.7% (79.7%–96.9%). The McNemar's test showed that there was no significant difference in the diagnostic performance of the two techniques in the diagnosis of intestinal endometriosis ($p = 606$). 9 patients had multicentric intestinal endometriosis (multiple lesions affecting different digestive segments); MR-e identified multicentric disease in 8 patients and CTC in 7 patients ($p = 0.782$). 3 patients had cecal lesions, which were identified by CTC in all the cases and by MR-e only in one patient ($p = 0.619$). No adverse events occurred during CTC and MR-e; no patient required to interrupt the exams. The intensity of pain experienced during CTC was higher than the intensity of pain perceived during MR-e ($p < 0.001$).

Limitations, reasons for caution: Despite the large sample size of the study, few patients had multicentric disease and cecal lesions; future studies should assess the accuracy of the two techniques in diagnosing these intestinal nodules. The administration of radiation (although in low-dose) is a disadvantage of CTC.

Wider implications of the findings: Depending on the experience of the radiologist, both MR-e and CTC can be used to diagnose intestinal endometriosis. MR-e should be preferred to CTC because the patients better tolerate the exam and it does not required to expose the patients to radiation.

Trial registration number: Not applicable.

P-317 Pregnancy outcomes in women with endometriosis with and without adenomyosis: a 4-year retrospective study

E. Tafi[1], U. Leone Roberti Maggiore[1], A. Racca[1], C. Bondi[1], N. Aiello[1], F. Laraud[1], P.L. Venturini[1], S. Ferrero[1]
[1]*IRRCS AOU San Martino – IST, Academic Unit of Obstetrics and Gynaecology, Genoa, Italy*

Study question: Does adenomyosis influence the outcomes of pregnancy in women with endometriosis?

Summary answer: In women with endometriosis, diffuse but not focal adenomyosis increases the risk of small for gestational age babies (SGA), intrauterine growth restriction (IUGR), preterm birth.

What is known already: Several studies investigated the correlation between endometriosis and pregnancy outcome complications such as placenta previa, preterm birth, SGA, IUGR, gestational diabetes, pregnancy-induced

hypertension (PIH) and preeclampsia. However, no previous study compared these pregnancy outcomes in patients with endometriosis with and without adenomyosis.

Study design, size, duration: This is a retrospective analysis of a prospectively collected database during a four-year period. The study included 457 patients with endometriosis, among these patients 323 did not have adenomyosis, 82 had focal adenomyosis and 52 had diffuse adenomyosis.

Participants/materials, setting, methods: This study included patients with any form of endometriosis; the diagnosis was performed either by surgery and histology or by transvaginal ultrasonography. Adenomyosis was diagnosed by ultrasonography, it was classified in focal or diffuse. The study included patients who conceived spontaneously or by assisted reproductive techniques.

Main results and the role of chance: The three groups were similar in demographic characteristics (age, body mass index, parity, race, mode of conception). Endometriosis was histologically confirmed in 312 (68.3%) patients. Patients with diffuse adenomyosis and endometriosis had an increased risk of SGA (OR = 5.14, 95% CI 1.71–15.47; $p = 0.004$), IUGR (OR = 5.68, 95% CI 2.34–13.76; $p < 0.001$) and preterm birth (OR = 2.21 CI 95% 1.04–4.69; $p = 0.039$) compared with those with endometriosis without adenomyosis. Patients with diffuse adenomyosis compared with those with endometriosis only had similar other pregnancy outcomes: placenta previa (OR = 1.04, 95% CI 0.30–3.65; $p = 0.954$), gestational diabetes (OR = 0.52 95% CI 0.18–1.50; $p = 0.223$), PIH (OR = 1.14 CI 95% 0.24–5.27; $p = 0.872$), preeclampsia (OR = 2.11 CI 95% 0.42–10.76; $p = 0.368$). Patients with focal adenomyosis had similar pregnancy outcomes compared with those with endometriosis only: SGA (OR = 0.98, 95% CI 0.21–4.73; $p = 0.984$), IUGR (OR = 1.55, 95% CI 0.54–4.48; $p = 0.419$), placenta previa (OR = 1.10, 95% CI 0.40–3.06; $p = 0.855$), preterm birth (OR = 1.14 CI 95% 0.54–2.42; $p = 0.727$), gestational diabetes (OR = 0.96 95% CI 0.47–1.95; $p = 0.904$), PIH (OR = 0.35 CI 95% 0.45–2.75; $p = 0.318$), preeclampsia (OR = 0.65 CI 95% 0.77–5.49; $p = 0.694$).

Limitations, reasons for caution: The sample size is the main limitation of this study. Another potential limitation of the study is that the diagnosis of adenomyosis (in all the patients) and of endometriosis (in a proportion of the patients) was made by ultrasonography without histological confirmation.

Wider implications of the findings: The findings of this study suggest that pregnancies of patients with endometriosis and diffuse adenomyosis are more likely to be associated with SGA and IUGR; therefore, these pregnancies may need closer monitoring.

Trial registration number: Not applicable.

P-318 Effect of human endometriotic cyst fluids on mouse *in vitro* folliculogenesis and oocyte acquisition

D.Y. Lee[1], B.C. Jee[1], K.C. Kim[2], W.Y. Paik[3], S.H. Kim[4]
[1]*Seoul National University Bundang Hospital, OBGY, Seongnam-Si Gyeonggi-do, South Korea*
[2]*Hamchoon Women's Clinic, OBGY, Seoul, South Korea*
[3]*Gyeongsang National University Hospital, OBGY, Jinju, South Korea*
[4]*Seoul National University Hospital, OBGY, Seoul, South Korea*

Study question: Does the supplementation of human endometriotic cyst fluids (EMF) have a detrimental effect on *in vitro* follicle growth and oocyte acquisition in a mouse model.

Summary answer: Supplementation of human EMF negatively affects *in vitro* follicle growth, hormonal production and oocyte acquisition.

What is known already: An ovarian endometrioma contains free iron, reactive oxygen species, proteolytic enzymes and inflammatory molecules in concentrations from tens to hundreds of times higher than those present in peripheral blood or other types of benign cysts. The endometrioma is not surrounded by a true capsule, thus contents of endometrioma appear to across the lining cyst wall. It was postulated that the presence of an endometrioma per se may cause direct damage to the surrounding otherwise healthy ovarian tissues.

Study design, size, duration: Prospective experimental animal study. Supernatants of human EMF were added to the growth and maturation medium containing preantral follicles obtained from 7- to 8-week-old BDF1 mice. A total of 409 preantral follicles were randomly divided into four groups according to the final concentrations of human EMF; 0%, 2.5%, 5%, and 10%.

Participants/materials, setting, methods: After *in vitro* growth and maturation of mouse preantral follicles for 12 days, survival rate of follicles, oocyte acquisition, meiotic spindle integrity of MII oocytes and hormonal levels of 17β-estradiol and anti-Müllerian hormone (AMH) in the final spent media were assessed.

Main results and the role of chance: The survival rates of follicles at day 10 were significantly lower in three EMF-treated groups (56.1%, 30.6%, and 6.2%, respectively, $p < 0.05$ for each when compared with 83.6% in 0% EMF group). The acquired total oocytes (34.7%, 18.4% and 4.1%) or MII oocytes (10.2%, 3.1%, and 1%) per initiated follicle were also significantly lower in three EMF-treated groups ($p < 0.05$ for each when compared with 68.1% and 21.6% in 0% EMF group). Meiotic spindle was severely damaged in almost all of MII oocytes acquired from three EMF-treated groups. The level of 17β-estradiol was significantly lower in the 10% EMF-treated group and the levels of AMH were significantly lower in three EMF-treated groups when compared with those in 0% EMF group.

Limitations, reasons for caution: We used a mouse model to demonstrate a detrimental effect of human EMF on *in vitro* folliculogenesis.

Wider implications of the findings: Our results suggest that contents of ovarian endometrioma could affect directly folliculogenesis in the adjacent ovarian tissues. Our results can greatly contribute to understand the mechanism of endometrioma-induced ovarian damage.

Trial registration number: This work was supported by grant no. A120043 from the Korea Health Care Technology R&D Project, Ministry of Health and Welfare, Republic of Korea.

P-319 Freeze-all policy improves clinical outcome in patients with recurrent implantation failure: A randomized controlled trial

Y. Magdi[1], E. Darwish[2], M. Ahmed Elawady[3]
[1]*TopLab Company for ART Laboratories Consultations and Training, Research and Department Director, Cairo, Egypt*
[2]*TopLab Company for ART Laboratories Consultations and Training, Medical Director, Cairo, Egypt*
[3]*Faculty of Medicine, Benha University, Department of Community Medicine, Benha, Egypt*

Study question: Does a freeze-all policy of *in-vitro* human blastocysts improve the clinical outcome in patients with recurrent implantation failure (RIF)?

Summary answer: There was a statistically significant improvement in the clinical outcome in freeze-all group over the fresh embryo transfer (ET) group, in cases of RIF.

What is known already: There is a growing evidence that elective frozen-thawed embryo transfer in a non-stimulated cycle (freeze-all policy) would eliminate the risk of COS and resulting in better endometrial receptivity and lower uterine contractility as compared with fresh ICSI cycles. Many management approaches attempted to enhance ICSI outcome in cases of recurrent implantation failure, which aimed to improve quality of the embryos, receptivity of the endometrium and the embryo-endometrium interaction. However, there are no reports studied the effect of freeze all policy in improving the clinical outcome in patients with RIF.

Study design, size, duration: This randomized controlled study was conducted from February 2012 to August 2015 on 200 women with RIF, at least three failed previous ICSI attempts with at least 8 good embryos transferred under the age of 40 years. Patients were randomized to either the fresh ET group (control arm) or the freeze all group (study arm) according to a computer-generated list. Informed consent was obtained before allocation from all patients.

Participants/materials, setting, methods: Women were randomly divided in two groups of 100 women each. All patients underwent the same controlled ovarian hyperstimulation long protocol. Couples with testicular or epididymal sperm were excluded. Only Day 5 cycles resulted in blastocysts were included in this study. Cryopreservation of human blastocysts for freeze all group has been employed using vitrification, and then transferred in a consecutive natural cycle. Pretransfer morphology of blastocysts was assessed according to Gardner and Schoolcraft grading system.

Main results and the role of chance: No statistically significant differences were found in demographic data between the fresh ET group and freeze all group, including female age (33.52 ± 3.72 and 32.92 ± 3.34, respectively, $P =$

0.231), female BMI (24.85 ± 0.85 and 25.03 ± 1.38, respectively, $P = 0.267$), duration of infertility (6.72 ± 2.35 and 7.2 ± 2.11, respectively, $P = 0.13$), and number of previous ICSI attempts (3.8 ± 0.99 and 4.0 ± 0.94, respectively, $P = 0.144$). There was no statistically significant difference in endometrial thickness between patients of both groups (Fresh ET group 10.4 mm; Freeze all group 10.1 mm, $P = 0.351$).

The mean number of blastocysts transferred was similar between the two groups (Fresh ET group 2.28 ± 0.73; Freeze all group 2.08 ± 0.8). Quality of transferred blastocysts showed no significant differences between the fresh ET group and freeze all group [(Grade A blastocysts: 47.33% and 42.67, respectively, $P = 0.35$), (Grade B blastocysts: 30% and 37%, respectively, $P = 0.112$), and (Grade C blastocysts: 24.67% and 18.33%, respectively, $P = 0.196$)]. Clinical pregnancy rate (Fresh ET group 28%; Freeze all group 52%) and Ongoing pregnancy rate (Fresh ET group 20%; Freeze all group 44%) were statistically significant ($P = 0.001$). The implantation rate was also significant (Fresh ET group 17.0% and Freeze all group 44.33%; $P = 0.001$).

Limitations, reasons for caution: Further large scale multicentre randomised controlled studies are required to confirm our findings.

Wider implications of the findings: The results showed, for the first time, improvement in the clinical pregnancy, implantation, and ongoing pregnancy rates freeze-all policy group over the fresh ET group, in cases of RIF. Thus, newly developed freeze all policy may now offer an alternative option to improve the implantation efficiency for patients with RIF.

Trial registration number: NCT02681367.

P-320 Follicular phase endometrial stimulation (FES) in the transfer cycle in RIF cases: a Randomized control trial

K. Deepika[1], G. Pranesh[2], M. Vinaykumar[2], N. Garg[2], V. Navya[2], S. ksheerasagar[2], D. Soumya[2], P.S. Divyashree[2], P. Saran Malik[2], P.A. Baiju[2], S. Nivedita[2], V. Arveen[2], M. Ratnakar[2], V. Shwetha[2], K. Rao[2]

[1]*Bangalore Assisted Conception Centre, Reproductive Medicine, Bangalore, India*

[2]*Milann- The Fertility Center, Reproductive Medicine, Bangalore, India*

Study question: Does follicular phase endometrial stimulation in the transfer cycle improve the clinical pregnancy in comparison to that performed in the luteal phase in recurrent implantation failure (RIF) cases?

Summary answer: Follicular phase endometrial stimulation (FES) in the transfer cycle is beneficial in RIFs showing a higher trend in the clinical pregnancy and implantation rates.

What is known already: Scrapping of endometrium (Endometrial stimulation/biopsy) in the previous non-transfer cycle is one of the strategies to improve the implantation and clinical pregnancy rate in RIF cases. It leads to release of growth factors, cytokines, induces endometrial decidualization, increases angiogenesis all of which could lead to an improved outcome. The objective of this RCT was to test the hypothesis if endometrial stimulation performed in the follicular phase of transfer cycle could improve the probability of pregnancy in patients who have had two previous failed IVFs.

Study design, size, duration: This prospective randomized, double blinded, proof of concept study was conducted in a tertiary care center from August 2013 to December 2015 in 304 RIF cases defined as 2 previous failed ETs (fresh or frozen) with transfer of at least four good-quality embryos (grade 1) in women less <37 years. Block randomization was done with sealed envelope system using random number table. At recruitment written informed consent was taken. Approval taken from Institutional Ethical Board.

Participants/materials, setting, methods: Endometrial stimulation (ES) was performed using a Pipelle biopsy (Gynetics, Belgium) on outpatient basis. Group A: (Intervention group) – ES performed on day 4–6 of transfer cycle ($n = 49$ fresh cycles; 51 = frozen cycles); Group B: (Intervention group)- ES performed on day 20–22 of previous cycle ($n = 49$ fresh cycles; 51 = frozen cycles. Group C: (Control group)- no ES in previous 3 cycle ($n = 49$ fresh cycles; 51 = frozen cycles).

Main results and the role of chance: [I] Fresh cycles: Of the 151 patients recruited, 4-refused to participate. The baseline, stimulation and embryological characteristics were similar in all 3 groups. 147 patients underwent stimulation of which 22 patients [Group A ($n = 6$); Group B ($n = 9$); Group C ($n = 7$)] did not undergo a fresh embryo transfer and hence were excluded for the analysis.

[II] Frozen embryo transfer (FET) cycles: Of the 153 patients, cycles were canceled in 13 patients [Group A ($n = 4$); Group B ($n = 5$); Group C ($n = 4$)] and hence excluded. The age, BMI and endometrial thickness, the mean number of embryos thawed, survived and transferred were similar in all 3 groups. The sub-endometrial blood flow was better in group A reaching up to zone 3–4 [GA (2.98 ± 0.87); GB (2.67 ± 0.89); GC (2.26 ± 0.82); $p = 0.09$].

[III] Outcomes: (a) Primary outcome: Although the results did not show a statistical significance in the fresh cycles, a trend towards a better clinical pregnancy was seen in group A ($p = 0.09$). In the FET cycles, the clinical pregnancy was statistically significant ($p = 0.04$) in group A.

(b) Secondary outcome: The implantation rate in the fresh cycles was [GA: 23/90 = 25.5%; GB: 15/92 = 16.3%; GC: 13/92 = 14.1%; ($p = 0.07$)] showing a trend towards better implantation in group A. In the FET cycles, this was statistically significant ($p = 0.04$).

Limitations, reasons for caution: Limitations of the study was the sample size and the live birth rate. Live birth rate is being collected and will be reported when available.

Wider implications of the findings: The study demonstrates a better cycle outcome in the intervention group (A and B) compared to no intervention group (C) in RIFs with FES in the transfer cycle showing a higher trend towards clinical pregnancy and implantation. However large, multicenter randomized studies are needed to confirm the above findings.

Trial registration number: None.

P-321 Comparison of intracytoplasmic sperm injection (ICSI) cycles outcome in two groups of patients with endometriosis with and without sclerotherapy

S. alborzi[1], M. alborzi[1], L. kooshesh[2]

[1]*Shiraz University of Medical Science, Obstetric and Gynecology Ward, Shiraz, Iran*

[2]*Shiraz University of Medical Science, Anatomy Department, Shiraz, Iran*

Study question: Among aspiration ethanol sclerotherapy (AEST) and previouse laparoscopic surgery on treating endometrioma which modality is the preferred option with a more favorable outcome in intracytoplasmic sperm injection (ICSI) cycles.

Summary answer: Although sclerotherapy for endometrioma does not negatively affect implantation and pregnancy rates in embryo transfer cycles, recurrence of endometriosis is higher compared to laparoscopic surgery.

What is known already: The performance of laparoscopic surgery and AEST for treating endometrioma have been separately reported in earlier studies. However, the outcome of ICSI cycles for number and quality of oocytes, implantation rates, pregnancy rates and recurrence of endometrioma have not been concurrently compared in the two method.

Study design, size, duration: 61 patients which enrolled with infertility and endometrioma undergoing ICSI cycles from March 2014 to till January 2016.

Participants/materials, setting, methods: Women with infertility and endometrioma divided in two groups. In group 1, 31 patients received ICSI cycles and simultaneous sclerotherapy. In group 2, 30 patients with endometrioma were treated by laparoscopic surgery. If no pregnancy occurred after one year, for all the patients controlled ovarian stimulation and ICSI was used. In group1, ultra-sound guided aspiration of endometrioma and AEST was performed then ICSI was done. Number and quality of oocytes, implantation rates, pregnancy rates and recurrence of endometrioma were compared between the two groups.

Main results and the role of chance: The number of retrieved oocytes were 216 in group 1 (mean 6.96) and 146 (mean 4.8) in group 2. The number of mature oocytes were 184 in group 1 (85%) and 124 (84%) in group 2. The implantation rate for group 1 was 5.03% and.6.4% for group 2. The pregnancy rates were 22% and.20% for group 1 and group 2 respectively. Implantation rate in group 1 was 4.5% in fresh embryo transferred cycles versus 5.2% in freeze embryo transferring. No abortions occurred in any of the patients. One-year follow-ups revealed that none of the patients in group 2 showed evidence of recurrent disease but in one-third of patients in group 1, recurrence of endometrioma was detected.

Limitations, reasons for caution: Limitation of the study is number of cases, which if number of cases are increased, the results may be different.

Wider implications of the findings: If at the beginning of the management of endometrioma, AMH (anti mullerian hormun) level is above 2 ng/ml, laparoscopic cystectomy for endometrioma is still the management of choice and should be considered for patients with endometriosis with acceptable ovarian reserve tests.
Trial registration number: None.

P-322 Randomized controlled trial to evaluate the usefulness of GnRH agonist versus placebo on the outcome of IVF in infertile patients with endometriosis

E. Rodriguez-tarrega[1], A. Monzo[1], R. Quiroga[1], M. Romeu[1], P. Polo[1], T. Garcia-gimeno[1], P. Fernandez-colom[1], J.V. Martinez-sanchis[1], S. Martinez-cuenca[1], A. Abad[1], R. Taroncher[1], I. Molina[1], A. Pellicer[1]
[1]Hospital Universitari i Politecnic La Fe, Human Reproduction Unit, Valencia, Spain

Study question: Could improve clinical pregnancy rate a 3-month pre-treatment with GnRH agonist administered immediately before *in vitro* fertilization in infertile patients with endometriosis?
Summary answer: Regarding our study results, a 3-month pre-treatment with GnRH agonist prior IVF did not improve clinical pregnancy rate in infertile patients with endometriosis.
What is known already: Endometriosis causes infertility due to several mechanisms, such as fallopian tube obliteration and decreasing ovarian reserve. Furthermore, an inflammatory state has been demonstrated in follicular and peritoneal environment, which could impair oocyte and embryo quality and implantation rate.

Assisted reproductive techniques outcomes in endometriosis seem worse than in patients with other causes of infertility. The influence of adjuvant treatments on these outcomes has been investigated. A pretreatment with GnRH agonists before IVF could improve reproductive outcomes in terms of implantation and pregnancy rates in patients with endometriosis. However, most of the studies performed to date are not prospective and randomized.
Study design, size, duration: Prospective controlled, double-blind, randomized clinical trial.

The duration was of 36 months (between March 2012 and March 2015). Two hundred patients were enrolled.

Clinical and embryological outcomes were analyzed, as well as stimulation parameters. Clinical pregnancy rate was the primary endpoint.
Participants/materials, setting, methods: Patients: Two hundred infertile women with endometriosis diagnosed by laparoscopy and/or the presence of endometrioma on vaginal ultrasound were randomized into two groups.

Setting: Human Reproduction Unit. La Fe University Hospital.

Interventions: 3.75 mg triptorelin (group 1) or placebo (group 2) was administered on days 1, 28 and 56 after menstrual cycle. Ovarian stimulation, oocyte retrieval, fertilization, embryo culture and embryo transfer were performed according standard protocols, and were identical in both groups.
Main results and the role of chance: One hundred and eighty three patients were included for statistic analysis (Group 1, $n = 92$ and group 2, $n = 91$). Seventeen patients were excluded: two because of adverse effects, six withdrawn voluntarily, two because of screening failure, and seven because of protocol violation.

The mean duration of infertility was 2.9 years (±1.5). The average patient age was 33.7 years (±3.2, range 22–39). The mean BMI was 22.6 kg/m^2 (±2.8). The mean basal FSH level was 7.1 IU/L (±1.9).

Analyses of the covariates showed that duration of infertility, age, BMI, basal FSH and stage of endometriosis were not significatively different in both groups.

The amount of gonadotropins needed to ovarian stimulation and the number of stimulation days were significantly higher in group 1: 3002 IU (±949) vs. 2346 IU (±657), and 10.4 days (±2.6) vs. 9 days (±1.7), respectively in groups 1 and 2 ($p = 0.000$).

Estradiol levels on the day of administration of hCG were 1896.9 pg/mL (±765.8) and 2218.2 pg/mL (±795.4), respectively in groups 1 and 2 ($p = 0.000$).

Number of total oocytes, metaphase II, fertilized oocytes and embryos did not show statistical significative differences.

The clinical pregnancy rate was 25% and 34.1%, respectively in groups 1 and 2 ($p = 0.179$).

Limitations, reasons for caution: Patients affected of all stages of endometriosis have been included. However, partial analysis of data did not show statistical differences neither in the distribution of patients in both groups nor in IVF outcomes.

In 37 cases, surgical procedures took place more than 3 years prior to inclusion in the study.
Wider implications of the findings: According to these results, there is no indication for pre-treatment with GnRH agonist in infertile patients with endometriosis in order to improve IVF outcomes. This treatment increases both ovarian stimulation duration and total amount of gonadotrophins requiered, whithout improving pregnancy rate.
Trial registration number: Clinicaltrials.gov: NCT01581359 ID: ENDOFIV-010.

P-323 Clinical outcome after endometrial scratching (ES) in IVF-patients with a history of implantation failure

M. Murtinger[1], B. WIrleitner[1], T. Canic[1], P. Vanderzwalmen[1], M. Schuff[1]
[1]IVF-Centers Prof. Zech, Bregenz, Austria

Study question: Does ES prior to embryo transfer improve clinical outcome in IVF-patients with a history of implantation failure?
Summary answer: ES prior to blastocyst transfer might contribute to successful implantation in IVF-patients with a previously failed IVF attempts.
What is known already: Successful nidation of an embryo depends, beside embryo quality on the receptivity of the endometrium. The endometrium is a highly complex and dynamic tissue that undergoes several morphological and molecular changes during the menstrual cycle. Several studies indicate that ES might improve endometrial receptivity. Possible explanations include the secretion of different cytokines and growth factors, promotion of neo angiogenesis and at least alternations of endometrial gene expression which might improve synchrony between endometrium and blastocyst. However, the application of ES is not without controversy. Criticisms include amongst others the heterogeneity of studies and small numbers of patients included.
Study design, size, duration: We conducted a retrospective analysis of cycles with ES prior to embryo transfer (ET) in the time period between January 2010 and June 2015. Inclusion criteria for ES were at least one failed IVF-attempt in a previous cycle and blastocyst transfer. Clinical outcome of 190 ET was evaluated. Results after ES were retrospectively compared to patients previous in-house cycles before ES. Final outcome parameters were pregnancy rate (PR), birth rate (BR) and miscarriage rate (MR).
Participants/materials, setting, methods: Mean female age was 36.8 years (27–43). Mean number of failed IVF-cycles/patient prior ES was 4.1 ± 2.4, mean total number of ET/patients prior ES was 4.6 ± 2.5. The PR/ET rate in previous IVF-cycles prior ES was 12.7% (112/883). Generally, ES was performed once in the mid-luteal phase of the cycle prior ET. Progesterone was injected IM for luteal phase support. Blastocyst transfer was done on day 5 using a Wallace transfer catheter.
Main results and the role of chance: Following ES, a mean number of 1.8 blastocysts were transferred on day 5. We observed a PR of 29.5% (56/190). In 24.7% of patients clinical pregnancy was confirmed by positive heart beat (47/190). In 7 patients a miscarriage was reported (7/47). BR was 21.1% (40/190) including 33 singletons and 7 twins. In a sub-analysis only patients with ≥3 failed IVF-cycles were included (126 ET). In this sub-group a PR of 26.0% was obtained compared to 9.6% in previous cycles without ES. After ES in 23.0% of the patients PR was confirmed by positive heart beat and a BR of 15.9% was observed. No adverse effects of ES were observed. Our results indicate that patients with recurrent implantation failure (RIF) might benefit from ES.
Limitations, reasons for caution: This study is one of the largest performed on this topic. However, this is a retrospective study and non-randomized with its inherent limitations. Our results have to be confirmed by a randomized controlled trial before ES should be proposed as beneficial for patients with a history of implantation failure.
Wider implications of the findings: To the present day it is not unequivocally clear whether ES is helpful for ART patients and which sub-population of infertility patients might profit from this procedure. This large retrospective study is further indication that ES might support embryo implantation in patients with RIF.
Trial registration number: Not applicable.

P-324 Effect of prolonged gonadotropin releasing hormone (GnRH) agonist before IVF versus placebo on CYP19 A1 gene expression in granulosa cells in infertile women with endometriosis

A. Monzo[1], R. Quiroga[1], E. Rodriguez-Tarrega[1], M. Monterde[1], L. Martinez-Triguero[1], P. Fernandez-Colom[1], I. Peinado[1], P. Polo[1], M. Romeu[1], T. Garcia-Gimeno[1], P. Torres[1], M. de la Orden[1], I. Iniesta[1], E. Novella[1], A. Pellicer[1]
[1]*Hospital Universitari i Politecnic La Fe, Human Reproduction Unit, Valencia, Spain*

Study question: The expression of CYP19A1 gene was compared in mural granulosa (MGC) and cumulus cells (CC) in infertile women with endometriosis pre-treated with GnRH agonist prior IVF.
Summary answer: No significant difference in the expression of CYP19A1 gene in MGC nor CC was observed between groups after administration of GnRH agonist before IVF.
What is known already: Aromatase plays a fundamental role in the establishment of oocyte quality, which might be compromised in endometriosis. Some authors reported decreased aromatase activity in granulosa cells in women with endometriosis, which might lead to defects in steroideogenesis and abnormal oocyte functioning. Data on the expression of the aromatase gene in luteinized MGC are controversial and only one study evaluated the expression in CC and found reduced expression in CC of infertile women with endometriosis.

On the other hand, it has been suggested that the administration of GnRH agonist for a few month prior to IVF increases the pregnancy rate.
Study design, size, duration: A prospective blinded randomized trial was performed at our tertiary care assisted reproductive program. Sample included 40 infertile women with endometriosis. All patients were candidates for IVF-ET. Patients were randomized consecutively from October 2013 to March 2015 in two groups by using a computer-generated randomization: 20 women received GnRH agonist and 20 placebo every 28 days for three injections.
Participants/materials, setting, methods: Patients included had an indication for ART due to endometriosis diagnosed by laparoscopy and/or the presence of endometrioma on vaginal ultrasound. Samples were obtained individually only from the two aspirated follicle of each ovary. CYP19A1 gene expression in MGC and CC was quantitated through real-time polymerase chain reaction and follicular fluid concentration for estradiol, testosterone and androstenedione were measured. Oocyte and embryo quality were determined through morphological parameters and fertilization rate was calculated.
Main results and the role of chance: Both groups did not differ significantly regarding baseline clinical data in terms of age, serum FSH and estradiol level. Patients with minimal/mild endometriosis represented 72%.

Total gonadotropin dose were significantly higher in study group compared with control group (FSH (UI) = 2923.53 ± 862.11 and 2325.00 ± 764.39) ($p = 0.04$) and total number of fertilized oocytes (3.22 ± 1.99 and 5.21 ± 3.60) ($p = 0.04$) and fertilization rate (58.92 ± 28.25 vs. 77.23 ± 20.44) ($p = 0.03$) were significantly lower in the study group, respectively.

No significant differences were found between groups in the expression of the CYP19A1 in MGC (ΔΔMGC = 1.44 ± 1.85 and 1.23 ± 3.19) and CC (ΔΔCC = 2.15 ± 2.99 and 2.61 ± 3.96), respectively. The groups did not differ in CYP19A1 expression when compared MGC to CC.

Follicular hormones leves were lower in study group compared with control group (E2 (pg/ml) = 293495.4 ± 154806.6 vs. 400520.284892.9, Testosterone (ng/ml) = 3.10 ± 2.44 vs. 9.38 ± 7.94 and Androstenedione (ng/ml) = 6.86 ± 4.66 vs. 10.90 ± 11.67, respectively), although only testosterone level was significantly lower ($p = 0.00$).

The groups did not differ with regard to oocyte and embryo morphological parameters, although a trend toward lower embryo quality was found in the study group.
Limitations, reasons for caution: This randomized trial focused only in the evaluation of oocyte and embryo quality in patients with endometriosis after administration of GnRH agonist for 3 month before controlled ovarian hyperstimulation.

However, GnRH agonist appear to have other beneficial effects that may increase fecundity in patient with endometriosis through other mechanisms.
Wider implications of the findings: The admnistration of GnRH agonist did not confirm the potential hypothesized mechanism by which CYP19A1 aberrant expression influences the adquisiton of oocyte competence. However, we found lower follicular hormonal levels that might lead to abnormal oocyte functioning and favour the low number of fertilized oocytes and fertilization rate found.
Trial registration number: Clinicaltrials.gov: NCT01581359 ID: ENDOFIV -010.

P-325 Galectin-3 inhibitors as targeted therapy for endometriosis

C. Schembri Deguara[1], C. Davis[2], F. Cotter[3]
[1]*London, UK*
[2]*St Bartholomew's Hospital London, Reproductive Medicine, London, UK*
[3]*Queen Mary University of London, Experimental Molecolar Haem Oncology, London, UK*

Study question: Can pathways involved in Endometriosis be targeted for non-invasive therapy for the disease?
Summary answer: Galectin-3 inhibitor is a potential novel targeted future therapeutic in endometriosis. These compounds are already in clinical use as potent inhibitor of blood malignancies treatments.
What is known already: Galectin-3 is overexpressed in Endometriosis. Galectin-3 antagonists are potent inhibitor of blood malignancies, reducing mcl-1 and bcl-x_L whilst inducing noxa, upregulates p21, downregulates cyclin D1, and interrupts NFκB and akt signalling. It has no myelotoxicity and an acceptable toxicity profile, increasing the evidence of the potential use of a galectin-3 inhibitor as a novel therapeutic medication for women in their reproductive age, with Endometriosis.
Study design, size, duration: Initial TMAs on 200 endometriosis samples, in a prospective study, confirmed upregulation of Galectins and CyclinD1 levels. *In vitro* therapeutic experiments were carried out on primary ovarian and peritoneal endometriosis cells as well as normal uterine endometrial cells (96 well plate cultures) to assess for cellular response to Galectin-3 inhibitors in endometriosis and normal cells at varying concentrations of drug.
Participants/materials, setting, methods: Primary ovarian, peritoneal endometriosis and normal endometrial cellular samples were cultured in 96 well plates from a pooled cohort of otherwise healthy women (30.75 years) undergoing laparoscopic examination. Cultured cells were treated with the galectin-3 inhibitor at specified concentrations *in vitro*. Cellular viability response was observed using a fluorescence well plate reader. Fluorescence outputs for each well were assessed for cellular viability and compared between treated and untreated cells at various concentrations and across timelines.
Main results and the role of chance: Increased levels of Galectin-3 and Cyclin D1 in endometriosis tissues were confirmed with Tissue Microarrays on a set of 200 histologically confirmed endometriosis samples.

Ovarian endometriosis, peritoneal endometriosis and normal endometrial uterine cells were placed separately into 96 well plates for therapeutic studies. The drug at a specified concentration was added to each well containing viable cells in culture. Each therapeutic experiment was run in triplicate to strengthen result validity. At 72 h post treatment with Galectin-3 inhibitor there was an observed direct dose dependant relationship between treated endometriosis cells and percentage cell survival. The binding of Galectin-3 has shown a role in anti-apoptosis, anti-angiogenesis and inhibited cellular migration. Untreated cells maintained viability supporting this Galectin inhibitor as a potential targeted future non-invasive therapeutic in endometriosis.
Limitations, reasons for caution: Further *in vivo* modelling is required. The Galectin-3 inhibitor tested is however already in use clinically in CLL patients for the treatment of malignancy. Its safety profile in humans in known and the profile suggests it could be safe for use in young women of reproductive age.
Wider implications of the findings: Unlike current suppressive medical treatments, or invasive surgical techniques, the use of a therapeutic that directly inhibits endometriosis proliferation will potentially provide a cure for this progressively debilitating disease in young women.
Trial registration number: Ethical approved research and study (Ethics reference REC 10/H0711/24).

P-326 The menstrual phase independent proteome of the endometrium of women with endometriosis is distinctly different from women without – results from quantitative proteomic analysis

M. Hamdan[1,2,3], A. Manousopoulou[4], S. Garbis[4], Y. Cheong[1,2]
[1]*University of Southampton, Human Development and Health, Southampton, UK*
[2]*Complete Fertility Centre, Obstetrics and Gynaecology, Southampton, UK*
[3]*University of Malaya, Obstetrics and Gynaecology, Southampton, UK*
[4]*University of Southampton, Proteomic Unit, Institute of Life Sciences, Southampton, UK*

Study question: 1) Is the proteome of the endometrium of women with endometriosis different from those without endometriosis? 2) Are the differences menstrual phase independent?
Summary answer: Proteomic profiling of the endometrium from women with and without endometriosis has uncovered novel distinctly differentially up and down regulated proteins as potential candidate biomarkers.
What is known already: A number of studies have analysed the proteome of the endometrium of women with endometriosis ($n = 15$). However, due to methodological variation, studies have not managed to achieve consensus on their results. The inconsistencies were due to utilisation of techniques that 1) have high variability and 2) identify proteins at a low dynamic range.
Study design, size, duration: Sixteen endometrial samples [endometriosis (EN), $n = 8$; control (CN), $n = 8$] were collected between September 2013 and September 2015. There was no significant difference ($P > 0.05$) in age ($P = 0.829$, EN, 33.1 ± 4.35; CN, 32.5 ± 6.63), body mass index ($P = 0.88$, EN, 25.4 ± 4.60; CN, 25.7 ± 4.17) and baseline FSH [$P = 0.51$, EN, 6.9 ± 1.90; CN, 7.5 ± 1.83) between the two groups.
Participants/materials, setting, methods: Endometrial tissue was homogenised, proteins extracted and then reduced, alkylated and trypsin proteolysed. Peptides were iTRAQ labeled and analysed using 2D LC-MS proteomics.
Main results and the role of chance: Nearly 10,000 proteins were profiled from each of the two datasets in this study. Between the two analyses, 210 and 235 proteins were commonly up and down regulated respectively. The highly up regulated proteins were Liver carboxylesterase-1 (CES1) was significantly up regulated ($Log_2Ratio = 0.5$), Homeobox protein-B6 (HOXB6, $Log_2Ratio = 0.5$), Synaptotagmin-like protein 1 (SYTL-1, $Log_2Ratio = 0.4$), Tumour associated signal transducer 2 (TACSTD2, $Log_2Ratio = 0.5$), Microsomal Glutathione S-transferase 2 (MGST2, $Log_2Ratio = 0.5$) and Cluster Differentiation 99 (CD99, $Log_2Ratio = 0.5$). Adiponectin (ADIPOQ, $Log_2Ratio = –0.6$) was significantly down regulated across both datasets. Bioinformatics interpretation showed that phagocytosis of cells ($p = 0.0013$; activation z-score = –2.2) and migration of macrophages was predicted to be inhibited ($p = 0.01$; activation z-score = –2.0) in the endometrium from patients with endometriosis compared to controls.
Limitations, reasons for caution: The number of sample used for this study is small but sufficient for a biomarker discovery phase. Although the sample were thoroughly washed and cleaned during tissue procurement, there is always a possibility of contamination with blood that will interfere with the protein analysis.
Wider implications of the findings: Without the exclusion of low abundance proteins, our study has uncovered novel non-hormonally related proteins in the endometrium of women with endometriosis. Further verification and validation will be required using larger sample size using ELISA or immunohistochemistry.
Trial registration number: Nil.

P-327 Follicular fluid (FF) of infertile women with endometriosis causes poor oocyte maturation by inducing higher reactive oxygen species (ROS) and DNA damage in mouse oocytes

S. Lane[1], M. Hamdan[2,3,4], K. Jones[1], Y. Cheong[2,4]
[1]*University of Southampton, Centre of Biological Sciences, Southampton, UK*
[2]*University of Southampton, Human Development and Health, Southampton, UK*
[3]*University of Malaya, Department of Obstetrics and Gynaecology, Kuala Lumpur, Malaysia*
[4]*Complete Fertility Centre, Infertility Unit, Southampton, UK*

Study question: What are the factors affecting poor oocyte yield in women with endometriosis? Can FF cause poor oocyte maturation rate in endometriosis women and how does FF cause oocyte maturation arrest?
Summary answer: IFF from women with endometriosis causes increased metaphase I arrest but is reversible by inhibitors of oxidative stress, the DDR pathway or the SAC.
What is known already: FF contains factors that contribute to a healthy environment for oocyte maturation process within a developing follicle. Abnormal FF can affect the maturation process and cause poor oocyte yield in women with endometriosis when undergoing IVF/ICSI. This can lead to poor reproductive outcomes. In bovine oocyte, FF of women with endometriosis causes maturation arrest but the mechanism underlying the arrest is unknown. Higher Reactive oxygen species (ROS) in endometriosis may cause DNA damage and affect oocyte maturation process.
Study design, size, duration: FF from follicles containing mature oocytes were obtained from 16 infertile women between January and December 2014 during oocyte retrieval. Immature mouse oocytes were incubated without FF (No-FF), with control FF (Ct-FF) from patients with no endometriosis, or with FF from patients with mild (ME-FF) and severe (SE-FF) endometriosis.
Participants/materials, setting, methods: *In Vitro* maturation was performed using FF and maturation media in 1:1 ratio with and without time-lapse imaging. Oocytes were fixed and immunostained for visualisation of chromosomes, spindles, DNA damage and PBE after 14–16 h.
Main results and the role of chance: 1,668 immature mouse oocytes were incubated for 14–16 h in media with 15% or 50% FF. At 15%, 92/167 (55.1%) oocytes extruded a polar body in SE-FF group and was significantly lower compared to No-FF (132/190, 69.5%, $P = 0.001$, 95%CI) and Ct-FF (88/132, 66.7%, $P = 0.0442$, 95%CI). More marked effect demonstrated at 50% SE-FF (150/309, 48.5%) when compared to media with No-FF or with Ct-FF (No-FF, 216/286, 75.5%, $P < 0.0001$; Ct-FF, 172/242, 68.4%, $P = 0.0001$, 95% CI, Fisher's exact test]. There was delayed onset of PBE timing ($P > 0.05$) and arrested oocytes were mainly ($P = 0.008$) at Metaphase I without any evidence of abnormal spindle morphology or incorrect spindle attachment ($P > 0.05$). There was an increase intracellular ROS uptake in SE-FF group compared to No-FF ($P < 0.0001$, MD 0.81 [0.41 to 1.21] 95%CI; Ct-FF, $P = 0 < 0.0001$, MD –1.01 [–1.38 to –0.64] 95%CI) and higher level of DNA damage one-hour incubation with FF from women with endometriosis compared to (No-FF $P < 0.0001$, MD 0.9 [0.49 to 1.32] 95%CI; MF-FF, $P = 0.023$, MD –0.45 [–0.88 to –0.03] 95%CI) after exposure to SE-FF. Maturation rate reverted to normal ($P > 0.05$ vs. Control) when inhibitors to Spindle Assembly checkpoint (SAC), DNA damage response (DDR) or ROS were added in the media containing SE-FF.
Limitations, reasons for caution: This study is using animal models and may not necessarily be extrapolated to humans.
Wider implications of the findings: This study has shown that the decrease number of oocyte retrieved in women with endometriosis is related to the metaphase I arrest but a reverseable process. This has important clinical implications on *in vivo* and *in vitro* therapeutic interventions that may potentially improve the reproductive outcome of those with endometriosis.
Trial registration number: REC13/SC/0213.

P-328 Serum 17-alpha-hydroxyprogesterone (Sr. 17-α-OHP) level on day of blastocyst transfer: a discerning indicator of endometrial receptivity and successful implantation in IVF cycles?

B.N. Chimote[1], N. Nath[2], N. Chimote[3], A. Chimote[4], N. Chimote[1]
[1]*Vaunshdhara Clinic & Assisted Conception Centre, Embryology & Reproductive Endocrinology, Nagpur, India*
[2]*Vaunshdhara Clinic & Assisted Conception Centre, Biochemistry, Nagpur, India*
[3]*Vaunshdhara Clinic & Assisted Conception Centre, Embryology, Nagpur, India*
[4]*Vaunshdhara Clinic & Assisted Conception Centre, Gynecology, Nagpur, India*

Study question: To evaluate serum 17-α-OHP level on day of blastocyst transfer and explore its feasibility as a compelling marker of endometrial receptivity compared to endometrial thickness in IVF cycles.
Summary answer: Serum level of 17-alpha-hydroxyprogesterone (17-α-OHP) on day of blastocyst transfer is a pertinent indicator of enhanced endometrial response favorable for implantation in IVF cycles.
What is known already: Inadequate uterine receptivity is responsible for approximately two-thirds of implantation failures. Sonography, hysteroscopy, endometrial biopsy are considered the anatomical and functional markers of endometrial receptivity. An earlier study had reported significance of transvaginal ultra-sonographic evaluation of endometrial thickness on pregnancy rates. However, since the ovarian steroid dependent process of human embryo implantation occurs during a stringent window period; analysis of molecular mediators involved at the embryo-uterine junction during this phase may

give better insight into the functional assessment of endometrial receptivity. Although, endometrial biopsy samples are being evaluated, nevertheless, an in-cycle online marker of receptivity and implantation is still elusive.
Study design, size, duration: Prospective clinical study without randomization of 111 IVF cycles in women (mean age 30.86 ± 3.98 years) undergoing standard ovarian stimulation protocol with antagonist. Study was carried out from April 2014 to March 2015 at our IVF centre. All cycles involved day 5 blastocyst transfer. Serum 17-α-OHP levels were measured by radioimmunoassay on day of blastocyst transfer (dBT). Main outcome measure was Embryo Implantation Rate (EIR = total number of embryo sacs observed/total number of blastocycts transferred x 100).
Participants/materials, setting, methods: Luteal phase was supported with micronized Progesterone injection. βhCG >50 mIU/ml on day 14 post transfer was considered as positive indicator of implantation. Gestational sac with positive cardiac activity confirmed clinical pregnancy. Cycles were divided into Implantation success vs. Implantation failure depending on whether conception occurred or not and into Low and High dBT 17-α-OHP groups depending on median value of dBT 17-α-OHP levels. Statistical analysis was done using Graph-pad prism V software.
Main results and the role of chance: Overall clinical pregnancy rate was 28.83% (32/111) and embryo implantation rate was 20.32% (38 implantations/total 187 blastocysts transferred). Implantation/Conception success cycles ($n = 32$) showed significantly higher levels of 17-α-OHP on dBT compared to No-Implantation/Non-conception cycles ($n = 79$) {10 ng/ml vs. 7 ng/ml, $\chi 2$ $p = 0.01$}. Embryo implantation rates were significantly higher in the high (≥7.88 ng/ml, $n = 53$) dBT 17-α-OHP group compared to low (<7.88 ng/ml, $n = 58$) dBT 17-α-OHP group {31% vs. 11%, $\chi 2$ $p = 0.0058$}. 17-α-OHP levels on dBT correlated significantly with implantation (Spearman $r = 0.32$). Implantation failure occurred in 97.92% of cases in low group compared to 49.06% in the High dBT 17-α-OHP group giving an odds ratio and relative risk of no implantation as 4.44 and 1.65 ($p = 0.0004$) respectively. Conversely, the odds ratio and relative risk in favour of implantation in the High group was 4.44 and 2.69 respectively ($p = 0.0004$). Incidentally, endometrial thickness did not differ significantly between the low and high dBT 17-α-OHP groups (1.11 vs. 1.08 cm, $p = 0.46$) so also in the implantation success vs. implantation failure cycles (1.11 vs. 1.09 cm, $p = 0.64$). Understandably therefore, dBT endometrial thickness correlated very poorly with implantation (Spearman $r = 0.076$, $p = 0.44$). 17-alpha-Hydroxyprogesterone is thus a more convincing indicator of implantation and endometrial receptivity in ongoing IVF cycles.
Limitations, reasons for caution: Larger multicentric studies are required to establish 17-alpha-hydroxyprogesterone as a robust biomarker of implantation and endometrial receptivity.
Wider implications of the findings: Progesterone secreted by corpus-luteum gets converted to 17-α-OHP which in turn may lead to formation of estrogens required for development of secretary endometrium rendering it receptive for implantation. Measurement of dBT 17-α-OHP level may facilitate our clinical decision on whether to transfer embryo in same cycle or subsequent favourable cycle.
Trial registration number: Not Applicable.

P-329 Additional benefit of fibrin sealant patch in preservation of ovarian reserve during laparoscopic ovarian cystectomy

N. Aiello[1], U. Leone Roberti Maggiore[1], F. Laraud[1], C. Bondi[1], E. Tafi[1], A. Racca[1], P.L. Venturini[1], S. Ferrero[1]
[1]IRCCS AOU San Martino – IST, Academic Unit of Obstetrics and Gynecology, Genoa, Italy

Study question: Is additional hemostasis by hemostatic fibrin sealant patch (FSP) superior to that achieved by bipolar coagulation (BC) only in preserving ovarian reserve in patients undergoing laparoscopic ovarian cystectomy?
Summary answer: In women with bilateral endometriomas, post-operative anti-Müllerian hormone (AMH) levels, was less diminished when ovarian hemostasis was obtained combining FSP and BC versus BC only.
What is known already: There is a consensus that surgical excision of ovarian endometriomas may damage ovarian reserve. The methods used to obtain the hemostasis after stripping of endometriomas might influence ovarian reserve.
Study design, size, duration: This study was based on a retrospective analysis of a prospectively collected database of patients who underwent laparoscopic stripping of unilateral (UE; $n = 30$) or bilateral endometriomas (BE; $n = 20$). After surgical excision of endometriomas, hemostasis was obtained either by BC or by minimal BC plus the application of FSP (Tachosil, Takeda, Rome, Italy) according to surgeons' preference.
Participants/materials, setting, methods: This study included women undergoing laparoscopic stripping of unilateral or bilateral endometriomas with largest diameter ≥4 cm. Exclusion criteria were: age ≥40 years, previous surgery on the ovaries or for endometriosis, previous oophorectomy. Ovarian reserve was assessed before surgery and at 6 months from surgery by measuring antral follicle count (AFC) and serum AMH. The prevalence of ovarian adhesions was assessed by ultrasonography at 6 months from surgery.
Main results and the role of chance: The mean age of the study population was 32.5 (±3.6) years. Both in patients with UE and in those with BE, the baseline AFC ($p = 0.773$ and $p = 0.764$, respectively) and the AMH levels ($p = 0.941$ and $p = 0.824$, respectively) were similar the two treatment groups. In patients with UE, the AFC of the operated ovary did not change after surgery both in patients treated by BC ($p = 0.419$) and in those treated by FSP ($p = 0.659$); at 3-month follow-up, the AFC of the operated ovary was similar between the two treatment groups ($p = 0.814$) and also AMH levels did not differ (0.548). In patients with BE, the total AFC did not change after surgery both in patients treated by BC ($p = 0.398$) and in those treated by FSP ($p = 0.840$), while a significant reduction in AMH levels was observed in both in patients treated by BC ($p = 0.002$) and in those treated by FSP ($p < 0.001$); at 3-month follow-up, the total AFC was similar between the two treatment groups ($p = 0.444$), while AMH levels were significantly higher in patients treated by FSP versus BE (0.031). In addition, the use of FSP did not increase the prevalence of postoperative adhesions both in patients with UE ($p = 0.337$) than in those with BE ($p = 0.110$).
Limitations, reasons for caution: The main limitation of the current study is the retrospective design. Another important limitation of this research is the small sample size.
Wider implications of the findings: In women undergoing surgical excision of bilateral endometriomas, the use of FSP provides a potential additional benefit in the preservation of ovarian reserve. Future studies in larger population of patients should confirm these preliminary results.
Trial registration number: Not applicable.

P-330 The relation between spontaneous hemoperitoneum in pregnancy (SHiP) and endometriosis – data from a nationwide Dutch consorted action

M. Lier[1], J.H. van Waesberghe[2], J. Maas[3], D. van Rumpt – van de Geest[4], S. Coppus[5], J. Berger[6], B. van Rijn[7], P. Janssen[8], T. Schaap[9], M. de Boer[10], J. de Vries[10], F.W. Jansen[11], I. Brosens[12], C. Lambalk[1], V. Mijatovic[1]

[12]Catholic University Leuven, Leuven Institute for Fertility and Embryology, Leuven, Belgium

Study question: What can we learn from the largest case series of SHiP (Spontaneous Hemoperitoneum in Pregnancy), especially when SHiP is related to endometriosis?

Summary answer: Clinicians should be aware of SHiP when pregnant women with a history of endometriosis present with severe abdominal pain, hypovolemic shock or fetal distress.

What is known already: Spontaneous Hemoperitoneum in Pregnancy is a rare, but potentially life-threatening complication, which occurs predominantly during the third trimester of pregnancy. SHiP is associated with adverse pregnancy outcome for both mother and child. The etiology is largely unknown, but endometriosis is the major risk factor for SHiP. Since pregnancies in endometriosis patients are more often facilitated by assisted reproductive techniques, the incidence of SHiP may increase. Therefore, a greater awareness of adverse pregnancy outcomes in these women is essential.

Study design, size, duration: In collaboration with the members of the Dutch Working Group on Endometriosis we identified unpublished unique cases of SHiP that occurred in the Netherlands in the period 2008–2015. The data are retrieved from the original patient files. For this case series, no approval of the institutional review board was required. Patients' written consent to publish was obtained in all cases.

Participants/materials, setting, methods: The risk of excessive bleeding from pelvic endometriosis during pregnancy is presented by 15 events of SHiP in 11 women diagnosed with endometriosis. Recurrence of SHiP, present in four of these cases, is a novel finding in the literature.

Main results and the role of chance: SHiP occurred predominantly in the second ($n = 4$) and third trimester of pregnancy ($n = 5$), but also in the first trimester ($n = 1$), during labor ($n = 3$) or several weeks postpartum ($n = 2$). In four cases recurrence of SHiP was described, in one of these cases the second event of SHiP occurred in a consecutive pregnancy. The earliest and major presenting symptom was an acute onset of abdominal pain, often combined with a fall in hemoglobin level. Ultrasound examination or MRI was helpful in observing free peritoneal fluid in ten cases. When recurrences of SHiP are counted separately, midline laparotomy was performed in nine episodes of SHiP, of which four were converted from a laparoscopy. Pfannenstiel laparotomy was performed in four cases. Two cases did not require immediate intervention and expectant management was chosen. The necessity of surgical interventions ($n = 13$) in pregnancy ($n = 11$) were due to maternal indications ($n = 7$), fetal indications ($n = 2$) or both ($n = 2$). No maternal or perinatal mortality was reported, despite the urgency of a cesarean section at preterm age (27–34 weeks gestation, $n = 5$). In ten cases endometriosis was causal in the pathogenesis of SHiP. However, in the remaining case endometriosis was confirmed several years later.

Limitations, reasons for caution: Since the exact prevalence of SHiP is unclear, a nationwide registration network is warranted in order to record cases of SHiP in a prospective way. This network (NethOSS) is currently set up and will allow us to give an exact incidence number for the Dutch population.

Wider implications of the findings: This case-series shows that awareness and adequate multidisciplinary intervention results in absent maternal and perinatal mortality, although a high percentage of preterm births remains. In order to further improve the outcome, growing knowledge of this serious complication is advocated. Appropriate counseling should be considered when these women want to conceive.

Trial registration number: Not applicable.

P-331 Impaired endometrial receptivity is the possible cause of infertility in women with genital tuberculosis – retrospective analysis of 689 patients with tubal infertility undergoing IVF

S. Sharma[1], M. Chetani[1], I. Saha[1], G. Bose[1], P. Chakraborty[1], E. Subramani[2], S. Kundu Nag[1], B.N. Chakravarty[1]
[1]*Institute of Reproductive Medicine, IVF, Calcutta, India*
[2]*IIT Kharagpur, SMST, Kharagpur, India*

Study question: What is the leading cause of infertility in women with genital tuberculosis (GTB)- tubes or the endometrium?

Summary answer: Endometrium is probably the main cause of infertility in GTB.

What is known already: GTB invariably affects the fallopian tubes and endometrial involvement is noted only in about 50% of the cases. It results in infertility by affecting the tubes (tubal obstruction and dysfunction), reducing implantation, forming uterine synechia and least commonly due to ovulatory failure. Successful pregnancy is very low even after complete treatment in GTB. *In-vitro* fertilization (IVF) remains the most successful treatment modality in these women. As GTB impairs implantation by reducing endometrial receptivity markers, there is a low pregnancy rate even after IVF.

Study design, size, duration: Retrospective analysis of case records of infertile women with tubal factor infertility registered for IVF at our tertiary hospital and reproductive health research unit between November 2011 and January 2015. 689 patients between the ages of 25 and 40 with tubal factor infertility (excluding endometriosis) undergoing first IVF cycle were analyzed. Tubercular tubal infertility (GTB group) and non tubercular tubal factor infertility (NTB group) was found in 277 patients 412 patients respectively.

Participants/materials, setting, methods: 246 patients in GTB and 398 in NTB group who completed their IVF cycle were evaluated. Endometrium of 88 patients who failed to conceive following IVF cycle but had either miscarriage or recurrent implantation failure in the past was collected and analyzed. Endometrial receptivity including αvβ3 integrin, E-cadherin, MECA-79, mucin-1, pinopodes and leukemia inhibitory factor (LIF)/LIF receptor- signal transducers and activators of transcription 3 (STAT3) expressed in the endometrium were analyzed and compared with fertile group.

Main results and the role of chance: Analyzing past obstetric history, we noted a higher miscarriage rate in women with GTB (50/246) while occurrence of ectopic pregnancy (23/398) was more common in NTB group. In 31 patients of GTB group embryo transfer was cancelled, of which 16 cycles were due to thin endometrium (<6 mm). Cycle characteristics were comparable in both groups in terms of demographic profile, dose of gonadotropin, number of oocytes retrieved, number of embryos formed but endometrial thickness was significantly lower in GTB than NTB group (9.5 ± 2.09 vs. 10.08 ± 1.5; $p < 0.0001$). Doppler indices like end diastolic velocity ($p < 0.05$) was significantly less and systiolic/diastolic ratio ($p < 0.0001$) significantly higher in GTB group. Pregnancy rate was significantly lower in GTB group than NTB (17.07 vs. 35.67; $p < 0.0001$). Live birth rate was significantly lower (5.28% vs. 24.62%; $p < 0.0001$) but biochemical pregnancy (7.72% vs. 2.26%; $p < 0.0013$) was significantly higher in GTB group in comparison to NTB group. Significantly reduced levels of endometrial receptivity markers LIF/LIF receptor, and STAT3 signaling pathway were observed in endometrium of women who underwent endometrial sampling in comparison to fertile control. *In vitro* studies confirmed our findings demonstrating that 65 kDa mycobacterial heat shock protein (HSP65) reduced decidualization of human endometrial stromal cells (hESC) significantly via decreased LIF-STAT3 signaling.

Limitations, reasons for caution: This is a retrospective study and we didn't compare the endometrial receptivity markers between NTB and fertile group. Furthermore, various other cytokines and related receptor-mediated signaling pathways were not evaluated in the present study.

Wider implications of the findings: Past miscarriage history, increased chances of biochemical pregnancy and low live birth rate after IVF in GTB group suggests possible role of endometrial affliction in GTB. Further prospective trials are needed to fully understand the cause of implantation failure in patients with genital tuberculosis patients.

Trial registration number: Not applicable.

P-332 Meta-analysis of endometrial receptivity-associated genes

S. Altmäe[1], U. Võsa[2], M. Suhorutšenko[1], L. Aghajanova[3], P. Adler[4], L. Giudice[3], C. Simón[5], A. Salumets[1]
[1]*Competence Centre on Health Technologies, Competence Centre on Health Technologies, Tartu, Estonia*
[2]*Molecular and Cell Biology, University of Tartu, Biotechnology, Tartu, Estonia*
[3]*University of California San Francisco, Obstetrics, Gynaecology and Reproductive Sciences, San Francisco, CA, USA*
[4]*University of Tartu, Institute of Computer Science, Tartu, Estonia*
[5]*Obstetrics and Gynaecology, Valencia University, Igenomix & Fundación IVI, Valencia, Spain*

Study question: To identify the meta-signature and putative biomarkers of receptive endometrium.

Summary answer: Using a novel meta-analysis approach, we identified a meta-signature of receptive endometrium involving 57 genes.

What is known already: Previous microarray-based transcriptome studies of the endometrium have revealed hundreds of simultaneously up- and down-regulated genes that are involved in endometrial receptivity. However, the overlap between the studies is relatively small, and we are still searching for

potential diagnostic biomarkers. Numerous limitations of microarray technology together with differences in study design have made it difficult to perform a meta-analysis that would identify potential biomarkers with sufficient power and reliability/credibility.
Study design, size, duration: We performed a systematic review and meta-analysis of transcriptome studies on pre-receptive- and receptive-phase endometria from healthy fertile women.
Participants/materials, setting, methods: A systematic review of the literature was conducted up to October 2015 in PubMed and Scopus databases. Of the final 14 eligible studies, nine were included in the meta-analysis. The pooled dataset obtained represented 164 endometrial samples – 76 from pre-receptive- and 88 from receptive-phase endometria. The up- and down-regulated genes were ranked by their fold changes. A robust rank aggregation (RRA) algorithm was used for meta-analysis of the gene lists, followed by enrichment analysis.
Main results and the role of chance: We identified a meta-signature of endometrial receptivity involving 57 genes as putative receptivity markers, including *ANXA4*, *APOD*, *CD55*, *CLDN4*, *COMP*, *DPP4*, *EDN3*, *GADD45A*, *GPX3*, *HABP2*, *IGFBP1*, *IL15*, *MAOA*, *MMP7*, *PAEP*, *SLC1A1*, *SPP1* and *S100P*. The meta-signature genes highlight the importance of immune responses, the complement cascade pathway and the involvement of extracellular vesicles in mid-secretory endometrial function.
Limitations, reasons for caution: Because of the limited number of gene lists in the meta-analysis, the RRA results are likely to be influenced by sampling bias and depend heavily on each dataset used in the analysis.
Wider implications of the findings: The identified meta-signature genes and pathways could serve as promising and sought-after biomarkers of endometrial receptivity and pregnancy establishment, and also markers of uterine pathologies.
Trial registration number: 0.

P-333 Epigenetic analysis of aromatase coding gene, CYP19A1, in endometrial tissue of women with endometriosis during menstrual cycle

E. Khateri[1], M. Shahhoseini[1], R. Favaedi[1], P. Afsharian[1], R. Aflatoonian[2]
[1]*Department of Genetics, Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Iran*
[2]*Department of Endocrinology and Female Infertility, Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Iran*

Study question: Is there any correlation between altered expression of *CYP19A1* gene with epigenetic changes on its promoter region, in endometrium and endometriotic lesions of women with endometriosis?
Summary answer: Hyper-acetylation and hypo-methylation of *CYP19A1* regulatory regions are in correlation with increased level of aromatase gene expression, which may contribute to the progression of endometriosis.
What is known already: Epigenetic aberrations such as DNA methylation and histone modifications appear to be involved in various diseases such as endometriosis. Endometriosis is defined as the presence of endometrium like tissue outside of uterine. It is proofed that endometriosis is an estrogen dependent disease and one of the key enzymes in estrogen biosynthesis is aromatase. Aromatase encoded by the gene *CYP19A1,* has 10 tissue specific promoters on its regulatory region. Here, we investigated epigenetic alteration of **PII and PI.3** promoters of *CYP19A1* and its correlation with mRNA expression during menstrual cycle.
Study design, size, duration: This is a case-control laboratory study in which, ectopic lesions and eutopic endometrium samples were collected by laparoscopy from 20 women with documented endometriosis. As a control group, endometrial tissues were collected from 20 healthy fertile women who underwent laparoscopy for tubal ligation surgery during menstrual cycle. Informed consent was collected from each participant.
Participants/materials, setting, methods: Relative expression analysis of *CYP19A1* was evaluated by quantitative real-time PCR. The DNA binding of MeCP2 and specific histone modifications in **PII and PI.3** promoters region of *CYP19A1* gene were examined by chromatin immunoprecipitation (ChIP) technique.
Main results and the role of chance: Expression profile of *CYP19A1* gene revealed significant increase ($p < 0.05$) in mRNA level in ectopic lesion and eutopic endometrium in patients *vs.* control group, during menstrual cycle. In endometriosis patients, incorporation of MeCP2 in promoter **PII** of *CYP19A1* was significantly lower than control group ($p < 0.05$), which showed a harmonious pattern between mRNA expression of *CYP19A1* and methylation level of its promoter region (PII). Significant hyperacetylation of lysine 9 of histone 3 (H3K9ac) of promoters **PII** and **PI.3** observed in patients affected endometriosis ($p < 0.05$). Furthermore, significant methylation level at lysine 9 of histone 3 (H3K9me2) of promoter **PI.3** was detected between patients and control group ($p < 0.05$), whereas no significant difference of methylation was detected in **PII** promoter.
Limitations, reasons for caution: For getting more information we need to investigate large number of endometriosis patients and control group, and also evaluate epigenetic alterations of *CYP19A1* in other promoters of this gene.
Wider implications of the findings: Our results showed that high expression of *CYP19A1* in patients with endometriosis might be due to epigenetic alterations through regulatory region of *CYP19A1,* either through DNA methylation or histone modification. Also, results showed probable epigenetic switch between PII and pI.3 promoters of *CYP19A1* gene in endometriosis patients.
Trial registration number: NA.

P-334 Collagen for sustained release of growth factors for treating patients with poorly developed thin endometrium

C. Kim[1], C. Kim[1], J.H. Lee[1], J.W. Moon[1], B.M. Kang[1], J.H. Ko[2], S.N. Park[2]
[1]*Division of Reproductive Endocrinology and Infertility, Department of Obstetrics and Gynecology, College of Medicine, University of Ulsan, Asan Medical Center, Seoul, Korea*
[2]*Regenerative Medicine Research Center, Dalimtissen Co., Ltd., Seoul, Korea*

Study question: Does collagen enable sustained release of growth factors and improve their treatment effect on poorly developed thin endometrium of infertile women?
Summary answer: Collagen enables sustained release of epidermal growth factor (EGF) and improves the treatment effect of EGF on poorly developed thin endometrium of infertile women.
What is known already: Although several treatment modalities have been offered to patients with thin endometrium, treatment for them is still challenging. Several growth factors and cytokines are required for proper preparation of the endometrium. Granulocyte colony-stimulating factor (G-CSF) and EGF have been shown to cure patients with thin endometrium. However, study on sustained release of growth factors for treating patients with thin endometrium has not been reported.
Study design, size, duration: *In vitro* release test of EGF and granulocyte-macrophage colony-stimulating factor (GM-CSF) was performed. In addition, we analyzed the results of a total of 66 consecutive infertile women with thin endometrium <6 mm despite estradiol treatment who underwent intrauterine treatment with either EGF-loaded collagen solution (study group, $n = 37$) or EGF alone solution (control group, $n = 29$) between March 2014 and November 2015 for this retrospective study.
Participants/materials, setting, methods: For *in vitro* release test, 0.8% collagen gel was mixed with EGF or GM-CSF solution in phosphate buffered saline (PBS). The growth factor-loaded gels were incubated in PBS at 37 °C and supernatant was taken at 4, 8, 24, 48 and 72 h after mixture. In the study group, slow intrauterine infusion of 0.8% collagen in which 50 ng/ml EGF was loaded was performed every 2–3 days during the follicular phase of 3–4 menstrual cycles.
Main results and the role of chance: Percentages of released EGF and GM-CSF from 0.8% collagen gel at 24 h after mixture were 58.5 ± 3.7 and 51.9 ± 2.3%. Percentages of released growth factors at 72 h was significantly higher in EGF of 83.5 4.8% compared with 58.3 ± 3.0% in GM-CSF loading ($p < 0.001$). Endometrial thickness after EGF treatment compared with before treatment significantly increased in both study and control groups ($p < 0.001$, $p < 0.01$, respectively). When study and control groups were compared after treatment, endometrial thickness was significantly higher in the study group ($p = 0.002$) and resistance index (RI) of subendometrial artery (SEA) was significantly lower in the study group ($p < 0.001$).
Limitations, reasons for caution: Compared with EGF, released amount of GM-CSF from collagen gel was much smaller. In addition, our study may have a limitation to evaluate the effect of EGF-loaded collagen solution on thin endometrium due to a small number of sample available and retrospective nature.
Wider implications of the findings: This is the first study to evaluate the effect of collagen on sustained release of growth hormones for intrauterine treatment

of thin endometrium. This new treatment regimen may have a new therapeutic potential for infertile women with poorly developed thin endometrium.
Trial registration number: No.

P-335 Establishment of a new 3D model to investigate the embryo-maternal interface

D.M. Baston-Büst[1], S.J. Böddeker[1], J.S. Krüssel[1], A. Bielfeld[1]
[1]*Medical Center University of Düsseldorf, Department of OB/GYN and REI UniKiD, Düsseldorf, Germany*

Study question: Can a 3D model of the embryo-maternal interface be established that resembles the *in vivo* situation better than the commonly applied 2D models?
Summary answer: We were able to establish a viable 3D two spheroid model of maternal and embryonic cells.
What is known already: Common human cell culture models of early implantation processes are mostly based upon 2D cell models of maternal cells which are incubated with embryonic spheroids or embryo secretory products so far. Further possibilities contain artificial media/groundings – for example matrigel – allowing a 3D proliferation and growth.
Study design, size, duration: Control (same cell type either maternal or embryonic) versus treatment (maternal and embryonic spheroids); 8 performances in each condition; treatment duration 0–120 h.
Participants/materials, setting, methods: 2D culture of maternal endometrial stromal cells (cell line St-T1; kind gift of Prof. Jan Brosens[1]), endometrial cells with knock-down of Syndecan-1 (KdS1[2]) and embryonic cells (HTR-8/SVneo; ATCC®CRL-3271™) for proliferation. For spheroid formation, 3×10^4 St-T1 cells and 2×10^4 HTR-8 cells were cultured in hanging droplet culture for 48 h. In order to identify maternal and embryonic cells, these were incubated either with MitoTracker® or stained with vimentin or cytokeratin 7. Immunohistochemistry and spheroid confocal laser microscopy.
Main results and the role of chance: The spheroid formation worked well and robust and was repeatable severalfold. In order to measure implantation objectively, we performed central point distance measurements between the spheroids. After 12 h of confrontation of maternal stromal and embryonic cells the distance was reduced significantly. The knock-down of Syndecan-1 resulted in a shortened, but still statistically significant converge of the different cell types.
Limitations, reasons for caution: Only *in vitro*.
Wider implications of the findings: This new model enables insight into the early embryo maternal interaction due to its unique resemblance of the *in vivo* situation compared to the established 2D models. In upcoming investigations, signaling pathways will be evaluated to reveal the cellular impact on the interaction.
Trial registration number: nn.

P-336 GnRHa induces both apoptosis and autophagy of endometriotic tissues by down-regulation of estradiol levels in women with endometriosis

Y.P. Lei[1,2], R. Endah[3], T. Chii-Ruey[1,3,4]
[1]*Taipei Medical University, Center for Reproductive Medicine and Sciences, Department of Obstetrics and Gynecology, Taipei, Taiwan R.O.C.*
[2]*National Yang-Ming University, School of Nursing, Taipei, Taiwan R.O.C.*
[3]*Taipei Medical University, Graduate Institute of Clinical Medicine, College of Medicine, Taipei, Taiwan R.O.C.*
[4]*Taipei Medical University Hospital, Center for Reproductive Medicine, Taipei, Taiwan R.O.C.*

Study question: To determine whether endometrial cell autophagy is altered by aberrant mTOR activity and is associated with apoptosis in endometriotic cysts treatment with GnRH agonist (GnRHa).
Summary answer: GnRHa simultaneously induces apoptosis by upregulating Bax/Bcl-2 Ratio and autophagy by enhancing the conversion of LC3-I to LC3-II in human endometriotic tissue.
What is known already: GnRH analogs (GnRHa) are the most widely used hormonal treatments for endometriosis. Nevertheless, the effect of GnRHa treatment on the eutopic endometrium of patients with endometriosis and the activation of apoptosis through these events remain unknown. In this study, we illustrated the effects of GnRHa in patients with endometriosis after GnRH agonist therapy to identify proteins that might provide further information concerning the mechanisms underlying the functions of GnRHa.
Study design, size, duration: A prospective controlled study in patients with stage III-IV endometriosis in a university hospital. The study group was treated with GnRHa at least 1 month before laparoscopic surgery ($n = 15$), and the control group ($n = 15$) without GnRHa treatment. Tissue specimens were collected from both groups during laparoscopic surgery. In flow cytometric analysis, we used CRL-7566 endometriosis cell line (ATCC, Manassas, VA, USA). Cells were pre-treated with estradiol (E2) before the treatment with or without GnRHa.
Participants/materials, setting, methods: The expression levels of apoptosis- (Bax/Bcl-2 ratio, p-mTOR, p-Akt and cleaved caspase 3) and autophagy-related proteins (LC3-II and Beclin-1) with or without GnRHa therapy were determined by Western blot, IHC, and flow cytometric analysis using Annexin V-FITC and PI staining. The data were expressed as the mean ± SD of 3 or more independent experiments and statistical analysis was performed using Student's *t*-test.
Main results and the role of chance: GnRHa treatment induced apoptosis via upregulation of Bax/Bcl-2 ratio ($p < 0.05$), Annexin V binding capacity and caspase-3 activation in endometriosis. In addition, cytochrome c release and caspase-3 cleavage were also demonstrated by IHC staining. GnRHa induced autophagy in endometriotic tissue was shown by a significant increase in LC3-II expression, a hallmark of autophagy. Besides, GnRHa downregulated the phosphorylation of major components of mTOR pathway, such as p-Akt at Ser473, p-mTOR and its downstream substrates p-p70S6K (p70 ribosomal protein S6 kinase) and p-S6K ($p < 0.05$). E2 is a potent inhibitor of apoptosis and it regulates the expression of several apoptotic proteins, including Bcl-2 and mTOR in endometriotic tissues. Indeed, compared with GnRHa treatment, decreased mTOR activity in endometriotic tissues *without GnRHa treatment* inhibited autophagy and apoptosis induction. The present study strongly illustates that downregulation of Bcl-2, leading to an increase in the Bax/Bcl-2 ratio and subsequent activation of caspases 3 and aberrant Akt-mTOR activity in endometriotic tissues following GnRHa treatment, may be a plausible explaination which leads to simultaneously apoptosis and autophagy of endometrial cells. Therefore, it can be postulated that altered induction of autophagy by aberrant mTOR activity is a feasible mechanism that facilitates the decreased apoptosis found in endometriotic tissues.
Limitations, reasons for caution: In this study we compared the results obtained by IHC with those obtained by Western blot analysis for profiling cellular signaling pathway. However, due to the endometriotic-derived stromal cells of patients treated with GnRHa consists of very slow growing cells, it has been difficult to analyze by flow cytometry.
Wider implications of the findings: In the present study, we first investigated the therapeutic effect of GnRHa induces the simultaneous activation of apoptosis and autophagy by modulating the Akt-mTOR signaling pathway in endometriotic tissues.
Trial registration number: TMU-JIRB 201305035.

P-337 Cytokine expression profile of *in vitro* cultured endometrial stromal and epithelial cells during the window of implantation (WOI) – a promising tool for receptivity assessment

T. Chaushev[1], D. Parvanov[1], G. Stamenov[2], B. Dzhambazov[3]
[1]*Medical Center Nadezhda Reproductive Sofia, Research, Sofia, Bulgaria*
[2]*Medical Center Nadezhda Reproductive Sofia, Obstetrics and Gynecology, Sofia, Bulgaria*
[3]*Plovdiv University "Paisii Hilendarski", Department of Developmental Biology, Plovdiv, Bulgaria*

Study question: Which cytokines are differently secreted by primary endometrial stromal and epithelial cells, cultured with and without E2 and P4, and in what quantities?
Summary answer: Significant changes in expression of IL-21, TNF-alpha, G-CSF, GM-CSF, RANTES, IL-6, HGF and IL-17A of endometrial stromal and endometrial epithelial cells were observed.
What is known already: Endometrial epithelial cells (EEC) and endometrial stromal cells (ESC) actively secrete a variety of cytokines and growth factors which is thought to be crucial for implantation in different species, including human. It is well known that EEC secrete granulocyte-macrophage

colony-stimulating factor (GM-CSF), leukemia inhibitory factor (LIF), colony stimulating factor (CSF-I) and TNF-α. ESC secrete interleukin-6 (IL-6), macrophage chemo-attractant protein-1 (MCP-1). Some growth factors and cytokines are maximally produced by EEC during the mid-secretory phase of the endometrial cycle, such as LIF, IL-11, IL-6, CSF-I, GM-CSF, CCL11, CCL14, CCL21, Glycodelin A and HB-EGF.

Study design, size, duration: In the present study, we examined the profile of 21 cytokines in (1) the conditioned media (*RPMI*-1640 supplemented with *10% FBS*) and (2) conditioned media with addition of E2 (0.1 nM) and P4 (100 mM) of primary cell cultures from human endometrial stromal cells (ESC) and epithelial cells (EEC). Endometrial cells were obtained from mid-secretory phase samples from 28 healthy women. The levels of cytokines in the culture supernatants were assayed after 48 h incubation.

Participants/materials, setting, methods: Nine cytokines (IL-4, IL-6, IL-10, IL-15, IL-17A, IL-22, TNF-alpha, IFN-gamma and GM-CSF) in the supernatants were analyzed using ELISA. Twelve cytokines [MIP-1 beta, MCP-1, VEGFA, PDGF-BB, MIG, RANTES, HGF, MMP9, EGF, G-CSF, Calcitonin and IL-12 (p70)] were analyzed by a FACS Calibur flow cytometer using FlowCytomix Multiplex Kit. Student's paired *t*-test was used to compare the changes in cytokine profile of endometrial cells cultured with and without E2 and P4.

Main results and the role of chance: Under basal conditions in the control group, endometrial stromal and epithelial cells exhibited specific profiles of secreted cytokines. Our results showed that the stromal cells secrete higher quantities of GM-CSF (ESC vs. EEC: 0.19 vs. 0.14 pg/ml), HGF (ESC vs. EEC (mean values): 2488 vs. 116 pg/ml) and significantly lower quantities of IL-6 (ESC vs. EEC: 0.18 vs. 0.28 pg/ml), IL-21 (ESC vs. EEC: 0.50 vs. 1.08 pg/ml), TNF-alpha (ESC vs. EEC: 0.19 vs. 0.39 pg/ml) and G-CSF (ESC vs. EEC: 2.75 vs. 12.38 pg/ml) in the culture medium, compared with epithelial cells. Administration of E2 and P4 resulted in significantly ($P < 0.05$) different secretion of RANTES (0.3-fold increase) and EGF (5.8-fold increase) in endometrial epithelial cells and IL-6 (1.5-fold increase), HGF (2.9-fold decrease) and IL-17A (1.3-fold decrease) in endometrial stromal cells.

Limitations, reasons for caution: A limitation of this study is the relatively low number of patients. Although the data were obtained in human primary endometrial cells, they result from *in vitro* studies. Thus, caution is needed in their translation for *in vivo* conditions. Similar analysis should be performed in patients with repeated implantation failure.

Wider implications of the findings: This study supports the importance of E2 and P4, specifically during the implantation window. Understanding the differences in levels and change in cytokine profile of *in-vitro* cultured endometrial cells could help to create a diagnostic tool for receptivity assessment and to develop treatment strategies for patients with repeated implantation failure.

Trial registration number: NA.

P-338 Endometriosis is associated with high-risk of ovarian, endometrial, cervical and thyroid cancer: a nationwide retrospective cohort study

G.L. Lai[1], C.R. Tzeng[2,3], C.C. Yeh[1,4]
[1]*Taipei Medical University, School of Public Health, Taipei, Taiwan R.O.C.*
[2]*Taipei Medical University, Department of Obstetrics and Gynecology, College of Medicine, Taipei, Taiwan R.O.C.*
[3]*Taipei Medical University and Hospital, Center for Reproductive Medicine and Sciences, Taipei, Taiwan R.O.C.*
[4]*China Medical University, Department of Public Health, College of Public health, Taichung, Taiwan R.O.C.*

Study question: Is endometriosis associated with high-risk of cancers?

Summary answer: Endometriosis is associated with increasing risk of overall cancers especially with ovarian, endometrial, cervical, and thyroid cancer.

What is known already: The relationship between cancer and endometriosis was still unclear. Many reports suggested that endometriosis associated with increased risk of gynecological cancers, especially ovarian cancer but the conclusion was still inconsistent.

Study design, size, duration: A retrospective population-based cohort study was performed by linking to National Health Insurance Research Database (NHIRD) in Taiwan. A total of 19,378 women with newly identified endometriosis from 2000 to 2008 and 96,890 multivariable-matched controls (1:5) were selected.

Participants/materials, setting, methods: Sociodemographic and other potential confounding factors were selected as adjusted variables from database. They were compared between the endometriosis and control cohort using a Chi-square test. The Cox regression model adjusted for potential confounders was used to assess the risk of cancers due to endometriosis.

Main results and the role of chance: After adjusted potential confounders, the adjusted hazard ratio associated with endometriosis was 1.64 (95% confidence interval (CI) 1.49–1.81) for overall cancers, 4.77 (95% CI 3.40–6.70) for ovarian cancer, 4.19 (95% CI 2.91–6.04) for endometrial cancer, 2.67 (95% CI 1.93–3.70) for cervical cancers, and 1.64 (95% CI 1.15–2.35) for thyroid cancers.

Limitations, reasons for caution: Endometriosis may delay diagnosis by asymptomatic that lead to estimate the latent period of endometriosis and cancer occurring hardly and overestimate hazard ratio between cancer and endometriosis.

Wider implications of the findings: Estrogen stimulation and chronic inflammation might be as putative mechanisms to endometrial cancer. Besides, estrogen receptors participate in cellular processes contributing to enhanced mitogenic, migratory, and invasive properties of thyroid cells. The investigation of association between endometriosis and cancers would advance the exploration of endometriosis etiology.

Trial registration number: IRB permit number: CMU-REC-101-012.

P-339 The impact of endometriomas on blastocyst euploidy in cases undergoing comprehensive chromosomal screening (CCS) for recurrent implantation failure (RIF)

F.K. Boynukalin[1], N. Findikli[2], M. Gultomruk[3], E.M. Bilgin[4], M. Serdarogulları[5], C. Celik[6], M. Bahceci[1]
[1]*Bahceci Fulya IVF Centre, Infertility Clinic, Istanbul, Turkey*
[2]*Bahceci Fulya IVF Centre, Embryology Laboratory, Istanbul, Turkey*
[3]*Bahceci Fulya IVF Centre, R&D Department, Istanbul, Turkey*
[4]*Bahceci Health Group, IVF Clinic, Istanbul, Turkey*
[5]*Bahceci Health Group, Embryology Laboratory, Istanbul, Turkey*
[6]*Bahceci Umut IVF Centre, Infertility Clinic, Istanbul, Turkey*

Study question: Does the presence of endometrioma have an impact on CCS results of embryos in ICSI cycles using array comparative genomic hybridization (CGH)?

Summary answer: The rate of aneuploidy in embryos detected by aCGH does not differ in patients with endometriomas. However live birth rate is lower cases with endometriomas.

What is known already: The impact of endometrioma per se on IVF/ICSI outcome has long been evaluated by numerous groups and it is still controversial. Endometriomas can be suspected to have profound effects on oocyte/embryo quality as well as certain embryo development characteristics. It is reported that endometrioma/endometriosis, can adversely affect the structural integrity of the oocyte spindle, potentially resulting in aneuploidy.

Study design, size, duration: Retrospective case-control study conducted in CCS cycles with women aged under 38 treated in Bahceci Fulya IVF Centre between January 2013 and January 2015 and includes only patients with recurrent implantation failure. Two groups of patients were selected: group A patients with endometrioma and group B patients with unexplained infertility. Each group included only the cases with trofectoderm biopsy.

Participants/materials, setting, methods: A total of 23 patients in group A were matched to 53 patients in group B representing respectively 27 and 69 oocyte pick up procedures, 16 and 42 embryo transfer. Each patient underwent a controlled ovarian hyperstimulation and ICSI with frozen embryo transfer. Primary end-point was rate of euploid embryos and secondary end points were implantation rate, clinical pregnancy rate, spontaneous abortion rate.

Main results and the role of chance: Mean age, BMI and number of previous attempts were similar in group A and B ($33.1 \pm 3.6/33.1 \pm 3.0$; $22.6 \pm 2.4/23 \pm 3.1$; $4.2 \pm 1.2/4.3 \pm 2.6$)($p < 0.05$). Number of oocytes harvested, number of MII oocytes, fertilization rates were also similar in group A and B. ($13.9 \pm 7.1/15.1 \pm 10$; $10.8 \pm 5.9/11.5 \pm 8.4$; 80.1/77.6%). There was no significant difference in the number of euploid blastocysts between group A (25/81, 30.9%) and group B (61/163, 37.4%). Implantation rates and clinical pregnancy were found to be 38.1%, 43.7% for group A and 52% and 64.2% for group B embryos respectively ($p < 0.05$). In group A LBR was significantly lower than group B (18.8% vs. 47.6%).

Limitations, reasons for caution: Data were collected retrospectively using the database of our clinic. Sample size is relatively small but our study provides statistically significance that endometriomas decreases LBRs. Further larger series are needed to confirm these findings.
Wider implications of the findings: To our knowledge, this is the first study evaluating the blastocyst euploidy rates in cases with endometriomas. The study provides statistically significance that endometriomas decreases LBRs. This result may support decreased endometrial receptivity caused by endometriosis.
Trial registration number: None.

P-340 Role of epigenetic modification and expression of HOX genes in hypersensitivity of endometriosis and novel treatment approaches

M. Golestan Jahromi[1], M. shahhoseini[2], P. Afsharian[2], R. Aflatoonian[3], M. Bazrgar[2], A. Aflatoonian[4]
[1]*Clinical and Research Center for Infertility, Yazd, Iran*
[2]*Royan Institute for Reproductive Biomedicine, ACECR, Genetics – Reproductive Biomedicine Research Center, Tehran, Iran*
[3]*Royan Institute for Reproductive Biomedicine, ACECR, Endocrinology and Female Infertility – Reproductive Biomedicine Research Center, Tehran, Iran*
[4]*Shahid Sadoghi University of Medical Scienses, Research and Clinical Center for Infertility, Yazd, Iran*

Study question: What is the cause of hypersensitivity in endometriosis and what are mechanisms of sensory nerve formation in eutopic or ectopic lesions?
Summary answer: Aberration in genes expression due to selective DNA methylation of gene involved in various aspect of sensory nerve formation, lead to pain sensation in endometriosis.
What is known already: Endometriosis is usually associated with infertility and pelvic pain such as chronic dysmenorrhea, intermenstrual abdominal and pelvic pain, back pain, dysuria and dyspareunia.

Nevertheless, no information is available on mechanisms of sensory nerve formation in eutopic or ectopic lesions. Since HOX genes have important roles in both reproductive tract and nerve growth, we decided to determine role of them in formation of new nerve fibers in endometriotic lesions.

At the other hand we designed another step as second phase of study to investigated epigenetic modification (DNA methylation) of promoter region of these genes.
Study design, size, duration: Samples obtained from fifteen patients (15 with and 15 without endometriosis) of reproductive age with normal menstrual cycles, where the same patient provided both eutopic and ectopic endometrium (endometriomas) and control samples were surgically checked for the absence of endometriosis.
Participants/materials, setting, methods: The expression profile of 84 genes of *HOX* family related to various aspects of nerve fibers formation (formation of nociceptors, dopaminergic neurons and signal transduction) was investigated using qRT-PCR array. Epigenetic modification (DNA methylation) assessed using Mecp2 antibody and qRT-PCR CHIP array technique. Informed consent was obtained from patients.

All measurements were performed in triplicates on independent biological replicates.
Main results and the role of chance: Our data showed significant over-expression of some genes which are involved in various aspect of development of sensory neurons in the tissue and signal transduction such as genes that involved in relay pain, touch and GABAergic neurons formation (VAX1, LBX1, LBX2 and PITX2), dopaminergic neurons (EN1 and PITX3), committed to a cutaneous sensory neuron fate (PAX3), chemosensory integration (PHOX2b), promote nerve formation (DRGX, EMX1, PHOX2B and OTP), various aspects of somatic motor neuron (ISL1, 2), neuronal migration (HLX) and touch/mechanosensory neurons (SHOX2) in euotopic and ectopic tissue versus control group. All of these genes have significant differences more than 30–1800 times in fold regulation between groups and *P* value for each of them is less than 0.001.

On the other hand, our data showed significant hypo-methylation of some genes which are involved in in relay pain, touch and GABAergic neurons formation (VAX1, LBX1, LBX2 and PITX2), dopaminergic neurons (EN1 and PITX3), committed to a cutaneous sensory neuron fate (PAX3), chemosensory integration (PHOX2b), promote nerve formation (DRGX, EMX1, PHOX2B and OTP), various aspects of somatic motor neuron (ISL1, 2), neuronal migration (HLX) and touch/mechanosensory neurons (SHOX2) in euotopic and ectopic tissue versus control group.
Limitations, reasons for caution: We investigated *HOX* genes expression profile in hypersensitivity of endometriosis, according to our finding; it seems that determining of another genes that may play a role in development of sensory neurons, could help to control of pain in endometriosis.
Wider implications of the findings: Due to epigenetic modification, overexpression (up to 1800 times) of some HOX family related genes that play critical roles in sensory, adrenergic and cholinergic neurons formation, lead to aberrant innervations of ectopic and euotopic tissues. therapeutic approach including novel methods (e.g., Using siRNA for gene silencing process) can be use.
Trial registration number: 13414.

P-341 Significant improvement in endometrial thickness with use of tamoxifen citrate in case with persistently thin endometrium: a retrospective study of 52 patients

S. Singh[1], S. Singh[1], N. Ashraf[1], R. Basheer[1], M. Ashraf[1]
[1]*Craft Hospital and Research Center, Reproductive Medicine, Kodungallur, India*

Study question: Does tamoxifen citrate increase endometrial thickness in women with earlier multiple cancelled embryo transfer cycles due to thin endometrium despite using estradiol valerate, pentoxifyllin, vitamin E, Sildenafil and granulocyte coloney stimulating factor ?
Summary answer: Use of tamoxifen results in significant improvement in endometrial thickness from 6.8 mm to more than 8 mm.
What is known already: Persistently thin endometrium is a very difficult entity to treat and is responsible for embryo transfer cancellation in a substantial number of women. The available modalities of treatment like high dose of estradiol valerate, sildenafil citrate, pentoxifyllin, vitamin E and granulocyte coloney stimulating factor have been useful in increasing the endometrial thickness only in few of these women. An earlier published small case series of 3 women with thin endometrium showed improvement in the thickness after using tamoxifen citrate.
Study design, size, duration: This is a historical case control study of 52 women with persistently thin endometrium with normal hysteroscopy and failed 2–3 cycle of estrogen replacement. All cases were recruited between February 2014 and November 2015. All these women had failed to achieve an adequate endometrium of 8 mm after using estradiol valerate 12 mg per day for atleast 21 days previously. In subsequent cycles, they failed to improve even with addition of above mentioned adjuvants.
Participants/materials, setting, methods: After initial failed attempt, they were given tamoxifen citrate 20 mg for 5 days from day 2 of periods. They underwent ultrasound for measuring follicle size and endometrial thickness from day 7/8 of periods. Cycles without dominant follicle were changed to estrogen replacement cycles by adding 8 mg of estradiol valerate. Ovulation day endometrial thickness was measured in case the follicular grew, or else, estradiol was continued for total of 21 days and endometrial thickness measured at repeated intervals.
Main results and the role of chance: 52 women were evaluated for 136 endometrial preparation cycles. Total 116 cycles using estradiol valerate, vaginal sidenafil citrate, oral pantoxiphylene, vitamin E and intrauterine instillation of G CSF were cancelled as mean endometrial thickness (ET) of these cycles was less than 6.8 mm. With addition of tamoxifen in the subsequent cycle, the ET showed significant improvement compared to the previous cycles. Of these, 43 women had improvement in endometrial thickness to > / = 8 mm, while for the remaining 9 women, endometrial thickness remained less than 6.9 mm. Out of these 43 women 35 women attained a mean of 9.8 mm thickness in first tamoxifen cycle while other 8 women reached mean endometrial thickness of 7.3 mm. In second tamoxifen cycle these women attained mean ET more than 8 mm. Overall, the biochemical pregnancy rate was 48% and clinical pregnancy rate was 39%.
Limitations, reasons for caution: It is a retrospective study with small sample size. The women acted as their own controls.
Wider implications of the findings: This study adds a new and potentially safer option for women with persistently thin endometrium. Further robust data in terms of large multicentric randomised controlled trials are needed to substantiate the findings since it will be difficult to get an adequately powered study in single centric study.
Trial registration number: Not applicable as it is a retrospective analysis.

P-342 Endometrial B-cell lymphoma 6 (BCL6) and Sirtuin 1 (SIRT1) Immunostaining are prognostic factors for implantation failure in the setting of ART

S.L. Young[1], J.W. Jeong[2], D.P. Schammel[3], B.A. Lessey[4]
[1]*University of North Carolina at Chapel Hill, Obstetrics & Gynecology, Chapel Hill, NC, USA*
[2]*Michigan State University School of Medicine, Obstetrics, Gynecology and Reproductive Biology, Grand Rapids, MI, USA*
[3]*Greenville Health System, Pathology Associates, Greenville, SC, USA*
[4]*Greenville Health System, Obstetrics and Gynecology, Greenville, SC, USA*

Study question: Does BCL6 immunostaining predict pregnancy rate among patients with unexplained infertility after embryo transfer?
Summary answer: BCL6 immunostaining is highly prevalent in women with unexplained infertility (UI) and a strong predictor of IVF failure.
What is known already: We recently reported BCL6 over expression as a biomarker for endometriosis in the setting of otherwise unexplained infertility (UI). Increased BCL6 immunostaining is also observed in the baboon model of endometriosis by 9 months after disease induction, while reduced post-surgical BCL6 expression is associated with improved pregnancy rates. Involvement of BCL6 in chronic endometrial inflammation is suggested by endometrial overexpression in chronic endometritis in the bovine model. BCL6 protein along with its binding partner, SIRT1, acting via hedgehog family proteins (e.g., Gli1) is a candidate mediator driving progesterone resistance and subfertility seen in patients with endometriosis.
Study design, size, duration: BCL6 and SIRT1 immunostaining of prospectively collected, mid-secretory endometrial samples was evaluated using HSCORE by a single observer, blinded to clinical information. Pregnancy outcomes were examined in 66 UI subjects undergoing an endometrial biopsy within 6 months prior to a single embryo transfer cycle. Comparison between medians utilized Mann-Whitney test and comparison of pregnancy rates utilized Fisher's exact test.
Participants/materials, setting, methods: Mid-secretory phase was defined as urine LH surge plus 6–10 days. Exclusion criteria included Age >40, BMI ≥30, use of medications known to affect reproductive hormones during the previous 3 months, known reproductive tract abnormalities, and endometrial dating >2 days discrepancy from expected histology. Immunostaining was performed using a monoclonal antibody on an automated system. The BCL6 and SIRT1 HSCORE cutoffs were based on previously reported and unpublished evaluation as endometriosis biomarkers.
Main results and the role of chance: Pregnancy occurred in 10/15 (66.7%) subjects with UI and negative BCL6 immunostaining as compared to 7/51 (13.7%) subjects with UI and positive staining ($p < 0.001$). SIRT1 staining was evaluated in a subset of subjects. Pregnancy occurred in 6/12 (50%) subjects with UI and negative SIRT1 staining as compared to 4/29 (13.8%) subjects with UI and positive staining ($p = 0.040$). Western blot immunostaining of an independent set of samples from controls and women with UI ($n = 33$) demonstrated a linear correlation coefficient of 0.653 ($p < 0.001$) and double immunofluorescence co-localized BCL6 and SIRT1 in the nuclei of women with UI, suggesting that known binding partners, BCL6 and SIRT1, may act together in an important pathway for endometrial dysfunction.

The high rates of BCL6 and SIRT1 overexpression in the UI population studied suggest that endometrial dysfunction is common in UI. The large difference in pregnancy rates for those positive and negative for BCL6 and SIRT1 immunostaining, suggest that these biomarkers may be a useful prognostic biomarker for endometrial dysfunction.
Limitations, reasons for caution: A small proportion of subjects with UI stained negative for BCL6 and SIRT1, limiting the statistical power of the pregnancy rate comparison. Many of the biopsied subjects with UI had previously undergone failed cycles, potentially skewing the UI population heavily toward those with endometrial dysfunction.
Wider implications of the findings: If confirmed by larger prospective studies, endometrial expression of BCL6/SIRT1 and related biomarkers could be a useful test to predict endometrial dysfunction in infertility patients as well as allow development of individualized and targeted therapies for implantation failure.
Trial registration number: Not applicable.

P-343 Identifying a subgroup of endometriosis patients with potential high risk for Endometriosis associated cancers

P. Lalitkumar[1], S. Vignesh-Srinivasan[1], K. Andersson[1], R. Green[1], K. Gemzell-Danielsson[1]
[1]*Karolinska Institute, Woman and Child Health, FRH-Lab, Stockholm, Sweden*

Study question: Is it possible to identify high risk women for Endometriosis Associated Cancer (EAC), based on cancer stem cell markers in their endometrium?
Summary answer: We could identify a subset of endometriosis women expressing aberrant levels of pre-malignant, epithelial-mesenchymal-transition (EMT) and cancer stem cell (CSC) markers in endometrium.
What is known already: Epidemiological studies show that a subset of women (0.7–2.5%) with endometriosis have higher risk for ovarian endometrioid and clear cell ovarian carcinoma. Now, it is very well known that endometrial stem cells (EnSC) are actively involved in endometrial regeneration and also are present in endometrioma. Though the mechanism is not clearly understood, a variety of molecular events have been postulated with the malignant transformation of endometriotic tissue. These include change in the expression of TP53, BCL-2, PTEN, ARID1A, CTNNB1.
Study design, size, duration: Biopsies were collected from endometrium ($n = 18$; P-EnSC) and endometrioma ($n = 11$; P-EndoSC) from patients undergoing surgery for endometriotic cyst. Patients who were not under hormonal treatment or carrying any intrauterine device for at least three months prior to surgery were enrolled. Endometrium was collection from a group of healthy fertile women ($n = 17$; H-EnSC). Biopsies were enzymatically digested and later EnSC and EndoSC populations were sorted with flow cytometry using markers CD90 CD73 and CD105.
Participants/materials, setting, methods: Customised gene expression assay were performed for panel of 40 genes belonging to the families of oncogenes, tumor suppressors, EMT, CSC, pluripotency, proliferation, anti-apoptosis, hormonal markers. Variability between patients for molecular expression were assessed by univariate PCA and multivariate OPLS-DA modelling (SIMCA 14 software). Molecular deregulation among patients were assessed by IPA. Invasion of P-EnSC, EndoSC in response to Paclitaxel and Cisplatin treatment were assessed using 3D spheroid invasion assay.
Main results and the role of chance: Real time PCR analysis showed a downregulated trend in tumor suppressor genes TP53/p53, ARID1A and upregulated trend in CD133/PROM1 and SMO expression. Based on heat map analysis of cancer stem cell relevant molecular expression in EnSC and EndoSC, we identified three patients as potentially high-risk' for EAC and named them as P-EnSC-hi or P-EndoSC-hi. The rest of the patients within each groups were called as low risk patients (P-EnSC-lo and P-EndoSC-lo) for EOC. Both P-EnSC-high-risk' and P-EndoSC- high-risk' had overexpression of pre-malignant genes TGF-β, TP53, FOS; CSC and EMT genes ER-α, SNAI1, KRAS, CTNNB1, NOTCH3 and EMT and most importantly ARID1A, previously shown to have strong association with EAOC. Moreover, trend curves with statistically significant genes within these subgroups revealed "low-risk" patients with gene expression pattern similar to H-EnSC, while high-risk' subgroup presented an expression trend more closely to the cancer profile similar to endometrial (Ishikawa) and ovarian cancer lines (SKOV3 and A2780). Functional assessment of subgroup risk status by invasion area in response to drug treatments by10 nM Paclitaxel and 10 μM cisplatin showed P-EnSC-hi subgroup with less invasion and more chemo-sensitivity compsring P-EnSC-lo, indicating role of P-EnSC in tumor progression (FC: –8.22, CI: 2.768 to 13.69, $P < 0.01$).
Limitations, reasons for caution: We included only endometriosis patients without any hormonal treatment. Although this improves the quality of the results, it limits the overall sample size. Though we tried to adopt a physiologically relevant *in vitro* model, an *in vivo* approach of testing tumorogenesis would have led to better understanding of EAC.
Wider implications of the findings: This study for the first time shows the possibility to identify women with endometriosis having high risk for endometriosis associated cancer (EAC), based on the molecular expression we have identified. This may potentially help in identifying patients with high risk for EAC and offer prophylactic measures to reduce EAC.
Trial registration number: NA.

P-344 Compartmentalized Gene Expression profile of receptive endometrium, ENPP3- a Novel biomarker for progesterone regulated endometrial receptivity

N.R. Boggavarapu[1], S. Lalitkumar[1], P. Lalitkumar[1], K. Gemzell-Danielsson[1]
[1]*Karolinska University Hospital, Women and Children Health, Stockholm, Sweden*

Study question: Identify potential progesterone regulated endometrial receptivity biomarker.
Summary answer: Progesterone regulated N-glycated Ectonucleotide pyrophosphatase/phosphodiesterase 3 (ENPP3) can potentially serve as biomarker for endometrial receptivity.
What is known already: With recent advances in omics technology, several studies were attempted to elucidate the gene expression of progesterone modulated receptive endometrium, but no unequivocal receptivity marker is yet defined in humans. We also lack a molecular marker that could be used to assess endometrial receptivity prior to embryo transfer. Such a biomarker if available, would benefit to assay the women undergoing IVF treatment, women with recurrent implantation failure and various endometrial receptivity disorders.
Study design, size, duration: Receptive ($n = 8$) and non-receptive ($n = 8$) endometrial biopsies were obtained during LH+7. Pure stromal and epithelial cells were isolated by Laser-capture microdissection (LCMD) and gene expression was studied by microarray, reconfirmed by real time PCR and immunohistochemistry. Expression of ENPP3 was analyzed in uterine fluid collected from receptive ($n = 6$) and non-receptive ($n = 6$) women by western blotting. *In vitro* functional assay with 3-dimension cell cultures was done to see the role of ENPP3 in human embryo implantation.
Participants/materials, setting, methods: Receptive and non-receptive (with 200 mg mifepristone on LH+2) endometrial biopsies were obtained from proven fertile women. Stromal and epithelial cells were dissected by LCM and gene expression studied by microarray (Affymetrix HuGene v1.0) and analysed by Ingenuity Pathway Analysis. Protein expression was studied by immunohistochemistry. Uterine fluids and endometrial tissue lysates were analyzed for the expression of glycated-ENPP3 by Western blot. Blastocysts were acquired through standard IVF or ICSI for 3dimensional cell cultures.
Main results and the role of chance: Top canonical pathway obtained on bioinformatics analysis is NRF2 mediated oxidative stress response and upstream regulators included transcription factor CBX5 (activated), CSF2 and EBF1 (inhibited). Microarray findings were validated by real time PCR and immunohistochemistry and were found to be in concordant with the microarray study, the expression of Metallothioneins (MT1G and MT2A) and ENPP3 were significantly down-regulated in both stromal and glands, whereas SFRP4 upregulated.

Very interestingly, both the protein and mRNA for ENPP3 expression showed significant down-regulation in epithelial compartment of treatment group ($p < 0.01$). No stromal immunostaining of ENPP3 was seen in either control or treatment group. Cyclical expression, highest in mid-secretory and lowest in proliferative phase ($p < 0.01$) was observed for ENPP3. N-Glycosylated ENPP3 was observed both in uterine fluid and endometrial tissue lysates. Depletion of progesterone down regulated its expression ($p < 0.01$). *In vitro* functional assay using 3-dimensional cell cultures confirmed the receptivity of the endometrial construct falling in line with the expression of ENPP3 ($p < 0.01$).

Paired *T*-Test and SAM methods were used for analysis of microarray data. Mann-Whitney's test was applied for immunohistochemistry and Western blot analysis.
Limitations, reasons for caution: Validation of the result with ENPP3 in a clinical set-up is required before extending it for clinical proposes. The physiological role of ENPP3 in endometrial receptivity and uterine fluid need to be investigated.
Wider implications of the findings: ENPP3 may offer a diagnostic tool for endometrial receptivity in women, especially in IVF before planning embryo transfer. There is also a possibility to develop an inhibitor or molecule that could alter the function of ENPP3 and thus use it for fertility control.
Trial registration number: NA.

P-345 Does low dose r – FSH ovarian stimulation negotiate thin endometrium problem in oocyte donation program?

A. Chimote[1], B. Chimote[2], N. Chimote[2], N. Chimote[3]
[1]*Vaunshdhara Clinic and Assisted Conception Centre, Gynecology, Nagpur, India*
[2]*Vaunshdhara Clinic and Assisted Conception Centre, Embryology, Nagpur, India*
[3]*Vaunshdhara Clinic and Assisted Conception Centre, Reproductive Endocrinology, Nagpur, India*

Study question: To evaluate whether low dose ovarian stimulation enhances estrogen receptivity and endometrial thickness better than exogenous estrogen supplementation for successful embryo implantation in oocyte donation progrmmes.
Summary answer: Administration of low dose r-FSH enhances endometrial thickness and gradation resulting in improved receptivity required for successful implantation of ensuing blastocyst.
What is known already: It is generally accepted that thin endometrium (<7 mm) observed on ultrasound results in lower implantation rates in IVF procedure probably due to obvious reason of abnormality in estrogen receptors on the endometrium. Embryo implantation, clinical and ongoing pregnancy rates are significantly higher in patients with an endometrial thickness >9–10 mm. The target cross-section endometrial thickness is >7 mm, with a triple-line endometrial pattern (grade), whereas endometrial thickness <6 mm is associated with a decreased probability of achieving a full-term pregnancy. Ultrasound monitoring of endometrial development plays a key role in steroid replacement for donor egg programs or frozen embryo transfer.
Study design, size, duration: Out of 167 women undergoing oocyte donation program during January 2014 to July 2015, 67 women with thin endometrium (<7 mm on day 14) did not achieve pregnancy. Blastocyst transfer was done despite thin endometrium since pregnancies in endometrium <3.7 mm have been reported. These 67 women were subjected to minimal stimulation protocol of 50–75 IU of r–FSH in the next cycle. Blastocyst transfer was done in 63 of these 67 women.
Participants/materials, setting, methods: 67 women undergoing their second oocyte donation cycle with Protocol B involving minimal stimulation with r–FSH were compared with their own previous cycle involving standard estrogen supplementation from day 2 alongwith added sildenafil from day 5 (protocol A). All women, whether undergoing protocolA/B, received luteal phase support from day 14. First cycle involved fresh blastocyst transfer whereas Frozen–thawed blastocyst transfer was done in second cycle.

TVS monitoring of endometrial thickness and gradation was done serially from day 14 to day ET.
Main results and the role of chance: Endometrial thickness on day 14 in women undergoing Protocol B was significantly higher as compared to those undergoing Protocol A (8.0 ± 2.0 mm vs. 5.3 ± 1.5; $p = 0.0015$). The endometrial echo-pattern in group B was also significantly enhanced (3.1 ± 0.32) as against that in group A (2.4 ± 0.24; $p = 0.0328$). Similarly, Day 18 monitoring of endometrial response showed extremely significant difference in endometrial thickness (9.2 ± 2.0 mm vs. 6.1 ± 1.4 mm; $p = 0.0001$) as well as echo-pattern/grade of endometrium (3.7 ± 0.4 vs. $2.\ 7 \pm 0.4$; $p = 0.002$) when protocol B was followed. Finally, on the day of blastocyst transfer too, the endometrial response showed a rising trend in endometrial thickness and gradation (1.1 ± 1.05 mm, pattern 3.9 ± 0.2) in Protocol B compared to protocol A women (8.0 ± 2.0 mm; 3.1 ± 0.5) respectively. Whereas no pregnancy resulted in any of the 67 women in their first cycle with Protocol A; out of the 63 women who had blastocyst transfer in their second cycle with protocol B, 15 resulted in clinical pregnancies (Pregnancy rate 23.09%) and 2 were ectopic pregnancies.
Limitations, reasons for caution: This is the first study employing minimal stimulation protocol in patients with thin endometrium undergoing oocyte donation programs. Although this study has a small sample size, yet it cannot be compared with studies that include adjuvents and intrauterine perfusions with cytokines to improve endometrial thickness. Therefore, large multicentric study is warranted.

Wider implications of the findings: Thin endometrium is a very difficult problem to deal with for clinicians world over. Administration of low dose r-FSH may aid in tiding over the problem of thin endometrium to some extent, thus improving clinical pregnancy rates in oocyte donation programmes as observed in this study.
Trial registration number: Not Applicable.

P-346 Endometrium co-culture, 3D endometrium co-culture, 3D polymeric carrier aided endometrium co-culture: comparative effects on implantation

S. Karahuseyinoglu[1], G.N. Sahin[2], A.C. Taskin[3], D. Yucel[4]
[1]*Koc University, School of Medicine, Histology and Embryology, Istanbul, Turkey*
[2]*Koc University Graduate School of Health Sciences, Reproductive Biology, Istanbul, Turkey*
[3]*Koc University, College of Science, Istanbul, Turkey*
[4]*Acibadem University School of Medicine, Histology-Embryology, Istanbul, Turkey*

Study question: Can 3D endometrial co-culture systems composed of or coated with extracellular matrix components and endometrial cells increase adhesion and invasion of blastocysts?
Summary answer: 3D culture systems and 3D Polymeric cell carriers coated with appropriate cell and/or extracellular matrix components can aid blastocyst adherence and invasion.
What is known already: In spontaneous pregnancies, the rate of implantation failure in first trial is 25–40%. In ART cases maximum implantation rate was shown to be 40–60% in the metaanalyses. It was well confirmed that each good quality embryo can not implant in every cycle.

The cross talk between the hatched blastocyst and the endometrium can only occur in a very short period- the window of implantation'. Implantation occurs in three phases: apposition/attachment-adherence/penetration.

This biological event is driven by a complicated mechanism. Most of the *in-vitro* co-culture methods do not support invasion of the blastocysts and only adherence can be maintained to some extent®.
Study design, size, duration: 1. routine endometrial co-culture.

2. three-dimensional culture of mouse endometrium epithelial and stromal cells on Matrigel®.

3. polymeric sponge coated by collagen and endometrial epithelial and stromal cells.

Experiments were repeated three times.

Implantation parameters were evaluated by IF and by WB and qRTPCR.

Invasion depth was evaluated by laser scanning confocal microscope and SEM.

Data was quantified by related softwares for statistical analysis.
Participants/materials, setting, methods: Superovulated hybrid female and male (Balb/c) mice were used to obtain blastocysts (+endometrium).
A. **Blastocysts placed on:** 1. Endometrial epithelial+stromal cells together.

2. Stromal cells **inside** matrigel +epithelial cells **over** matrigel.

3. Endometrial cells on the **collagen** coated **poly (L-lactic acid-co-D, L-lactic acid) polymeric** carrier.
B. At hours 24, 48, 72, 96-evaluation for progesterone receptors and implantation markers.

1. Fixation for IF and SEM.
2. WB.
3. qRTPCR.

C. Evaluation of invasion and surface by LS confocal microscope and SEM
Main results and the role of chance: 1. Endometrial co-culture: -Adhesion of blasts: very early.

- Increase of E-cadherin and L-selectin: 24 h after incubation. E-cadherin expression did not decrease with incubation time.
- No progesteron receptor activity was seen after 24,48,72 h. At hour 96, the result was suspicious.
- No definitive decidual area formation after 24 h but a mild change in some multiadhesive glycoproteins was seen after 72 h. It may also be related to increase of fibroblast-like cells in the culture environment.
- No definite invasion sign.

2. Endometrial co-culture with Matrigel: -Adhesion: more intense compared to first group. Increase of E-cadherin and L-selectin.

- Occasional progesterone receptors on the stromal and epithelial cells. Mild increase with incubation.
- Increase of laminin and fibronectin in the area under the blastocyst, suggesting a probable decidual zone.
- Invasion under the blastocyst area accompanied with decrease in E-cadherin.
- Mild increase in LIF and Hox expression.
- Pinopode formation.

3. Endometrial co-culture with collagen coated polymeric foam: -Intense adhesion: Higher increase of E-cadherin and L-Selectin, at early phases.

- Progesterone receptors on endometrial cells.
- Increase of laminin and fibronectin.
- Invasion-accompanied with decrease in E-cadherin.
- Increase of LIF and Hox expression.
- Intense pinopode formation.

WB and qRTPCR results supported the semiquantitative findings by these first results.
Limitations, reasons for caution: 1. 1. These are the results of first trial, two repetitions will be completed.

2. In polymeric carrier group most implantation parameters are better, but invasion depth was shorter. This is probably caused by the hardly degradable property of the polymer. A foam composed totally of collagen will be tried.
Wider implications of the findings: 1. Here we propose two very effective *in-vitro* implantation models. Both of them can be used to see the *in-vitro* development of the blastocyst together with the newly developing city and syncythiotrophoblasts.

2. Polymeric cell carrier can be developed to be used in embryo transfers during ART cycles.
Trial registration number: This is not a clinical trial.

P-347 Enhanced endometrial receptivity and augmented live birth rate in IVF cycles is favoured by Low IL-6 levels in follicular fluid

N. Chimote[1], N. Chimote[2], A. Chimote[3], B. Chimote[1]
[1]*Vaunshdhara Clinic & Assisted Conception Centre, Embryology, Nagpur, India*
[2]*Vaunshdhara Clinic & Assisted Conception Centre, Reproductive Endocrinology, Nagpur, India*
[3]*Vaunshdhara Clinic & Assisted Conception Centre, Gynecology, Nagpur, India*

Study question: To correlate levels of IL-6 in follicular fluid with endometrial thickness on day of embryo transfer and subsequently study its effect on live birth rates.
Summary answer: Lower FF IL-6 level correlates with enhanced endometrial receptivity favourable for implantation and increased live birth rate in IVF cycles.
What is known already: IL-6 is known to be a pleiotrophic cytokine with multiple cellular effects. Measurements of serum and follicular fluid (FF) levels of IL-6 in women undergoing *in vitro* fertilization (IVF) have been shown previously to be associated with etiology of infertility, stimulation protocol, fertilization rates and pregnancy outcome.
Study design, size, duration: Retrospective analysis of data from non-PCOS, non-endometriotic women undergoing antagonist IVF cycles (n = 133) at our infertility centre from November 2014 to June 2015. Cycles were divided into Low (≤47.5 pg/ml) and High (>47.5 pg/ml) FF IL-6 groups.
Participants/materials, setting, methods: FF IL-6 levels were estimated in each cycle from FF pooled from follicles from which an oocyte had been obtained. After evaluation of fertilization and embryo development to blastocyst stage, D5 blastocyst transfer was done. Endometrial thickness measured in cm using TVS on day of embryo transfer and live birth rate were the main outcome measures.

Main results and the role of chance: Overall live birth rate was 28.57% (38/133). Low FF IL-6 group (n = 100) had significantly higher endometrial thickness (1.19 ± 0.02 vs. 1.04 ± 0.03 cm, p = 0.0053) and live birth rate {32% (32/100) vs. 18.18% (6/33); $p < 0.0001$} on day of embryo transfer than high FF IL-6 group (n = 33). FF-IL-6 levels correlated inversely with endometrial thickness on day of embryo transfer (Pearson r = –0.23, p = 0.0097). Lower Follicular fluid level of IL-6 on day of oocyte aspiration thus facilitates development of a good endometrium receptive for the incoming embryo to implant. This is clearly reflected in the significantly higher live birth rate observed in the low FF IL-6 group.
Limitations, reasons for caution: This study measured IL-6 levels in follicular fluid pooled from all follicles in each patient. Although tedious and time consuming, it would be more befitting to measure the levels in individual fluid aspirated from each follicle. Also, multicentric trials are required to ascertain IL-6 as a marker of endometrial receptivity.
Wider implications of the findings: Follicular fluid level of IL-6 may be an early indicator of developing endometrium having potential for successful embryo implantation.
Trial registration number: Not Applicable.

P-348 Frozen-thawed embryo transfers in natural cycles with spontaneous ovulation are associated with increased clinical pregnancy rates

M. Montagut[1], S. Santos-Ribeiro[2,3], N.P. Polyzos[2,4], S. Mackens[2], A. van de Vijver[2], L. van Landuyt[2], G. Verheyen[2], H. Tournaye[2], C. Blockeel[2,5]
[1]*IFREARES-Clinique Saint Jean du Languedoc, Department of Reproductive Biology, Toulouse, France*
[2]*Universitair Ziekenhuis Brussel, Centre for Reproductive Medicine, Brussels, Belgium*
[3]*Santa Maria University Hospital, Department of Obstetrics, Gynaecology and Reproductive Medicine, Lisbon, Portugal*
[4]*Faculty of Health, University of Aarhus, Department of Clinical Medicine, Aarhus, Denmark*
[5]*School of Medicine, University of Zagreb, Department of Obstetrics & Gynaecology, Zagreb, Croatia*

Study question: Among patients undergoing frozen embryo transfers (FET), are natural cycles (NC) associated with better clinical pregnancy rates (CPR), when compared to human chorionic gonadotropin (hCG)-triggered cycles?
Summary answer: NC without luteal phase support (LPS) are associated with the highest CPR, followed by NC with LPS (NC+LPS) and hCG-triggered FET with LPS (hCG+LPS).
What is known already: While some studies have associated NC with spontaneous ovulation with higher CPR, when compared to hCG-triggered cycles, the evidence on this topic is conflicting and information of the additional effect of LPS is lacking.
Study design, size, duration: This retrospective study included all (n = 2896) consecutive FETs of vitrified cleavage and blastocyst stage embryos warmed between January 2010 and April 2015 in a tertiary centre. The FETs were grouped by type as follows: NC (n = 1063), NC+LPS (n = 570) or hCG+LPS (n = 1263).
Participants/materials, setting, methods: We performed mixed-effect multilevel multivariable regression analysis to account for the clustering of FETs using embryos derived from the same patient and/or ovarian stimulation cycle. Adjustment for the following potential confounders was also performed: female age at oocyte retrieval, body mass index (BMI), number of oocytes retrieved, fresh cycle pregnancy outcome, embryo transfer rank, number of embryos transferred, embryo stage and grade, and endometrial thickness. Bonferroni adjustment for multiple comparisons was performed whenever indicated.
Main results and the role of chance: The CPR/FET was significantly higher in the NC group (44.6%) as compared with the NC+LPS (36.8%, p = 0.007) and hCG+LPS groups (26.4%, $p < 0.001$). The lower performance in terms of CPR in the hCG+LPS remained significant even after adjusting for potential confounding using multivariable regression analysis [adjusted odds ratio (95% confidence interval) compared to the hCG+LPS group: 2.24 (1.73–2.91) and 1.67 (1.35–2.06) for the NC and NC+LPS groups, respectively].

A sensitivity analysis restricting the sample only to the first FET performed by the couple in our centre was also performed. The predicted CPR in the multivariable logistic regression analysis were still significantly higher in the NC (52.8%) and NC+LPS (42.5%) groups when compared to hCG+LPS (31.6%, all Bonferroni-corrected pairwise comparisons with $p < 0.01$).
Limitations, reasons for caution: The interpretation of the findings of this study is limited by the retrospective nature of the analysis and the potential for unmeasured confounding.
Wider implications of the findings: While facilitating the endocrine monitoring of FETs, hCG ovulation triggering and the use of LPS in a NC should be reconsidered, in light of the potential negative effect on the pregnancy outcome.
Trial registration number: None.

P-349 Altered metabolic pathways in endometrial cells treated with mycobacterial heat shock protein HSP65 causes aberrant decidualization

P-350 Combined mRNA microarray and proteomic analysis of endometrium of women with repeated implantation failure (RIF) and fertile controls

E. Bastu[1], T. Gunel[2], A.T. Baykal[3], I. Demiral[1], M.K. Hooseini[2], E. Gumusoglu[2], E. Akgun[3], B. Baykal[3], H. Eren[1], T. Tunc[1], Y. Yesil[1], F. Buyru[1]
[1]*Istanbul University School of Medicine, Department of Obstetrics and Gynecology, Istanbul, Turkey*
[2]*Istanbul University Faculty of Science, Department of Molecular Biology and Genetics, Istanbul, Turkey*
[3]*Acibadem University School of Medicine, Department of Medical Biochemistry, Istanbul, Turkey*

Study question: Is there a difference in gene and protein expressions in the endometrium between women with RIF and fertile control during window of implantation?
Summary answer: In RIF patients, gene analysis revealed 6 down-regulated genes, 9 up-regulated genes, while differentially expressed proteins exhibited 145 down-regulation, 129 up-regulation compared to fertile controls.
What is known already: Implantation failure remains an unsolved obstacle in reproductive medicine and is a major cause of infertility in otherwise healthy women. Inadequate uterine receptivity is responsible for approximately two-thirds of implantation failures, whereas the embryo itself accounts for only one-third of failures. Therefore, the management of repeated implantation failure (RIF) is one of the most difficult issues in assisted reproduction. We performed global gene profiling, using microarray technology, of endometrium during the window of implantation for patients with RIF versus fertile controls. In addition, we have pursued validation of gene expressions by proteomic analysis.
Study design, size, duration: In this prospective cohort study, mRNA and protein fractions were extracted from 45 endometrial biopsies obtained from women with repeated implantation failure (RIF) (n = 24) or fertile controls (n = 21) during the window of implantation (LH+7 to LH+10). Endometrial biopsies were collected using a Pipelle. Total RNA was isolated from endometrium tissue samples.
Participants/materials, setting, methods: mRNA and protein fractions were extracted from 45 endometrial biopsies obtained from women attending the infertility and gynecology clinics of an university hospital with repeated implantation failure (RIF) (n = 24) or fertile controls (n = 21) during the window of implantation (LH+7 to LH+10) and analyzed using microarray and LC-MS/MS in university genomic and proteomic laboratories, respectively. RIF patients had undergone ≥3 IVF failures; fertile controls had a history of ≥1 live birth.

Main results and the role of chance: In this study, we have applied a genome-wide transcript-level changes approach using oligo microarrays representing 37,600 genes, in order to define the genome profile of RIF patients as compared with fertile controls. Gene-array analysis revealed 15 genes exhibiting modified expression levels in RIF patients. Of these, 6 genes (40%) were down-regulated and only 9 genes (60%) were up-regulated. Classification of the down and up regulated genes to biological pathways revealed EIF2 signaling, acute phase response signaling, LXR/RXR activation, regulation of eIF4 and p70S6K signaling and FXR/RXR activation pathways. Proteomics analysis yielded the identification of 1531 proteins and 274 of these were calculated to be statistically significant ($p < 0.05$, fold change >40%). Differentially expressed proteins in RIF patients exhibited 145 down-regulation and 129 up-regulation.
Limitations, reasons for caution: The study model needs validation in larger study populations.
Wider implications of the findings: mRNA expression and proteomic analysis of endometrium differed in women with RIF and fertile controls. Such genomic and proteomic analyses could be used to allow a better understanding of the endometrial receptivity and the development of semi-invasive diagnostic tests for detecting endometrial receptivity.
Trial registration number: N/A.

P-351 NMR based metabonomics for identification of serum markers in women with dormant genital tuberculosis

K. Chaudhury[1], E. Subramani[2], M. Dutta[2], M. Joshi[3], S. Srivastava[3], B. Chakravarty[4]
[1]*Indian Institute of Technology-Kharagpur, Kharagpur, India*
[2]*Indian Institute of Technology-Kharagpur, School of Medical Science and Technology, Kharagpur, India*
[3]*Tata Institute of Fundamental Research, National Facility for High-field NMR, Mumbai, India*
[4]*Institute of Reproductive Medicine, Assisted Reproductive Technology, Kolkata, India*

Study question: Can NMR based serum metabolic profiling discriminate dormant genital tuberculosis (GTB) women from controls?
Summary answer: Metabolites including 3-hydroxybutyrate, succinate, citrate, acetate, L-glutamine, L-lysine, L-arginine, L-proline and L-threonine hold promise as potential candidate markers for detection of sub-clinical GTB women.
What is known already: NMR based metabolic profiling has emerged as an useful tool for identification of biomarkers in biological fluids. It is reported that *Mycobacterium tuberculosis* in the endometrium significantly alters the energy metabolism and amino acid biosynthesis in dormant GTB cases. Also, dormant GTB impairs the receptive status of the endometrium leading to infertility.
Study design, size, duration: Women with dormant GTB ($n = 26$) and unexplained infertile women with repeated IVF failure as controls ($n = 26$) were included in the study. Serum samples were collected from these patients at the tertiary infertility care center during the period September 2011–March 2013.
Participants/materials, setting, methods: Unexplained infertile women having at least 3 IVF failure with and without dormant GTB were recruited for this study. 700 MHz proton NMR spectra of serum were recorded for both the groups. Multivariate analysis including principal component analysis, partial least squares discriminant analysis and orthogonal projection to latent structure-discriminant analysis was applied to all the spectra. Multiple correlation analysis of endometrial tissue and serum metabolites was performed.
Main results and the role of chance: A clear metabolic differentiation between women with dormant GTB and controls was observed. Metabolites including 3-hydroxybutyrate, succinate, citrate, acetate, L-glutamine, L-lysine, L-arginine, L-proline and L-threonine were found to significantly upregulated in serum of women with dormant GTB compared with controls ($p < 0.05$). Pearson's correlation analysis showed a significant positive (0.317–0.652, $p < 0.05$) and negative correlation –0.261to –0.619, $p < 0.05$) between the expression of endometrial tissue metabolites and serum metabolites.
Limitations, reasons for caution: Dormant GTB diagnosis with conventional techniques including culture, smear and PCR remains a challenge, owing to the paucibacillary nature of the tubercular bacilli and false positivity and negativity. Intra- and inter-individual variability, impact of diet and medication, population stratification should be minimized to identify putative metabolite markers.
Wider implications of the findings: The set of metabolite markers identified may be explored for diagnosis of dormant GTB which would eventually help clinicians in early management.
Trial registration number: None.

P-352 Endometrial expression of Leukemia Inhibitory Factor (LIF), LIF-Receptor and HOXA-11 but not HOXA-10 is significantly impaired in women with unexplained infertility during implantation window

C. Margioula-Siarkou[1], S. Petousis[1], S. Milias[2], K. Ravanos[3], G. Mavromatidis[1], C. Haitoglou[4], Y. Prapas[3], N. Prapas[3], D. Rousso[3]
[1]*Aristotle University of Thessaloniki, 3rd Department of Obstetrics and Gynecology, Thessaloniki, Greece*
[2]*General Army Hospital, Department of Histopathology, Thessaloniki, Greece*
[3]*IAKENTRO, Advanced Medical Center, Thessaloniki, Greece*
[4]*Aristotle University of Thessaloniki, Laboratory of Biochemistry, Thessaloniki, Greece*

Study question: Is endometrial expression of HOXA-10, HOXA-11, LIF and LIF-R significantly different between fertile and infertile as well as within sub-groups of infertility during implantation window?
Summary answer: Endometrial expression of LIF, LIF-R and HOXA-11 but not HOXA-10 is significantly impaired in women with unexplained infertility during implantation window.
What is known already: HOXA-10, HOXA-11 and Leukemia Inhibitory Factor (LIF) with its receptor (LIF-R) have been indicated to play a significant role for the process of adhesion, embedment and implantation of blastocyst. Nevertheless, the possible relationship between their endometrial expression and infertility has not yet been clarified. Furthermore, no conclusions have been made regarding the expression patterns of HOXA-10, HOXA-11, LIF and LIF-R in the various sub-fertility groups during the implantation window.
Study design, size, duration: A prospective observational study was initiated on March 2013 at IAKENTRO, Infertility Treatment Center, Thessaloniki and 3rd Department of Obstetrics and Gynecology, Aristotle University of Thessaloniki. The present manuscript reports the results obtained until December 2015.
Participants/materials, setting, methods: Women having delivered at least one alive newborn were the study's control group (fertile women, group 1) while infertile women the patients' group (infertile women, group 2). An endometrial biopsy was obtained on 7^{th}–8^{th} postovulatory day. Expression of HOXA-10, HOXA-11, LIF and LIF-R was assessed in both epithelial and stromal cells by immunohistochemistry. Primary outcome was h-score. Parameters were compared between fertile and infertile women. A sub-analysis of expression was performed for various sub-fertility categories.
Main results and the role of chance: There were overall 90 women (25 fertile and 65 infertile) meeting the inclusion criteria. Endometrial tissue was obtained by 20 fertile and 55 infertile, of which 22 women were diagnosed with poor ovarian reserve, 13 with tubal infertility, 5 with endometriosis and 15 with unexplained infertility. Mean age was 31.1 ± 4.8 years for group 1 and 37.5 ± 3.8 for group 2 ($P = 0.001$). LIF and LIF-R h-score was significantly decreased in epithelial cells of infertile women compared with fertile controls ($P = 0.05$ and $P = 0.006$, respectively). No significant difference was observed regarding HOXA-10 and HOXA-11 epithelial endometrial expression as well as stromal expression of all molecules between two groups. LIF-R endometrial expression was found to be impaired in all sub-groups of infertility. Besides, LIF, LIF-R and HOXA-11 epithelial h-score presented their lowest values in women with unexplained infertility. Specifically, LIF epithelial h-score was 0.4 ± 0.2, LIF-R epithelial h-score 1.4 ± 0.2 and HOXA-11 epithelial h-score 0.1 ± 0.05 in women with unexplained infertility, the difference being significantly different with fertile controls ($P = 0.02$, $P = 0.03$ and $P = 0.005$ respectively).
Limitations, reasons for caution: Results presented in the abstract are based only on immunohistochemistry without having performed real-time PCR. However, this is the first study to report on expression levels of these molecules in the various sub-groups of infertility.
Wider implications of the findings: Our results indicate the significant role of HOXA-11, LIF and LIF-R in the aitiopathogenetic drawback complex of

unexplained infertility. As LIF-R epithelial expression was found to be impaired in all sub-groups of infertility, LIF-R seems to have a basic role in reassuring fertility along with a normal implantation process.
Trial registration number: The present trial has been approved by Institutional Review Board and Ethical Committee of AUTH.

P-353 3D Ultrasound assessment of effect of controlled ovarian stimulation on endometrioma volume

A. Seyhan[1], B. Urman[2], B. Balaban[1], B. Ata[2]
[1]*American Hospital, Women's Health and Assisted Reproductive Technologies Center, Istanbul, Turkey*
[2]*Koc University School of Medicine, Obstetrics and Gynecology, Istanbul, Turkey*

Study question: Do endometriomas grow during controlled ovarian stimulation (COS) for ART?
Summary answer: Endometrioma volume increases during COS.
What is known already: Mean diameter of endometriomas before and after COS was compared in only one prior study and they were found similar.
Study design, size, duration: Women with endometriomas who underwent COS and oocyte pick –up were prospectively recruited over one year. An a priori sample size calculation revealed that 14 women would be required to detect a clinically significant change in endometrioma from a preset volume. Institutional ethics committee approved the protocol and each women provided informed consent.
Participants/materials, setting, methods: Twenty – five women with 28 endometriomas were recruited. Each underwent 3D ultrasound scan with Voluson E8 using sono automated volume calculation (SonoAVC) software. Endometrioma volume was measured at the first day of gonadotropin injection (V1) and on the day of ovulation trigger (V2). Volumes were compared with related samples Wilcoxon signed rank test.
Main results and the role of chance: Mean age (SD) was 36.1 (4.6) years. Median body mass index (25th–75th percentile) was 22.9 (19.3–25.7) kg/m^2, antral follicle count was 5 (3–8), and serum anti-Müllerian hormone level was 1.11 (0.7–1.83) ng/ml. Nine (36%) women were stimulated in a GnRH antagonist protocol, 13 (52%) in a long, and 3 (12%) in an ultralong GnRH agonist protocol,. Mean duration of stimulation was 10.3 (2.3) days with median total gonadotropin dose of 4500 (3113–4950) IU/day. Median number of follicles >14 mm was 4 (2–7), number of cumulus oocyte complexes was 5 (4–9), and metaphase-two oocytes was 4 (3–7). None of the endometriomas were punctured during oocyte pick-up. One patient developed an ovarian abscess after the procedure. Median V1 was 22.2 ml (12–30 ml) and median V2 was 24.99 ml (11.2–37.4 ml) with a p value of 0.001. Twenty-three out of 28 endometriomas (82%) grew to some extent during COS.
Limitations, reasons for caution: The study was adequately powered. A single operator who had experience with SonoAVC performed all the scans. SonoAVC, like all volume acquisition software, requires manual post-processing, which in theory could have biased the operator.
Wider implications of the findings: Even though the 3 ml average growth was statistically significant, it could be regarded clinically insignificant. This growth may have not been noticed in the previous study due to the notorious variability of diameter measurements, which is an imperfect surrogate of volume in this setting.
Trial registration number: None applicable. Local ethics committee approved.

P-354 Endometrial expression of progesterone receptors but not avb3 integrins is significantly decreased in women with unexplained infertility and poor ovarian reserve

S. Petousis[1], C. Margioula-Siarkou[1], S. Milias[2], K. Ravanos[3], S. Tzonis[3], I. Kalogiannidis[1], C. Haitoglou[4], Y. Prapas[3], N. Prapas[3], D. Rousso[1]
[1]*Aristotle University of Thessaloniki, 3rd Department of Obstetrics and Gynecology, Thessaloniki, Greece*
[2]*General Army Hospital, Department of Histopathology, Thessaloniki, Greece*
[3]*IAKENTRO, Infertility Treatment Center, Thessaloniki, Greece*
[4]*Aristotle University of Thessaloniki, Department of Biochemistry, Thessaloniki, Greece*

Study question: Is endometrial expression of progesterone receptors and avb3 integrins significantly different between fertile and infertile as well as within sub-groups of infertility during implantation window?
Summary answer: Progesterone receptors' but not integrins' expression is significantly decreased in epithelial cells of infertile women with unexplained infertility and poor ovarian reserve.
What is known already: Progesterone receptors type A and B as well as integrins avb3 are enrolled in the normal implantation procedure of blastocyst. Especially for progesterone receptors, the observed down-regulation during mid-luteal phase is essential to reassure endometrial receptivity. No definite conclusions, however, have been made about the expression patterns of these implantation mediators in the various sub-groups of infertility both in epithelial and stromal cells during implantation window.
Study design, size, duration: A prospective observational study was initiated on March 2013 at IAKENTRO, Infertility Treatment Center, Thessaloniki and 3rd Department of Obstetrics and Gynecology, Aristotle University of Thessaloniki. The present manuscript reports the results obtained until December 2015.
Participants/materials, setting, methods: Women having delivered at least one alive newborn during the last year consisted the control group (group 1) while infertile patients' group (group 2). Infertile were also categorized to those with ovarian failure (group 2a), tubal factor (group 2b), endometriosis (2c) or unexplained infertility (group 2d). Endometrial biopsy was obtained by Pipelle on 7th and 8th postovulatory day. Total progesterone receptors' (TPR), type-B receptors' (PR-B) and integrins' avb3 expression was evaluated by immunohistochemistry. Primary outcome was h-score.
Main results and the role of chance: There were overall 90 women (25 fertile and 65 infertile) meeting the inclusion criteria, of which endometrial tissue was obtained by 20 fertile and 55 infertile. There were 22 women diagnosed with poor ovarian reserve, 13 with tubal infertility, 5 with endometriosis and 15 with unexplained infertility. Mean age was 31.1 ± 4.8 years for group 1 and 37.5 ± 3.8 for group 2 ($P = 0.001$). TPR and PR-B expression was significantly decreased in the epithelial cells of infertile women compared with fertile controls. Specifically, TPR epithelial h-score was 2.2 ± 0.2 for group 1 vs. 1.5 ± 0.2 for group 2 ($P = 0.01$), while PR-B epithelial h-score was 1.6 ± 0.2 for group 1 vs. 1.0 ± 0.1 for group 2 ($P = 0.04$). No significant difference was observed in the epithelial expression of integrins avb3 ($P = 0.52$). Furthermore, no significant difference was observed regarding the expression of any biomarker in stromal cells. When adjusting for the cause of infertility, TPR and PRB epithelial expression were significantly decreased in sub-groups 2a ($P = 0.01$ and $P = 0.03$ respectively) and 2d ($P = 0.001$ and $P = 0.006$ respectively) compared with group1, while expression was comparable between sub-groups 2b, 2c and group 1.
Limitations, reasons for caution: This study reports only on protein profiling but not on mRNA levels as well. However, to our knowledge, this is the first report of endometrial expression levels of progesterone receptors in the various sub-groups of infertility, indicating significantly impaired expression in women with unexplained infertility and poor ovarian reserve.
Wider implications of the findings: The reduced expression of progesterone receptors especially in women with unexplained infertility may present a major aitiopathogenetic cause of infertility in such cases. Endometrial biopsy should be performed in all women that intend to perform IVF in order to evaluate endometrial receptivity.
Trial registration number: The present trial has been approved by Institutional Review Board and Ethical Committee of AUTH (A9352/25.7.2012)

P-355 Effects of low doses of mifepristone on the human embryo implantation process in a three-dimensional human endometrial *in vitro* co-culture system

C. von Grothusen[1], N.R. Boggavarapu[1], C. Berger[1], J. Menezes[2], K. Gemzell-Danielsson[1], P.G. Lalitkumar[1]
[1]*Karolinska Institutet, Department of Women's and Children's Health, SOLNA, Sweden*
[2]*Fertilitetscentrum, Fertilitetscentrum, Stockholm, Sweden*

Study question: Could low doses of mifepristone during the receptive phase affect embryo implantation and endometrial receptivity markers?

Summary answer: A low dose mifepristone (0.5 μM) inhibited embryo implantation in the *in vitro* model; expression of endometrial receptivity markers were similarly affected by both doses.
What is known already: Mifepristone is a progesterone antagonist. It has been previously studied both *in vivo* and *in vitro* for its effect on endometrial receptivity. Also, it is considered a potential drug for contraception. It has been shown that a high dose of 200 mg administered on day LH+2 can inhibit implantation due to its effect on endometrium. We investigate here the effects of lower doses mifepristone administered during receptive phase on endometrial receptivity in an *in vitro* model mimicking *in vivo* conditions.
Study design, size, duration: Three-dimensional cell cultures were constructed from endometrial epithelial and stromal cells. Cultures were primed for five days with progesterone and estrogen to reach a state mimicking the receptive phase of the human endometrium. The cell cultures were divided into three groups and treated with: 0.5 μM mifepristone ($n = 8$) or 0.05 μM ($n = 10$) or vehicle as control ($n = 10$). The groups were compared for embryo implantation rate and expression of endometrial receptivity markers.
Participants/materials, setting, methods: Endometrial biopsies were collected from healthy, fertile women on day LH+4. Epithelial and stromal cells were isolated. Stromal cells were mixed with collagen gel and placed in a cell insert and epithelial cells seeded on top. After culturing five days, an embryo was added to each culture with either treatment/vehicle. Implantation rate was noted after five days and embryos removed. Cultures were processed for RNA extraction and real-time PCR analysis. *T*-test was used compare groups.
Main results and the role of chance: Implantation rate in the 0.5 μM mifepristone group was significantly ($p < 0.01$) reduced as 0/8 embryos attached to the endometrial construct, compared to 7/10 in the control group. Though implantation was also reduced in the 0.05 μM group (4/10 embryos attached) this was not significant. Interestingly, the expression of known endometrial receptivity markers FOXO1, FGF2, COUP-TFII, HOXA10, HAND2, OPN, LIF, PRL, PGR and IGFBP2 were expressed similarly in both treatment groups and differed from control. Furthermore, the expressions of IL6, IL1A and VEGFA were affected in the 0.05 μM group compared with the control. This indicates a dose dependent effect of mifepristone on the endometrium and that a low dose of 0.5 μM is sufficient to inhibit implantation as studied *in vitro*.

From the literature, it is known that 0.5 μM dose corresponds to an oral dose of 5 mg and we here show that exposure to mifepristone at this dose during the receptive phase *in vitro*, is enough to inhibit implantation.
Limitations, reasons for caution: The model used here is one of the best for endometrial receptivity and implantation, but it has limitations. It does not contain all cell types found *in vivo* and metabolic clearance of mifepristone is not the same as *in vivo*.
Wider implications of the findings: The results from this study take us a step closer towards rationalized use of mifepristone during receptive phase for preventing unwanted pregnancies.
Trial registration number: N/A.

P-356 *In vitro* evaluation of therapeutic effects of red ginseng and identification of associated miRNAs in endometriosis

M.K. Kim[1], S.K. Lee[2], B.H. Yun[1], J.H. Park[2], S.K. Seo[1], S. Cho[2], Y.S. Choi[1], B.S. Lee[1]
[1]Severance Hospital, Obstetrics and Gynecology, Seoul, South Korea
[2]Gangnam Severance Hospital, Obstetrics and Gynecology, Seoul, South Korea

Study question: What is the potential therapeutic effects of red ginseng and the target miRNAs that are associated with therapeutic effects of red ginseng on endometriosis?
Summary answer: We identified that red ginseng induces alteration of the proliferative and fibrotic properties of the endometrial cells in endometriosis patients, and several miRNAs are involved.
What is known already: Recent discoveries indicate that several miRNAs are involved in the pathogenesis of endometriosis and red ginseng, especially Rg3-enriched extracts, is known to have anti-inflammatory and anti-proliferative effects in various cell types. We hypothesized that red ginseng may have similar effects in endometriosis through modulation of miRNAs.
Study design, size, duration: This study involved 20 cases of endometrial stromal cells from the patients with endometriosis, Ishikawa cell lines, and 10 endometrial cells from the patients without endometriosis (control group). All the cells were treated with Rg3-enriched red ginseng extracts and the test results were obtained after 48 h of red ginseng treatment.
Participants/materials, setting, methods: MTT assay was performed to determine the adequate red ginseng dose. Primary endometrial cells from the patients with endometriosis and Ishikawa cell lines were cultured and treated with red ginseng for 48 h. Real-time PCR was performed to analyze Ki-67, Col-1 and CTGF and microRNA microarray analysis was performed before and after red ginseng treatment. Contraction and migration assay was performed to evaluate fibrosis and migration potentials of the cells after red ginseng treatment.
Main results and the role of chance: The endometrial cells from the patients with endometriosis and Ishikawa cell lines were cultured and treated with 0.4 mg/ml of red ginseng extract for 48 h and the cell proliferation marker, Ki-67, and the fibrosis markers, Col-1 and CTGF (connective tissue growth factor), were significantly decreased in endometrial stromal cells (Ki-67; $p = 0.030$, Col-1; $p = 0.004$, CTGF; $p = 0.001$), and showed no significant changes except Col-1 ($p = 0.012$) in Ishikawa cell lines. MiRNA microarray revealed several miRNAs that were found to be differentially expressed after red ginseng treatments. Among those miRNAs, we identified mir-27b-5p, which has been implicated to be involved in modulating fibrotic responses from previous studies. The expressions of mir-27b-5p were significantly lower in the endometrium of patients with endometriosis compared to those without endometriosis ($p = 0.037$), and red ginseng treatment for 48 h significantly increased the expression of this miRNA ($p = 0.02$). Additionally, we also identified mir-18b-5p, which is known to target CTGF, and the expression of mir-18b-5p showed trends toward decreased expressions after red ginseng treatment. ($p = 0.063$). Contraction assay revealed significant reduction of contraction in endometrial cells from the patients with endometriosis after red ginseng treatment but no significant changes were noted in migration potentials of the treated cells.
Limitations, reasons for caution: This study was yet performed only *in vitro*. More data from *in vivo* model is needed for more conclusive results.
Wider implications of the findings: Red ginseng effectively alters fibrotic properties of endometrial stromal cells from the patients with endometriosis, and inhibition of fibrosis by red ginseng seems to be associated with modulation of miRNAs expressions. Red ginseng and modulation of associated miRNAs may provide new therapeutic approach for endometriosis.
Trial registration number: Not required.

P-357 Differential profile of transcripts detected by RNA-Seq in eutopic endometrium of infertile women with endometriosis and fertile controls during the implantation window

M. Da Broi[1], C.V. Rocha Jr[1], J. Plaça[2], K. Peronni[3], J. Meola[1], W. Silva Jr[2], R.A. Ferriani[1], P.A. Navarro[1]
[1]Ribeirão Preto School of Medicine, University of São Paulo, Department of Obstetrics and Gynecology, Ribeirão Preto, Brazil
[2]Ribeirão Preto School of Medicine, University of São Paulo, Department of Genetics, Ribeirão Preto, Brazil
[3]Ribeirão Preto School of Medicine, University of São Paulo, Department of Cellular and Molecular Biology and Pathogenic Bioagents, Ribeirão Preto, Brazil

Study question: Is the eutopic endometrium of infertile women with endometriosis molecularly different from the eutopic endometrium of fertile women during the implantation window?
Summary answer: The eutopic endometrium of infertile women with endometriosis appears to be molecularly similar to fertile women during the implantation window, without considering the disease stages.
What is known already: Some studies suggest that the expression of critical molecules for the implantation process may be altered in eutopic endometrium from infertile women with the disease. However, all of them have methodological limitations and none evaluated by RNA-Seq all transcripts differentially expressed in eutopic endometrium of infertile women with endometriosis during the implantation window. This information would allow a more complete understanding of this event in these patients and contribute to the elucidation of the mechanisms involved in the etiopathogenesis of disease-related infertility.
Study design, size, duration: We performed a prospective case-control study from November 2011 to November 2015 at the Human Reproduction Division

of the University Hospital HCFMRP-USP. The sample size was calculated to identify or rule out a major difference between the groups, so that 5 patients each would be sufficient to rule out a two standard deviation difference with a power of 90% and alpha of 5%.

Participants/materials, setting, methods: Endometrial biopsies were collected during the implantation window (confirmed by histological dating, according to Noyes criteria) from 6 infertile patients with endometriosis (3 endometriosis I/II, 3 endometriosis III/IV), 6 infertile controls and 5 fertile controls. The RNA-Seq was performed using the Illumina platform HISEQ2500, High Output, with paired-end library. The normalization of the data and the analysis of differential expression were performed using the R statistical environment DESeq2 package.

Main results and the role of chance: We did not identify any differentially expressed transcripts between the infertile and fertile control groups and between endometriosis (with no regard to the stage of the disease) and fertile control groups. However, five differentially expressed genes (*SCUBE1, CCL20, LGALS9C, TRIM29* and *WNT11*) were identified in the group with endometriosis III/IV, and 1 (*KANSL1-AS1*) in the endometriosis I/II group compared to fertile controls. Two differentially expressed genes (*KANSL1-AS1* and *VGLL3*) were identified by comparing the endometriosis I/II and the endometriosis III/IV groups. According to the enrichment analysis, although the differentially expressed genes identified in the eutopic endometrium of infertile patients with advanced disease do not belong to the same pathway, most of them are involved in the biological processes of cell proliferation, vascularization, immune and inflammatory response, cell fate and chemokine and cytokines signaling.

Limitations, reasons for caution: The main limitation was the small sample size evaluated due to the restrictive eligibility criteria adopted, limiting the generalizability of the results obtained. On the other hand, the strict eligibility criteria eliminated factors potentially related to the impairment of endometrial receptivity, increasing the internal validity of the study.

Wider implications of the findings: We evidenced no differentially expressed transcripts comparing the eutopic endometrium of infertile women with endometriosis and fertile controls. The subdivision of endometriosis group into disease stages suggests molecular differences, especially in advanced disease. Future studies with appropriate size are necessary to investigate these deregulated genes in the different endometriosis stages.

Trial registration number: This is not a clinical trial.

P-358 Is luteal phase support successfully performed using 25 mg/day of subcutaneous progesterone in controlled ovarian stimulation cycles with GnRH agonist triggering?

E.E. Lara[1], P. Díaz-Gimeno[2], A.B. Casas[3], V. Garrigós[1], A. Ballesteros[3]
[1]*IVI Barcelona, Oocyte Donation Unit, Barcelona, Spain*
[2]*Fundación Instituto Valenciano de Infertilidad FIVI, Functional Genomics & Bioinformatics, Valencia, Spain*
[3]*IVI Barcelona, Reproductive Medicine Unit, Barcelona, Spain*

Study question: Is 25 mg/day subcutaneous progesterone as effective as 50 mg/day intramuscular progesterone for luteal phase support in controlled ovarian stimulated cycles with GnRH agonist triggering?

Summary answer: 25 mg/day subcutaneous progesterone is as effective as 50 mg/day intramuscular progesterone preparing the endometrium in controlled ovarian stimulated cycles with GnRH agonist triggering.

What is known already: Daily administration of 25 or 50 mg of Subcutaneous Progesterone (SCP) has shown the same predecidual transformation in endometrial biopsies. It also has been indicated that Luteal Phase Support (LPS) with 25 mg/day SCP vs. vaginal progesterone had non significant differences in IVF cycles clinical outcomes.

LPS is necessary to prepare the endometrium for embryo implantation, specially in controlled ovarian stimulated (COS) cycles where a GnRH agonist is used for triggering. For these cases 50 mg/day Intramuscular Progesterone (IMP) is often used in clinical practice to improve clinical outcome.

Study design, size, duration: After COS antagonist protocol with standard doses of subcutaneous FSH 150–225 IU/day, 24 donors were randomized in one of two groups of this eight months interventional and randomized clinical trial. Follicle puncture was done 36 h after a bolus of GnRH agonist. Age, BMI, endometrial thickness (>7 mm) and blood levels of Luteinizing Hormone, Estradiol, Progesterone on P-2, P0, and P+5 (according to oocyte recovery day) were evaluated. Endometrial histology and transcriptomics were analyzed.

Participants/materials, setting, methods: 24 oocyte donors were included in one of two groups after COS antagonist protocole with GnRH agonist (triptorelina) triggering. They received daily progesterone starting on oocyte recovery day (P0): 25 mg SCP Prolutex® (n = 12) or 50 mg IMP Prontogest® (n = 12). Endometrial biopsies were collected on day P+5 in 23 donors. Endometrial receptivity transcriptomics profile was measured by using Endometrial Receptivity customized Array (ERA), and histological endometrial dating was performed by two different pathologists.

Main results and the role of chance: Statistical description of both treatments showed homogeneous distributions between them regarding population variables and COS cycle parameters. Only progesterone blood levels at day P+5 was significantly different between groups (p-value = 0.0001). From the histological point of view, all the biopsies were dated in the secretory phase: 65.2% in media secretory, 13% in early secretory and 21.7% in late secretory phase. Endometrial histology showed non significant differences in the secretory dating phase between SCP and IMP (p-value = 0.3395).

Regarding deeper transcriptomic level, 88.24% of ERA genes showed the same trend of gene expression values in both treatments. Despite having the statistical power of 92% to detect differences in gene expression, it only was obtained a few changes in the global transcriptomic profile, 28 differential expressed genes have been detected, and four of them (1.6%) were changing significantly with a high gene expression difference between treatments (adj-p-value < 0.05, |FC| > 3), specially IGFBP1 (adj-p-value = 5.05E-04, Fold Change = 15.32) and CXCL13 (adj-p-value = 1.86E-06, Fold Change = 8.37) up and down regulated respectively in SCP.

Limitations, reasons for caution: Although histological or global molecular differences were not found in endometrial preparation of this donor population, further research is needed in IVF cycles in order to confirm that those few molecular changes are not affecting clinical pregnancy outcome.

Wider implications of the findings: Our findings, using histological and deeper transcriptomic endometrial evaluation, suggest that 25 mg/day of SCP in COS cycles with GnRH agonist triggering could be effective for LPS. With the same approach, LPS in IVF cycles could be improved with 25 mg/day of SCP for the wellness of patients.

Trial registration number: EudraCT Number: 2015-000290-12, ClinicalTrials.gov ID: NCT02567552.

P-359 GSTM1 polymorphisms in endometriosis in Greek women

D. Mavrogianni[1], E. Liokari[1], I. Douridas[1], D. Lourantou[1], G. Giannoulis[1], A. Vlismas[2], A. Protopapas[1], D. Loutradis[1], P. Drakakis[1]
[1]*University of Athens, School of Medicine, Athens, Greece*
[2]*Hammersmith Hospital Imperial College, IVF unit, London, UK*

Study question: Can the absence of the *GSTM1(Glutathione S-transferase mu 1)* allele be associated with endometriosis?

Summary answer: Absence of this allele may be associated with endometriosis and tends to have a statistically significant association with the age of initiation of the symptoms.

What is known already: *GSTM1* is a member of the GST family proteins which catalyze the conjugation of glutathione to potentially genotoxic compounds. It is also shown that the homozygous null deletions of *GSTM1* cause the loss of its encoded enzyme, participating in the detoxification of a large range of environmental contaminants. Previous studies suggested that the null genotype of *GSTM1* can lead to high endometriosis risk, especially in European and Asian populations. Thus, it might promote the occurrence and development of endometriosis.

Study design, size, duration: We studied 49 Greek women with no miscarriages and with at least one successful pregnancy and 29 Greek women with endometriosis.

Participants/materials, setting, methods: The study was conducted in a University hospital. We used endometriotic tissue from 29 women with infertility and histologically confirmed endometriosis, as well as blood samples from 49 controls, who have had at least one successful pregnancy. For each sample, genomic DNA was isolated and PCR was performed using specific for the *GSTM1* gene primers. The presence of the *GSTM1* allele was identified by gel electrophoresis.

Main results and the role of chance: According to statistical analysis, 34,5% of endometriosis cases have the homozygous null genotype in contrast with 18,4% of controls (95% CI, p = 0,171). The absence of allele tends to have a statistically significant association with the age of initiation of symptoms (p = 0.044) Additionally when blood sample and endometriotic tissue from the same woman were studied for the presence of the allele, a different genotype was found in 10 out of 29 women. To our knowledge this is the first study in which this polymorphism is detected in different tissues. The above findings may be relevant to a cellular and molecular explanation of the causes of endometriosis.
Limitations, reasons for caution: This is a prospective study. The presence of GSTM1 polymorphism will be studied in more samples to verify the results.
Wider implications of the findings: Concerning the mechanisms underlying endometriosis a possible impact of environmental factors may be evaluated. The establishment of a genetic profile may improve the prediction of the reappearance of endometriotic lesions. An association of the polymorphism with clinical characteristics may help clinicians in consulting and planning treatment in patients with endometriosis.
Trial registration number: Not a trial.

P-360 Effect of endometrial injury on reproductive outcome in assisted reproduction: an observational study

N. Garg[1], G. Harthshone[1], T. Ghobara[1], J. Rai[1], S. Keay[1], R. Agarwal[1]
[1]*University Hospitals Coventry and Warwickshire, Centre for reproductive medicine, Coventry, UK*

Study question: To analyse the effect of endometrial injury before IVF or ICSI on clinical pregnancy outcome.
Summary answer: Endometrial scratching performed before IVF/ICSI increased clinical pregnancy outcome in the second attempt of IVF/ICSI, unlike overall comparison.
What is known already: Since over 10 years, endometrial scratching is performed prior to IVF, hoping for better pregnancy outcome. However, there are no large randomised studies which support the routine clinical practice. Studies have shown to increase pregnancy rate by 10–70% in patients who had endometrial injury compared to women who didn't have. The endometrial injury could enhance chances of implantation, by modulating implanting gene expressions which help by increasing production of cytokines, interleukins, growth factors, macrophages, dendritic cells and helping in decidualisation.
Study design, size, duration: It is retrospective observational study at centre for reproductive medicine at the University Hospital. All women who had IVF/ICSI including embryo tranfer between January 2015 and July 2015 were included. There were 106 patients who had endometrial scratch (informed choice) and 315 patients who did not have the endometrial scratch. Demographic data and reproductive outcome were compared between the two groups using the chi-square test.
Participants/materials, setting, methods: The patient's information from the data base was recorded. Women who had the endometrial scratch, the duration between endometrial scratch and oocytes retrieval were recorded. All patients had endometrial scratch by pipelle. The sample obtained was discarded. 1 or 2 embryos were transferred on day 2, 3 or 5 after eggs retrieval. The luteal phase was supported by progesterone pessary and injections in some. The pregnancy test was done 14 days after transfer.
Main results and the role of chance: Out of 421 patients who under went IVF/ICSI, 106 patients had endometrial scratch. The baseline data were similar in both the groups and statistically not significant. There was no difference between age, parity, number of attempts of IVF/ICSI, and treatment protocol(long protocol or antagonist cycle) in 2 groups. 61/106 (57%) of patients who had endometrial scratch got pregnant compared to 159/315 (51%) percent in control group(p value 0.20, statistically not significant). Patients who had second attempt of IVF/ICSI in endometrial scratch group, 22/29 (75%) got pregnant.
Limitations, reasons for caution: It is a retrospective observational study. The number of patients was less, hence, it is difficult to suggest which patients would benefit. All the patients did not have intervention in the previous proliferative phase of menstrual cycle as suggested by other studies.
Wider implications of the findings: The study suggests endometrial injury in the second attempt of IVF/ICSI increases pregnancy rate. Previous studies have shown endometrial scratch helps to improve pregnancy rate in women with unexplained recurrent embryo implantation failure.
Trial registration number: –

P-361 Transvaginal ultrasonography accelerated video recording is a reliable method for the assessment of uterine peristalsis before embryo transfer

A. Castillo[1], B. Moliner[1], F. Sellers[1], J. Llacer[1], J.C. Castillo[1], A. Bernabeu[1], R. Bernabeu[1]
[1]*Instituto Bernabeu, Reproductive Medicine, Alicante, Spain*

Study question: It is accelerated video recording a useful tool to measure uterine contractions?
Summary answer: Accelerated video recording of transvaginal ultrasonography scan is a reliable method to assess the uterine contractions before embryo transfer in egg recipients with substitutive cycle.
What is known already: Implantation rate after embryo transfer is a limiting factor in the success of IVF treatments, thus efforts must be devoted to improving uterine receptivity in clinical practice. Uterine peristaltic wave frequency before embryo transfer has been inversely related to the clinical pregnancy and treatment with oxytocin antagonists has been suggested to improve the outcomes of IVF treatments. In the near future, the assessment of uterine contractions could be a useful tool in the clinical practice.
Study design, size, duration: Study to evaluate the variability intra- and inter-observer. Uterine peristaltic activity was prospectively assessed before blastocyst transfer in 20 oocyte recipients between March and December 2015.
Participants/materials, setting, methods: 2D scan of mid-sagittal plane of the uterus was recorded while a 6 min video. The records were analysed at 20× regular speed using a VLC media player. Three independent experienced observers performed three evaluations of every video. Intraclass correlation coefficient (ICC) was used to validate the variability.
Main results and the role of chance: All patients presented contractions during the evaluation. The average was 1.64 per min (1.5–1.74). The ICC to evaluate the inter-observer variability was 0.839 (0.7 a 0.93; p = 0.000). Regarding the intra-observer variability, the ICC was 0.95 (0.9 a 0.98; p = 0.000) for the observer "A", 0.948 (0.9 a 0.98; p = 0.000) for the observer "B" and 0.839 (0.7 a 0.93; p = 0.000) for the observer "C".
Limitations, reasons for caution: All the participants in the study were egg recipients and results could be different in embryo transfers after ovarian stimulation.
Wider implications of the findings: Having this reliable tool, efforts must be carried out to clarify whether the uterine peristalsis may be a marker of uterine receptivity. In this case, trials may be developed to investigate the possibility to reduce contractility.
Trial registration number: Nothing to disclose.

P-362 Intralipid in women with recurrent implantation failure in IVF/ICSI cycles. a double blinded randomised controlled trial

I. Gamaleldin[1], E. Lenguerrand[2], V. Akande[3], M. Fouad[4]
[1]*Bristol Centre for Reproductive Medicine, maternity unit, Bristol, UK*
[2]*Bristol University, Research Department, Bristol, UK*
[3]*Bristol Centre of Reproductive Medicine, Obstetrics and Gynecology, Bristol, UK*
[4]*Ain Shams University Hospitals, Obstetrics and Gynecology, Cairo, Egypt*

Study question: Does Intralipid use in women with recurrent implantation failure in IVF/ICSI cycles improve Live birth rates?
Summary answer: Intralipid use in women with Recurrent Implantation Failure in IVF/ICSI cycles is not associated with improved Live birth rates.
What is known already: Recurrent embryo implantation failure (RIF) is a disorder with potentially devastating physiological and psychological manifestations for those affected. Although its prevalence is not uncommon, many of the mechanisms involved still require elucidation. Evidence from both animal and human studies suggests that Intralipid, administered intravenously, may enhance suppression of natural killer cell activity. Up to our knowledge, this is the first RCT assessing the efficacy and safety of Intralipid in women with recurrent implantation failure after IVF/ICSI cycles.

Study design, size, duration: A Double Blinded Randomised Controlled Trial was performed from October 2012 till April 2015 on 100 women with history of Recurrent Implantation Failure after IVF/ICSI cycles.
Participants/materials, setting, methods: 100 Women with recurrent implantation failure were randomised into two groups.
Group I: Subjects (n = 50) who were treated with Intralipid 20% starting 6–7 days before embryo transfer followed by a repeated dose in case of a positive pregnancy test. ***Group II:*** Subjects (n = 50) who were treated with placebo starting 6–7 days before embryo transfer followed by a repeated dose in case of a positive pregnancy test. Clinical pregnancy rates and live birth rates were compared in both groups.
Main results and the role of chance: There was no evidence of improved live birth and pregnancy rates in women who received Intralipid Infusion compared to placebo. Results were reported according to intention to treat analysis ((ITT) with a relative risk (RR) of 1.56, 95% CI [0.74,3.27], P value 0.244 for live birth rates and RR 1.46, 95% CI [0.81,2.64], P value 0.207 for clinical pregnancy rates. 2 live birth cases in the Intralipid arm were born with middle ear anomaly that required corrective surgery.
Limitations, reasons for caution: There was a tendency towards increase in pregnancy and live birth rates in the intralipid arm, however this increase was not statistically significant. This may be due to small sample size. Also, finding of middle ear congenital anomalies may be related to repeated intralipid dosing practised in our IVF centre..
Wider implications of the findings: According to our findings, intralipid is not only not effective in improving live birth and pregnancy rates, It is proven to be associated with congenital middle ear anomalies.
Trial registration number: Trial registration number, Clinical Trials. gov. ID NCT02487940.

POSTER VIEWING SESSION

ETHICS AND LAW

P-363 What are the appropriate roles of induced germ cells at fertility clinics?

T. Ishii[1], R.A. Reijo Pera[2]
[1]*Hokkaido University, Office of Health and Safety, Sapporo, Japan*
[2]*Montana State University, Department of Cell Biology and Neurosciences and Department of Chemistry and Biochemistry, Bozeman, MT, USA*

Study question: In due consideration of the advances in stem cell research, what purpose justifies the clinical use of germ cells derived from human pluripotent stem cells?
Summary answer: Autologous induced pluripotent stem cell (iPSC)-derived spermatozoa might become a reproductive option for male cancer survivors.
What is known already: Without using donor gametes, there is no assisted reproductive technology (ART) treatment for patients with few or no gametes. Recent research suggests that germ cells may be induced from a patient's somatic cells by controlling the cell fate, which may be integrated into new ART treatments for infertile couples and even same-sex couples in the future. There are currently no clinically validated induced germ cells. However, with the advent of genome editing, stem cell research will advance rapidly, urging us to consider the potential upcoming ethical and societal issues associated with the clinical use of induced germ cells.
Study design, size, duration: The risks, burdens and limitations of three approaches for inducing human germ cells from pluripotent stem cells were scrutinized. Since the benefits of induced germ cells are likely found in self-use by a couple to have a genetically related child, the clinical justification was contemplated regarding four scenarios in same sex couples, in couples having a sick child and in patients of older and younger ages. Finally, the relevant regulatory issues were considered.
Participants/materials, setting, methods: This analysis includes works published in English until August 2015, and which were available through PubMed.
Main results and the role of chance: Germ cell induction involves the reversal of human development, thus underscoring the need for ensuring the developmental potential of induced germ cells and for assuring the health of the resulting offspring. Two induction approaches using autologous iPSCs deserve further consideration, despite the possibility of genomic instability during reprogramming as well as the cumulative burden of *de novo* mutations in the somatic cells of origin. The induction of germ cells from cloned embryonic stem cells was rejected for genetic and ethical reasons. Taking into account the fact that germ cell induction is currently far more advanced in male cells than in female cells, the ethical analysis of the four scenarios concluded that the reproductive use of induced spermatozoa might be justifiable as an option for males who have lost viable gametes due to cancer treatment. The first reproductive use of induced spermatozoa should occur in a clinical trial. In the provision of informed consent, the predictable risks, such as embryonic arrest, implantation failure, miscarriage and the birth of a child with congenital anomalies, must be carefully explained.
Limitations, reasons for caution: The study of human embryos alone is insufficient for avoiding the risks associated with ART treatment. Although the intergenerational monitoring of mouse offspring derived from induced germ cells will provide valuable insight into safety, additional studies using other animal species, particularly non-human primates, are needed before contemplating clinical applications.
Wider implications of the findings: Further social discussions about the appropriate role of ART using induced germ cells should be held before initiating this new ART. A legal analysis demanded the establishment of appropriate regulations in order to avoid troubles associated with the misuse of induced germ cells at fertility clinics.
Trial registration number: None.

P-364 Assessing the use of assisted reproductive technology in the United States by non-U.S. residents

D. Kissin[2], A. Levine[1], S. Boulet[2], R. Berry[1], D. Jamieson[2], H. Alberta[1]
[1]*Georgia Institute of Technology, School of Public Policy, Atlanta, GA, USA*
[2]*Centers for Disease Control and Prevention, Division of Reproductive Health, Atlanta, GA, USA*

Study question: To assess the frequency and trends of assisted reproductive technology (ART) use in the United States by non-residents (country of residence, treatments received, and outcomes).
Summary answer: ART use among non-residents is increasing in the U.S. and involves higher use of oocyte donation, gestational carriers, and pre-implantation genetic diagnosis than among residents.
What is known already: Travel across national borders in pursuit of treatment with ART raises medical and public health concerns. Little is known about the number of patients participating in cross-border reproductive care (CBRC), the specific ART treatments these patients receive, or the outcomes of these treatments.
Study design, size, duration: We conducted a population-based retrospective cohort study of all ART cycles (n = 1,080,935) reported to the National ART Surveillance System (NASS) in the U.S. from January 2006 to December 2012.
Participants/materials, setting, methods: We used NASS data to assess the frequency and trends of ART cycles performed by non-residents in the U.S.; to assess whether non-resident patients disproportionately used donated oocytes, gestational carriers, and pre-implantation genetic diagnosis; and to compare embryo transfer rates, live birth rates, and multiple birth rates for U.S. resident and non-resident ART cycles.
Main results and the role of chance: The non-resident share of all U.S. ART cycles grew each year, increasing from 1.2% (n = 1,683) in 2006 to 2.2% (n = 3,966) in 2012 and, during that period, patients from 141 countries had ART treatment in the U.S. The data also indicate that, compared with resident ART cycles, non-resident cycles had higher use of oocyte donation (10.7% vs. 41.8%), gestational carriers (1.6% vs. 12.2%), and PGD (5.1% vs. 18.1%). U.S. resident and non-resident cycles had similar average number of embryos transferred, live birth and multiple birth rates.
Limitations, reasons for caution: Although NASS collects information on residency status for all individuals using ART in the U.S., misclassification is possible. In addition, NASS lacks information on the reasons that non-residents travel to the U.S. for ART treatment.

Wider implications of the findings: CBRC makes up a small but growing share of ART usage in the U.S. The disproportionate use by non-resident CBRC patients of third-party ART techniques, involving oocyte donation, gestational carriers, and pre-implantation genetic diagnosis raises important ethical, policy and legal issues of international scope.
Trial registration number: Not applicable.

P-365 Attitudes of altruistic anonymous and identity-release oocyte donors towards future contact with donor offspring

V. Söderström – Anttila[1], A.M. Suikkari[1], A. Rotkirch[2], A. Miettinen[2]
[1]*Väestöliitto Fertility Clinics LTD., Helsinki Clinic, Helsinki, Finland*
[2]*Population Research Institute, Väestöliitto, Helsinki, Finland*

Study question: What are oocyte donors' attitudes towards future contact with donor offspring, will they share information about the donation(s) with children of their own?
Summary answer: Of past donors, 90% felt pleased or had neutral feelings towards contact with donor offspring and 91% had told/planned to tell their own children.
What is known already: There is limited knowledge about past donors´ attitudes about being contacted by donor offspring and feelings towards the potential donor offspring. One study of women who had donated in 2007-09 in an egg-sharing program in London found that 27 donors expressed goodwill and curiosity towards potential children while 3 were negative or ambivalent. Among identity-release donors a subset of donors has also been reported to have negative attitudes towards contact with donor offspring. No study has reported how donors will react to contact between donor offspring and their own children.
Study design, size, duration: A retrospective cross-sectional survey of all women who had donated oocytes between 1990 and 2012 at three fertility clinics in Finland was carried out in spring 2013. A self-administered questionnaire was sent out to a total of 569 former oocyte donors including anonymous or identity-release donors unknown or known to the recipient couple.
Participants/materials, setting, methods: The response rate was 75.3%. 371 donors were unknown to the recipient and were included in the study. The mean follow-up time after the donation was 11.4 years. Before 2008, donors were officially non-identifiable (anonymous) but they had a possibility to report to the clinic willingness to be contacted by the donor offspring. After 2008 all persons born as a result of gamete donation can, from the age of 18, receive identifying donor information (identity-release).
Main results and the role of chance: To learn whether the attitudes of donors was affected by the Finnish Assisted Reproduction Technology (ART) Act of 2007 we divided the 371 respondents into two groups: Group 1: women whose first donation took place between 1990 and 2007 ($n = 290$; voluntary registration 61.3%) and Group 2: women whose first donation took place between 2008 and 2012 ($n = 68$). Forty-one percent thought that the parents should inform the child of the way of conception (Group 1 36% vs. Group 2 64%; $p < 0.001$). Of the donors, 72.4% would be pleased about being contacted by donor offspring, 20.3% felt neutral and 7.4% expressed negative feelings towards contact with a donor offspring (no significant group differences).

Among donors who had children of their own ($n = 308$; 83%), 48% had informed and 43% planned to inform their own children, whereas 9% had decided not to inform. Disclosure about donation to own children did not differ between the groups. The majority (69%) of donors with children of their own would support their children if they would want to maintain contact with donor offspring. Less than one percent was against or would be upset about contact between donor offspring and donor's own children.
Limitations, reasons for caution: Although the response rate was high, 25% of all former donors in the three participating clinics could not be included due to lack of response.
Wider implications of the findings: Through 22 years and independently of the 2007 ART legislation, the majority of past donors have positive or neutral feelings towards being contacted by a person born of the donation. Based on these results legislation that promotes use of identifiable donors can be recommended.
Trial registration number: None.

P-366 The role of ethical consultation services in private IVF centers in the United States

L. King[1], K. Thornton[2], S. Bayer[2], A. Penzias[2]
[1]*Beth Israel Deaconess Medical Center, Harvard Medical School, Harvard Center for Obstetrics and Gynecology, Boston, MA, USA*
[2]*Boston IVF, Harvard Medical School, Boston, MA, USA*

Study question: What is the optimal role and composition for ethics committees in private IVF centers in the United States?
Summary answer: The optimal role and composition of private IVF center ethics committees is not yet known. We describe the role we have found for expert consultation.
What is known already: Much has been written about ethics committees in large hospitals; however, little is written about the role, composition and organization of private ethics committees. Private IVF centers have, at best, very limited access to hospital or university based ethics committees and are potentially left adrift without ready access to expert ethical advice. As technology in assisted reproduction advances we are faced increasingly with difficult requests to perform procedures which challenge established ethical principles and social morays.
Study design, size, duration: None.
Participants/materials, setting, methods: Large academic private IVF center. University based Bioethics Center.
Main results and the role of chance: Herein we report the evolution of our experience from an informal internal ethics committee to formal external expert consultation. Initially, cases with ethical quandaries were brought to our quality assurance committee, comprised of physicians, nurses, embryologists and mental health professionals.

Case discussions focused on perceived ethical principles. We came to a general consensus regarding offering or denying treatment by treating each case as a unique event without subjecting the points of contention to a systematic application of the Belmont principles.

On occasions where consensus could not be reached, we sought a formal opinion from bioethicists at our hospital of record.

Faced with an increasing number of issues as technology evolved, we contracted with Harvard Medical School's Center for Bioethics. Under this unique agreement, we will develop clinical guidelines and protocols regarding ethically charged scenarios to help guide decision making in a thoughtful, formal and structured manner through application of ethical principles.

Our ethics consultation team consists of a multi-disciplinary group invited from a wide variety of specialties and backgrounds. Further, the team has developed a curriculum which involves the teaching of ethical principles to our staff and fellows through a combination of didactic as well as case based discussions.
Limitations, reasons for caution: A formal ethics consultation service may not be the solution for every IVF clinic. However, our hope is to draw upon our experience in this collaboration and create a casebook as a guide for smaller practices.
Wider implications of the findings: Assisted Reproduction is fraught with ethical questions. Application of ethical principles in a meaningful way requires specific expertise. Incorporation of rigorous ethical analysis to the practice of assisted reproduction may be facilitated by the creation of a casebook as further guidance to providers.
Trial registration number: None.

P-367 The general public's opinion on stem cell based fertility treatments: who should decide and on what?

S. Hendriks[1], R. Vliegenthart[2], S. Repping[1], E. Dancet[3]
[1]*Academic Medical Center, Center for Reproductive Medicine, Department of Obstetrics and Gynecology, Amsterdam, Netherlands*
[2]*University of Amsterdam, Department of Communication Science, Amsterdam, Netherlands*
[3]*Leuven University, Department of Reproduction and Development, Leuven, Belgium*

Study question: Should individual patients and their physicians or a national committee of representatives decide on the conditions for accepting stem cell based fertility treatments?

Summary answer: According to the Dutch general public, patients and physicians cannot decide themselves on the conditions for accepting stem cell based fertility treatments.
What is known already: Current fertility treatments do not result in parenthood for one in three couples. Several stem cell based fertility treatments are being developed for these couples. This spurs a debate on the legitimacy of treatment indications and on the conditions for clinical introduction. Whether patients and their physicians can decide themselves on the conditions for accepting these treatments or whether this should be decided on a national level is contested. In line with our democratic principles and as they include and/or represent the targeted couples and the future children, we asked the opinion of the general public.
Study design, size, duration: In November 2015 a cross-sectional survey was disseminated among 1250 respondents of an actively recruited panel that is representative of the general Dutch adult population in terms of several demographic characteristics.
Participants/materials, setting, methods: Conditions important for accepting stem cell based fertility treatments were defined by literature review and interviews with patients and gynecologists. A non-directive questionnaire was developed, reviewed by experts from seven different disciplines (e.g., political science) and tested among the general public. Finally, we asked whether the acceptability of nine conditions should be defined by patients and their physicians or by a national committee of representatives. Regression analysis examined whether demographic characteristics were determining.
Main results and the role of chance: A total of 778 members of the general public completed the survey (response rate: 62%). Fifteen percent of them had sought medical assistance for infertility. Most respondents (51%) indicated the decision-maker should differ per condition, instead of all conditions being decided on by a national committee of representatives (35%) or individual patients and their physicians (14%). The vast majority (≥75%) stated that a national committee of representatives should decide on the acceptability of the potential risks of major birth defects and of late-onset chronic diseases in the child. According to most respondents the same applied to: the destruction of embryos (72%), the risk of minor birth defects (68%), the risk of cancer for the intended parents (66%), the limited similarities between the treatment and natural conception (55%), and the limited success rates (53%). Individual patients and their physicians could solely decide on high treatment costs (53%) and high treatment burden (55%). Depending on the condition, the national committee of representatives should be an independent medical-ethical board (29–50%), a professional association of physicians (11–17%) or the government (11–16%). Respondents who highly valued religion or had conservative political views were more likely to prefer a national committee of representatives.
Limitations, reasons for caution: The perspective of the general public may change over time and might differ across countries as it is influenced by many factors. The likelihood at which harmful consequences will occur in humans is and will remain uncertain prior to large-scale clinical application.
Wider implications of the findings: A responsible and well-designed decision-making process should be put into place for deciding on the required conditions for clinical application of stem cell based fertility treatments, rather than waiting for patients and physicians to take this decision. The general public supports an independent medical-ethical board as the most prominent decision-maker.
Trial registration number: Not applicable.

POSTER VIEWING SESSION

FEMALE (IN)FERTILITY

P-368 Cost-effectiveness of social freezing in Germany – estimates based on a Markov model

V. Ziller[1], C. Klüber[1], F.P. Krüger[1], U. Wagner[1]
[1]*University Medical Center Giessen and Marburg, Department of Gynecology, Endocrinology and Reproductive Medicine, Marburg, Germany*

Study question: Is "social freezing" in Germany cost effective if compared to natural conception and IVF?
Summary answer: Based on actual pregnancy probabilities and pricing social freezing is not cost effective today.
What is known already: As the age of women bearing their first child is increasing in today's society and fertility declines with increasing female age, social freezing is an emerging procedure that offers the possibility to push childbearing age at wish. For oocyte freezing healthy women need to endure medical procedures with extra risk and cost. As in Germany cost is not reimbursed, it is of upmost interest to debate cost efficiency of this technique.

We therefore developed a Markov model to estimate cost-effectiveness of different strategies to use oocyte freezing to postpone pregnancy for social indication based on the numbers given in Germany.
Study design, size, duration: We developed three strategies to delay childbearing until the age of 40. Reference strategy: no action until 40 and if no spontaneous conception (SC) occurs after one year, three cycles of standard IVF. Strategy I: three cycles of oocyte freezing at the age of 25/28/30/35/38 and thawing at 41 after SC for one year and strategy II: no action until the age of 40, followed by trying SC.
Participants/materials, setting, methods: We used an adapted Markov model to estimate cost-effectiveness between the three Strategies. Chances of a pregnancy were calculated with a life birth after standard IVF/ICSI, after IVF with thawed oocytes and after natural conception. The cumulative life birth rate to conceive within 5 years, cost per woman, cost per life birth were calculated. The probabilities to move from one state into another and the cost were based on published data (e.g., German-IVF-Registry (DIR)).
Main results and the role of chance: Cumulative life birth rate at 45, after five years trying to conceive for the reference strategy, NC and IVF/ICSI at the age of 41 was 73.03%, cost per women were 7,790.22€ and per life birth 10,666.89€. Cumulative live birth rate for strategy I, oocyte freezing at the age of 25/28/30/35/38 using them at the age of 41 were in the range from 87.00% (25) to 75.46%(38). Cost per woman from 9,880.05€ (25) to 13,928.10€ (38) and cost per life birth 11,346.57€ (25) to 18,457.17€ (38). Cumulative life birth rate for strategy II, SC without any treatment was 70.29%. For women using strategy I the chance for a life birth increases by 3.33% (38) to 19.12% (25) compared to IVF/ICSI and by 7.35% (38) to 23.76% (25) compared to natural conception. Per 100 women per strategy, this would result in 2 (38) to 14 (25) additional life births with social freezing compared to IVF/ICSI and 5 (38) to 17 (25) compared to natural conception. Cost increases by 26.83% (25) to 78.79% (38) for social freezing compared to IVF/ICSI. If we compare IVF/ICSI to natural conception, the chances increase by 3%. That would be 4 additional life births.
Limitations, reasons for caution: This study has several limitations. Even if effect of age on fertility has been widely studied data on natural conception especially at higher age are limited. The same is true for data on oocyte freezing, fertilization and pregnancy rates. The model might therefore vary for different assumptions.
Wider implications of the findings: Based on our results social freezing in Germany leads to additional pregnancies but also to higher cost today. This should be taken into account when counseling our patients and should be re-evaluated in the future with adapted numbers, e.g., upcoming data on success rates.
Trial registration number: N/A.

P-369 Pain perception and side effects during sonohysterography with balloon catheters: a randomized comparative study of cervical with uterine catheter placement

F. Zafarani[1], F. Ahmadi[1], A. Vosough[1]
[1]*Royan Institute for Reproductive Biomedicine, Department of Reproductive Imaging, Tehran, Iran*

Study question: To assess whether the location of the balloon catheter either the uterus or cervix during sonohysterography can affect the pain perception and vasovagal reactions rate.
Summary answer: The position of the catheter did affect the magnitude of pain and vasovagal reaction rates between the groups.

What is known already: Saline infusion sonohysterography and other intrauterine investigations methods may cause uterine cramping, pain and vasovagal reactions. According to the few previous studies the position of catheter placement can affect the magnitude of pain and amount of saline required during the sonohysterography.
Study design, size, duration: This study was a double blind randomized controlled trial on 300 patients undergoing sonohysterography between May 2012 and May 2014. Eligible women were randomly allocated to undergo intrauterine or intracervical balloon catheter placement. The Primary outcome measures included the degrees of pain perceptions after inflation and deflation of balloon catheter at the end of sonohysterography. Secondary outcomes included total time of procedure, total volume of required saline, spontaneous catheter expulsion and vasovagal reaction rates.
Participants/materials, setting, methods: The infertile patients aged 18–45 years were enrolled in this study. The examination was scheduled in the early follicular phase. A 2 lumen 6-French catheter was placed in the lower uterine segment or 1 cm into cervical canal and inflated with 1.2 mL of sterile saline. Pain was measured with a 10 point-VAS. Patients were monitored during and 30 min after the examination to diagnose and treat of intolerable pain and vasovagal reactions.
Main results and the role of chance: One hundred and forty eight subjects were randomly assigned to intracervical balloon insertion and 152 to intrauterine placement. There were no significant differences in inflation and deflation pain and total procedure time between two groups. Intracervical placement requires less significant volume of saline compared with intrauterine placement which reduces the risk of intrauterine infection and spread of malignant endometrial cells into the peritoneal cavity. The nulliparous women experienced significantly more pain after initial inflation ($P = 0.04$). Pain scores were not associated with patient's age, volume of saline infused and presence of pathology. But pain scores were significantly correlated with total procedure time.

Patients using intracervical balloon placement had a significantly higher rate of spontaneous expulsion of the catheter ($P = 0.004$). There were no statistically significant differences in occurrence of vasovagal reactions between two groups. None patient in both group experienced severe vasovagal reaction (manifesting as vomiting and syncope).
Limitations, reasons for caution: Due to slipping of the balloon from intracervical to intrauterine position and vice versa (about 10% of patients) outcome measures were assessed based on the intent-to-treat principle.
Wider implications of the findings: According our results, there is not sufficient evidence to suggest routine intracervical catheter placement for sonohysterography.

Intrauterine catheter placement can be considered in parous patients to avoid fluid reflux and spontaneous catheter expulsion. While intracervical catheter placement is suggested in nuliparous to improve patient satisfaction and to minimize perceived pain.
Trial registration number: NCT01936116.

P-370 A retrospective analysis of outcomes of 585 selectively reduced multiple pregnancies in IVF/ICSI-ET cycles

Q. Chen[1], H. Ye[1], X. Ding[1], X. Shen[1], G. Huang[1], H. Deng[1], H. Wen[1], L. Pei[1], P. Zeng[1]
[1]Chongqing Maternity and Children Health Care Hospital, Genetic and Reproductive Institute, Chongqing, China

Study question: To investigate whether selective fetal reduction in early pregnancy has any effects on obstetric and fetal outcomes of reduced multiple pregnancies produced through IVF/ICSI-ET cycles.
Summary answer: As compensating for multiple pregnancies, fetal reduction was effective in reducing the rate of multiple pregnancy, while it was not helpful for the pregnant outcome.
What is known already: As compared with primary singleton pregnancies, whether fetal reduction to singleton further compromises the outcomes of the reduced pregnancies has not reached an agreement. There were studies showing a comparable miscarriage rate, mean gestational age and neonatal weight when reduced singleton, twin, and triplet pregnancies compared to non-reduced pregnancies. While other studies found the rates of low birth weight and preeclampsia in reduced singleton were increased compared to the primary singleton, and the rates of preterm delivery and low birth weight of reduced twins were increased compared to the primary twins.
Study design, size, duration: A total of 1785 IVF/ICSI-ET cycles which reached clinical pregnancy at our IVF center from January 2002 to June 2014 were studied, including 585 selectively reduced multiple pregnancies and 1,200 primary singleton pregnancies which were selected by nested case control study method. Maternal and neonatal outcomes were compared between groups, with a value of $P < 0.05$ used for significance.
Participants/materials, setting, methods: Total of 585 cycles with fetal reduction to singleton were selected as study group, while 1,200 primary singleton cycles were set as control. The exclusion criteria included: (1) age >37, chromosomal abnormalities, uterine factors (fibroid, adenomyosis, deformity) and endocrine disorders (PCOS, thyroid disease and diabetes, etc.); (2) time of IVF/ICSI cycles ≥3; (3) intrauterine merger ectopic pregnancy and ectopic pregnancy.
Main results and the role of chance: The mean maternal age of the reduced singleton group was 30.1 ± 3.4, with no significant difference compared to the primary singleton group (30.3 ± 3.4). Both BMI and duration of infertility had no significant difference between the two groups. Comparing to primary singleton group, the number of embryos transferred, the incidence rates of pregnancy complications and preterm delivery were significantly higher ($P < 0.05$), while the complete abortion rate and gestational age were significantly lower ($P < 0.05$) in the reduced singleton group. There was also no significant difference in complications during delivery between the two groups.

The incidence rate of low birth weight, perinatal mortality and birth defects in the reduced singleton group was significantly ($P < 0.05$) higher than the primary singleton group. There was no significant difference in neonatal diseases between the two groups.
Limitations, reasons for caution: There are some limitations for our study, the most significant of which come from its retrospective nature. Besides, the lack of comparison in embryo quality between the two groups which might be the reason for early abortion. Further large and multicenter study will be needed for more solid conclusions.
Wider implications of the findings: Reduction surgery is only taken as a compensated measure after multiple pregnancies occurred, whereas to limit the number of transferred embryos is the essential way to improve the outcomes of IVF/ICSI-ET cycles. Moreover, prenatal follow-up should be reinforced after reduction to decrease risks during pregnancy.
Trial registration number: No trial registration number.

P-371 Body mass index and pregnancy outcomes after single blastocyst transfer: an evaluation of obese and morbidly obese (BMI >40 kg/m^2) North American women

M.A. Russo[1], S. Ates[2], T. Shaulov[2], M.H. Dahan[2]
[1]University of Ottawa, Department of Obstetrics and Gynecology, Ottawa, ON, Canada
[2]McGill University, Division of Reproductive Endocrinology and Infertility, Montreal, QC, Canada

Study question: To examine the live birth rate (LBR) after single, "ideal-quality" blastocyst transfer (SBT), in morbidly obese patients from a North American population.
Summary answer: LBR after SBT decreases substantially above a maternal BMI of 35 kg/m^2, with a further decrease above a BMI of 45 kg/m^2.
What is known already: Maternal BMI has been shown to have a negative effect on pregnancy outcomes achieved with IVF. However, this effect can be partially overcome by the transfer of multiple embryos. Recent studies from European populations have shown poorer pregnancy outcomes after SBT in obese women (BMI 30–35 kg/m^2) compared to women of normal weight (BMI 20–25 kg/m^2). Yet, the effect of BMI on reproductive outcomes after SBT, has never been evaluated in women with a BMI above 35 kg/m^2 or in North American women. This is significant given the higher prevalence of morbid obesity in North America compared to European populations.
Study design, size, duration: This is a retrospective, cohort study including 520 nulliparous and multiparous women, less than 40 years of age, undergoing their first, "ideal-quality" SBT between August 2010 and March 2014 at a University Centre. Each patient was included only once. 88 women had a BMI of at least 30 kg/m^2. The maximum BMI in the study was 57 kg/m^2. Live birth was defined as an infant born with signs of life at >24 weeks GA.

Participants/materials, setting, methods: Exclusion criteria: congenital or acquired uterine anomalies, hydrosalpinges, or donor embryos. Study outcomes were reported based on BMI categories. Statistics were analyzed with logistic regression to control for confounding effects and multiplicity. The following confounders were controlled for: female age, previous pregnancies, previous term deliveries, BMI, smoking status, baseline FSH level and antral follicle count, duration of infertility, total gonadotropin dose, and stimulation protocol. Data is presented as mean ± standard deviation or percentage.
Main results and the role of chance: The mean age was 32.9 ± 3.4 years (range 22–39 years). The mean BMI was 24.8 ± 6.2 kg/m^2 (range 17.0–57.0 kg/m^2). Among female age, previous pregnancies, previous term deliveries, BMI, smoking status, baseline FSH level and antral follicle count, duration of infertility, total gonadotropin dose, and stimulation protocol, BMI was the only statistically significant predictor of LBR ($p = 0.02$), with the exception of a previous term delivery of a live infant ($P = 0.0001$). Pregnancy outcomes were reported by BMI categories, including: <20, 20–24.9, 25.0–29.9, 30–40, >40 kg/m^2. The pregnancy rate (PR) for each group was 45%, 62%, 45%, 36%, and 20%, respectively ($p = 0.004$); the clinical pregnancy rate (CPR) per group was 36%, 52%, 38%, 26%, and 10% ($p = 0.009$); and the LBR per group was 35%, 50%, 38%, 26% and 10% ($p = 0.03$). The CPR and LBR in morbidly, obese women (BMI >40 kg/m^2) was over 50% less than that of obese women (BMI 30–39.9 kg/m^2). Similarly, the LBR of normal weight women (BMI 20–24.9 kg/m^2) was five times that of morbidly, obese women (BMI >40 kg/m^2). BMI was a significant predictor of LBR even when excluding women with PCOS ($n = 373$; $p = 0.014$).
Limitations, reasons for caution: This study is limited by its retrospective nature. Further, randomized prospective trials are needed to validate the relationship between BMI and pregnancy outcomes following SBT in morbidly, obese women; especially since the transfer of multiple embryos results in poorer pregnancy outcomes as a function of BMI.
Wider implications of the findings: A BMI between 20 and 24.9 kg/m^2 is ideal for patients undergoing SBT. Pregnancy outcomes are worse in patients with a BMI <20 kg/m^2 or >35 kg/m^2, with a further drop above a BMI of 45 kg/m^2. This is the first study to examine the effects of morbid obesity after SBT.
Trial registration number: Not applicable.

P-372 Randomized, open trial comparing a modified double-lumen needle follicular flushing system with a single-lumen aspiration needle in IVF patients with poor ovarian response

K. von Horn[1], M. Depenbusch[1], A. Schultze-Mosgau[1], B. Schöpper[1], G. Griesinger[1]
[1]*University of Schleswig-Holstein, Campus Lübeck, Reproductive Medicine, Lübeck, Germany*

Study question: To test for an increase in one cumulus-oocyte-complex by using a double-lumen needle follicular flushing system (Steiner-Tan®) vs. a 17G single-lumen needle (Gynetics®).
Summary answer: Flushing each follicle 3-times by a modified double-lumen needle does not increase the number of cumulus-oocyte-complexes in poor ovarian response IVF patients.
What is known already: Since the number of oocytes available for IVF is a determinant of pregnancy likelihood, it is paramount to maximize the chance of retrieval of an oocyte from any given follicle, especially in poor responders. Available flushing studies suffer from the use of double-lumen needles with vast dead space resulting in high flow restriction and low flow rate of medium, despite application of high pressure. The Steiner-Tan Needle® is a purpose build quasi-double lumen needle for follicular flushing. The needle, by its specific design, facilitates a high flow rate of flushing medium, which is injected by an automated pump.
Study design, size, duration: Prospective, single-centre, randomized, controlled, open superiority trial comparing a 17G single-lumen aspiration needle (Gynetics®) with the Steiner-Tan Needle® for follicular flushing in patients with ≤5 follicles >10 mm on the day of hCG administration; randomization blocked, allocation concealed; alternative hypothesis: Steiner-Tan Needle® flushing increases oocyte number by one from mean of 3 (estimated SD 1.5); sample size required $n = 80$ (alpha = 5%, beta = 20%, *t*-test, drop-out assumed as 7.5%).
Participants/materials, setting, methods: Patients with a BMI <35 kg/m^2, an indication for IVF/ICSI with or without ovarian stimulation presenting ≤5 follicles >10 mm on day of hCG. In both groups, all visible follicles regardless of size in both ovaries were aspirated. In the study group all aspirated follicles were flushed at least three times. IRB approval (University of Luebeck): EK 2014. Trial registration: 14–244.
Main results and the role of chance: This interim analysis includes the evaluated data after recruitment of 59 patients ($n = 28$ Steiner-Tan Needle®, $n = 31$ Gynetics® aspiration needle *per intention-to-treat*). The analysis *per-protocol* yielded similar results. Demographics and stimulation characteristics were highly similar between groups. The following results were found for the Steiner-Tan® vs. Gynetics® group: punctured follicles 4.1 (±2.3) vs. 4.2 (±1.9) ($p = 0.84$); COCs 2.3 (±1.9) vs. 3.2 (±2.4) ($p = 0.12$); metaphase II oocytes 1.4 (±1.4) vs. 2.1 (±1.5) ($p = 0.07$); 2PN oocytes 0.9 (±1.2) vs. 1.5 (±1.2) ($p = 0.08$); COCs per punctured follicle 0.57 (±0.4) vs. 0.75 (±0.5) ($p = 0.15$); average duration of oocyte-pick-up 3.8 (±2.2) vs. 1.8 (±1.3) min ($p = 0.01$). There is no significant difference in the subjective, peri- and postoperative pain and burden between the study and the control group using the *German Pain Questionnaire score* and the *Depression Anxiety Stress Scale*-21 (DASS 21).
Limitations, reasons for caution: The necessary sample size of 80 patients to reject the hypothesis of superiority has not been achieved at the time of writing. The complete dataset will be ready for presentation at ESHRE.
Wider implications of the findings: If flushing does not increase the number of oocytes, despite the use of an elaborate needle and flushing system, a larger efficiency trial on flushing is redundant, since an increase in the number of oocytes is the only conceivable mechanism of action.
Trial registration number: The trial registration number is NCT02365350.

P-373 The importance of the waist/hip circumference ratio and physical activity on the outcome of intracytoplasmic sperm injection cycles

G. Halpern[1], D.P.A.F. Braga[2,3,4], A.S. Setti[2,4], E. Ono[4], R.C.S. Figueira[5], A. Iaconelli Jr.[4,6], E. Borges Jr.[4,6]
[1]*Fertility Medical Group, Department of Nutrition, Sao Paulo, Brazil*
[2]*Fertility Medical Group, Scientific research, Sao Paulo, Brazil*
[3]*Universidade Federal de São Paulo UNIFESP, Disciplina de Urologia, Área de Reprodução Humana, Departamento de Cirurgia, Sao Paulo, Brazil*
[4]*Instituto Sapientiae, Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific Research, Sao Paulo, Brazil*
[5]*Fertility Medical Group, IVF Laboratory, Sao Paulo, Brazil*
[6]*Fertility Medical Group, Clinical Department, Sao Paulo, Brazil*

Study question: Are the outcomes of intracytoplasmic sperm injection (ICSI) influenced by male and female body mass index (BMI), waist/hip circumference ratio, physical activity and dietary practice?
Summary answer: The female waist/hip ratio and both male and female partner physical activity influence the ICSI outcome. No association was observed concerning BMI and dietary practices.
What is known already: The human fertility rate has declined over time and the underlying cause for this decline has not yet been elucidated. It has been suggested that this decline is associated with many external agents such as environmental factors, as well as eating habits and lifestyle. In both sexes, obesity, particularly abdominal obesity, may impair fertility. A parallel decline in the level of physical activity also exists; however, the evidence of its impact on assisted reproduction outcomes is still weak. It is important to understand which behaviors have the highest negative impact, so that appropriate recommendations can be provided to patients.
Study design, size, duration: This prospective cohort study included 3,913 embryos obtained from 602 couples undergoing ICSI cycles from January 2012 to December 2014, in which embryo transfer was performed on day 5. All patients were interviewed face-to-face by the same nutrition professional before the beginning of the treatment. The questionnaires contained information on weight loss diet, number of meals per day, and frequency of physical activity. The BMI and the waist/hip ratio were also measured.
Participants/materials, setting, methods: The study was performed at a private assisted reproduction centre and enrolled male and female partners. The influences of dietary practice, physical activity, BMI and waist/hip circumference ratio on ICSI outcomes were evaluated using linear and binary regression models. The response variables were: (i) fertilisation rate, (ii) embryo quality on days 2 and 3, (iii) blastocyst formation, (iv) pregnancy, (v) implantation, and (vi) take home baby chance (THB).
Main results and the role of chance: The female waist/hip circumference ratio negatively influenced the fertilisation rate (RC = –0.253, $R^2 = 1.5\%$, $p = 0.015$),

the embryo quality on day 2 (OR = 0.82, CI = 0.67–0.93, p = 0.036) and 3 (OR = 0.79, CI = 0.61–0.89, p = 0.028). No influence of physical activity frequency on any response variable was noted; however, when sedentary patients were compared to physically active patients, positive influences were observed. Physically active women had a higher fertilisation rate (RC = 3.994, R^2 = 1.8%, p = 0.021) and increased chance of high-quality embryos on days 2 (OR = 1.65, CI = 1.23–2.17, p = 0.025) and 3 (OR = 1.52, CI = 1.27–2.02, p = 0.026). Male physical activity did not influence any response variable. Nevertheless, when both the male and female partner were physically active, the chance of blastocyst formation (OR = 2.77, CI = 1.5–3.4, p = 0.037), pregnancy (OR = 1.43, CI = 1.22–1.69, p = 0.041) and THB (OR = 1.09, CI = 1.01–2.4, p = 0.048) were increased. No influence of BMI, being on a weight loss diet or the number of meals per day was noted for any ICSI outcomes.
Limitations, reasons for caution: As lifestyle comprises many factors such as eating habits, stress, and others, it is difficult to infer that a particular factor is the sole cause of reduced or increased ICSI outcomes. Nonetheless, any combination of lifestyle factors could have a significant and cumulative impact on fecundity and warrants due attention.
Wider implications of the findings: Our findings suggest that a lower waist/hip circumference ratio and physical activity have a protective effect on male and female fertility. Awareness about these factors and counseling on how to minimize its impact in each partner could increase the chances of a more favorable rate of conception and live birth.
Trial registration number: N/A.

P-374 Human Papillomavirus (HPV) positive sperm has a negative effect on pregnancy rates in intra-uterine insemination (IUI)

C. Depuydt[1], G. Donders[2], V. Marion[3], B. Johan[1], V.B. Davy[1], S. Geert[1], B. Eugene[1]
[1]*AML, Fertility and reproduction, Antwerpen, Belgium*
[2]*University Hospital Antwerpen, Obstetrics and Gynecology, Antwerp, Belgium*
[3]*Leuven Institute for Fertility and Embryology L.I.F.E., Obstetrics and Gynecology, Leuven, Belgium*

Study question: Investigate the relationship between HPV infection in sperm and pregnancy outcome after IUI.
Summary answer: Presence of HPV virions detected in sperm is associated with a negative IUI pregnancy outcome.
What is known already: Recent evidence identified HPV-infections as possible cause of male and couple infertility in IUI. In the cervix of infected women, serial measurements of type-specific HPV DNA can categorize HPV-infections in two HPV-induced processes: an infectious virion-producing pathway and a non-infectious transforming or cancer-inducing pathway. Because virions can bind to distinct sites on the spermatozoon's head, this may not only have a detrimental effect on sperm parameters but also on gamete interaction, since *in vitro* experiments have demonstrated that spermatozoa can not only transfer HPV-virions to the oocyte, but the transferred HPV-virions can also induce stage-specific maturation arrest in infected embryos.
Study design, size, duration: Non-interventional prospective study in which different sperm fractions (sperm pellet, swim-up and seminal plasma) were tested on left-over material after IUI for the presence of HPV types (6,11,16,18,31, 33,35,39,45,51,52,53,56,58,59,66,67 and 68) using quantitative real-time PCR.
Participants/materials, setting, methods: The HPV positivity was correlated with IUI outcome and sperm parameters (AML intermediate structure). We calculated that analysis of 1,500 IUI cycli is required to obtain adequate statistical power.
Main results and the role of chance: The HPV prevalence per IUI cycle was 13.6%. Men with HPV-positive sperm were two times less likely to achieve a pregnancy after IUI (5.00 vs. 11.52%; p = 0.0064 for n = 1,500). HPV negative men have significantly more grade A moving sperm (65.3%) than men with HPV (59.4%; p = 0.027).
Limitations, reasons for caution: It is possible that the pregnancy rate per cycle is higher in HPV positive men with HPV negative partners, than in HPV positive men whose partners are also HPV positive. Therefore both partners should be tested for the presence of HPV and ideally each time an IUI cycle is performed.
Wider implications of the findings: Because for HPV multiplicity of infection <10 virions, men can easily infect women. In addition these HPV infected women have longer duration of transient infections resulting in (longer) infertility. Considering the low IUI success rates IVF or ICSI might be indicated in HPV positive couples to increase the pregnancy rate.
Trial registration number: Not applicable.

P-375 Time to empty the bladder after a fresh embryo transfer does not affect pregnancy rates in IVF cycle

S. Llavador-Guerrero[1], J.C. García-Lozano[1], M.D. Lozano-Arana[2], J. Guisado-Fernandez[1], B. Sánchez-Andújar[2], J.L. Moliní-Rivera[1], G. Antiñolo-Gil[3]
[1]*Hospital Universitario Virgen del Rocío, Assisted Human Reproduction, Sevilla, Spain*
[2]*Hospital Universitario Virgen del Rocío, Laboratory, Sevilla, Spain*
[3]*Hospital Universitario Virgen del Rocío, Assisted Human Reproduction-Fetal Medicine, Sevilla, Spain*

Study question: The influence of the moment of empty the bladder after a fresh embryo transfer (ET) on pregnancy rates in IVF and when is more confortable.
Summary answer: Time to empty the bladder after a ET has no influence on pregnancy rates; delaying it doesn't suppose more success and it is more uncomfortable.
What is known already: Many factors influence the success of assisted reproductive techniques, from both patients and the embryo. Most important factors are maternal age, ovarian reserve, embryo quality, endometrial receptivity and ET technique. To facilitate the ET is necessary that the angle of the uterus is corrected. A full bladder allows it. It has shown that patients with less uterine contractions after ET are more likely to get pregnant and that there are movements of the embryo after ET. It has not shown any action after ET to increase pregnancy rates. We don't know the effect of empty the bladder after ET.
Study design, size, duration: This prospective, randomized, analytical and experimental study included a total of 99 patients from Human Assisted Reproduction Service of our hospital, and was conducted between August 2014 and November 2014. Patients were divided into three groups. Informed consent was signed by patients.
Participants/materials, setting, methods: Patients of our Assisted Reproduction Service with fresh ET were divided in three cohorts at randomization, by an Excel table that allowed a blinded study. A. Empty the bladder after the ET. B. Wait 20 min after ET to empty the bladder. C. Urinary catheterization after the ET. Patients came with full bladder and took rest for 20 min after ET. We compared pregnancy rates and satisfaction (telephone survey). It was analyzed with SPSS.
Main results and the role of chance: No significant differences between biochemical pregnancy rates and clinical pregnancy among the three study groups were found. Biochemical pregnancy rates and clinical pregnancy rates were 30.3%, 32.3%, 28.1% (p = 0.938) and 25% 29% 21.9% (p = 0.807) respectively for cohorts A, B and C. The implantation rate for group A was 0.16, 0.14 for group B and 0.11 for group C (p = 0.763). Patient satisfaction from 0 to 10 by the study groups A, B or C in terms of comfort bladder emptying was respectively: 8.65 ± 1.69, 5.3 ± 3.58 and 7.37 ± 2.69. As we can see, A group scored higher satisfaction.
Limitations, reasons for caution: Live birth rate was not studied. Studies are needed to indicate the live birth rate and larger n in order to obtain greater statistical power.
Wider implications of the findings: The moment of empty the bladder after a ET has no influence in pregnancy rates, so delay it supposes no more success and it is more uncomfortable for patients. Therefore, we should consider it in order to minimize the anxiety and discomfort that this question produces in patients.
Trial registration number: No required.

Abstract withdrawn by the author

P-377 Subcutaneous progesterone is effective and safe for luteal phase support in IVF: an individual patient data meta-analysis of the phase III trials

J. Doblinger[1], B. Cometti[2], S. Trevisan[2], G. Griesinger[3]
[1]*Paracelsus Medical University, Obstetrics and Gynecology, Salzburg, Austria*
[2]*IBSA Institut Biochimique SA, R&D Scientific Affairs, Lugano, Switzerland*

[3]University Hospital of Schleswig-Holstein, Department of Gynecological Endocrinology and Reproductive Medicine, Luebeck, Germany

Study question: To summarize efficacy and safety of subcutaneous (s.c.) progesterone as compared to vaginally administered progesterone for luteal phase support in patients undergoing IVF.
Summary answer: No statistical significant or clinical significant differences exist between subcutaneous and vaginal progesterone for luteal phase support.
What is known already: A recent Cochrane review reported that luteal phase support with progesterone is associated with higher rates of live birth or ongoing pregnancy as compared to placebo. Two large phase III studies (07EU/Prg06 and 07USA/Prg05) on s.c. progesterone were finalized in 2013. Both studies were designed and conducted to establish non-inferiority of ongoing pregnancy likelihood in patients undergoing IVF or ICSI and receiving luteal phase support with daily s.c. injections of 25 mg progesterone as compared to vaginally administered progesterone gel or progesterone tablets. Each study showed non-inferiority of s.c. progesterone in relation to vaginal progesterone.
Study design, size, duration: This meta-analysis collates data from two phase III trials (07EU/Prg06, NCT00827983; 07USA/Prg05, NCT00828191) performed according to GCP standards, resulting in a total sample size of 1,483 randomized patients, 1,435 of whom underwent embryo transfer. Outcomes of interest were ongoing pregnancy rate, live birth rate and OHSS risk. Analysis was performed on the level of individual patient data. A comprehensive literature search revealed no further randomized studies on s.c. progesterone usage in IVF.
Participants/materials, setting, methods: A sample size of 1,483 women between 18 and 42 were included in the study. In both studies inclusion criteria were similar, e.g., BMI <30 kg/m^2, <3 prior ART cycles (IVF, ICSI and related procedures), baseline (cycle day 2 or 3) FSH <15 IU/L and E_2 <80 pg/ml, normal uterine cavity as per recent hysterosalpingogram, sonohysterogram or hysteroscopic exam (i.e., no polyp or protruding sub-mucosal fibroid), at least 3 retrieved oocytes and written informed consent.
Main results and the role of chance: The administration of subcutaneous progesterone versus intra-vaginal progesterone had no impact on ongoing pregnancy likelihood (OR = 0.865, 95% CI 0.694–1.077; *P* = n.s.), live birth likelihood (OR = 0.889, 95% CI 0.714–1.106; *P* = n.s.) or OHSS risk (OR = 0.995, 95% CI 0.565–1.754; *P* = n.s.) in regression analyses accounting for clustering of patients within trials, while adjusting for important confounders. Only female age and number of oocytes retrieved were significant predictors of live birth likelihood and OHSS risk.
Limitations, reasons for caution: Licensing studies are conducted in a selected patient population and the external validity of the findings is limited to similar cohorts in daily practice. Furthermore, only IVF cycles with fresh ET were included in the two phase III studies.
Wider implications of the findings: Subcutaneous progesterone 25 mg/day represents a valid alternative to vaginal progesterone and is as efficacious and safe. No further clinical study on the use of s.c. progesterone has been published so far. We expect that the use of s.c. progesterone will be studied in various scenarios, such as frozen-thawed cycles.
Trial registration number: N/A.

P-378 Special considerations for fertility preservation in patients with cervical cancer

G. Ghourab[1], S. Lavery[1]
[1]Imperial NHS Trust, IVF Hammersmith, London, UK

Study question: The aim of this study was to evaluate outcome of cycles and future obstetrical challenges in patients with cervical cancer presenting for fertility preservation.
Summary answer: Even though initial results for outcomes of cycles of oocyte/embryo cryopreservation are promising, long-term results in relation to oncological and obstetrical outcome are still needed.
What is known already: Fertility preserving surgery has been shown to have high success rates in patients with early stage disease. In patients with tumour size ≥2 cm, downstaging with neoadjuvant chemotherapy followed by fertility preserving surgery is being performed, however this is still experimental and long term oncological outcomes are unknown. In this subgroup of patients, fertility preservation by means of oocyte/embryo cryopreservation may be performed, however there has been no previous data assessing outcomes of ART cycles in patients with cervical cancer, particularly with regards to route of oocyte collection with the presence of a cervical mass and future obstetric outcomes.
Study design, size, duration: Retrospective analysis of 15 patients diagnosed to have cervical cancer that presented for fertility preservation between the years 2007 and 2015. Data was obtained from the IVF Hammersmith database.
Participants/materials, setting, methods: Fifteen patients diagnosed with cervical cancer underwent 16 cycles of oocyte and/or embryo cryopreservation. Seven patients presented prior to excision of cervical mass; 4 had laparoscopic oocyte retrieval and 3 had trans-vaginal oocyte retrieval. One patient presented after radical trachelectomy and ovarian transposition and had laparoscopic oocyte retrieval then had a repeat cycle and underwent transvaginal oocyte retrieval from one accessible ovary. Seven patients presented after radical trachelectomy and had trans-vaginal oocyte retrieval of oocytes.
Main results and the role of chance: Mean age at presentation was 30 (range 24–38 years). Histological diagnosis: squamous cell in 13 patients, adenocarcinoma in 1 patient, and large cell neuroendocrine tumour in 1 patient. Stage of cervical cancer at presentation: lB1 in 6 patients, IB2 in 3 patients, IIB in 6 patients. Five patients had laparoscopic oocyte retrieval; mean number of days of stimulation was 9, mean total dose of recombinant FSH was 1,434 IU and mean number of oocytes collected was 6. Seven patients with previous radical trachelectomy had transvaginal oocyte retrieval; mean number of days of stimulation was 11, mean total dose of recombinant FSH was 2,736 IU and mean number of oocytes collected was 15. Three patients had trans-vaginal oocyte retrieval with presence of cervical mass; mean number of oocytes collected was 15 and cancer free period to date is 50 months, 32 months and 12 months respectively. Ten patients had embryo cryopreservation, 2 had oocyte cryopreservation and 2 had oocyte and embryo cryopreservation. Two patients had three cycles of frozen embryo replacement cycles in a surrogate, all of which did not result in a pregnancy. One patient had an elective single embryo transfer post trachelectomy that resulted in a clinical pregnancy.
Limitations, reasons for caution: This is a retrospective analysis of our database and sample size is small, hence not enough data is available to evaluate safety and possible recurrence rates when transvaginal oocyte retrieval is performed with the presence of a cervical mass. Data is also insufficient to conclude on future pregnancy outcomes.
Wider implications of the findings: Transvaginal oocyte retrieval with the presence of a cervical mass is a novel procedure, and in experienced hands may be performed safely and yield a higher number of oocytes than laparoscopic oocyte retrieval. Patients need to be aware about the future need for a surrogate prior to undergoing this.
Trial registration number: N/A.

P-379 Predicting the success of IVF: external validation of the van Loendersloot's model

R. Biancardi[1], M. Reschini[1], A. Busnelli[1], A. Paffoni[1], E. Somigliana[1], V. Sarais[2]
[1]Ospedale Maggiore Policlinico-Regina Elena, Obstetrics and Gynecology, Milano, Italy
[2]Scientific Institute San Raffaele, Obstetrics and Gynaecology, Milano, Italy

Study question: Is the predictive model for IVF success proposed by van Loendersloot et al. valid in a different geographical and cultural context?
Summary answer: The model discriminates well but less than in the original context where it was developed.
What is known already: Several independent groups have developed models with the aim of estimating the chance of pregnancy with IVF but only four of them were externally validated. One of these, the van Loendersloot's model, deserves particular attention and further investigation for at least three reasons: 1) the Area under the receiver operating characteristics curve (*c*-statistics) in the temporal validation setting was the highest reported to date (0.68), 2) the perspective of the model is clinically wise since it includes variables obtained

from previous failed cycles. It thus adapts to any woman entering an IVF cycle, 3) the model lacks geographical external validation.

Study design, size, duration: Retrospective cohort study of women undergoing oocytes retrieval for IVF between January 2013 and December 2013 at the infertility unit of the Fondazione Ca' Granda, Ospedale Maggiore Policlinico of Milan, Italy. Women were enrolled only for their first oocytes retrieval cycle performed during the study period. They were excluded if they underwent previous IVF cycles in other centers. The main outcome was the cumulative live birth rate per oocytes retrieval.

Participants/materials, setting, methods: Seven hundred seventy-two women were selected. Variables included in the van Loendersloot's model and the relative weights (beta) were used. The variable resulting from this combination (Y) was transformed into a probability. The discriminatory capacity was assessed using the *c*-statistics. Data is presented using both the original and the calibrated models obtained with a logistic regression. Performance was evaluated correlating the mean predicted chances of live births in the five quintiles and the observed rates.

Main results and the role of chance: Two-hundred-eleven live births (27%) were obtained. The *c*-statistics was 0.64 (95%CI: 0.61–0.67, $p < 0.001$). The slope of the linear predictor (calibration slope) expressed as an Odds Ratio was 1.81 (95%CI: 1.46–2.24, $p < 0.001$), corresponding to a beta of 0.630. The calibration intercept was +0.349 ($p = 0.13$). While a clear discrepancy exists using the original model, data appears properly distributed with the calibrated model. The Pearson coefficient of the correlation between the mean predicted chances of live births in the five quintiles and the observed rates was 0.99 ($p = 0.002$).

Limitations, reasons for caution: The selection criteria for access to IVF adopted in our center might be too stringent, leading to the exclusion of women with yet acceptable chances of live birth. The validity of the model in women at very low chance of live birth could not thus be tested.

Wider implications of the findings: The van Loendersloot's model can be used in other contexts but needs important calibration. It may be of help for counselling couples about their chance of success but it cannot be used to decline treatments. Further research is needed to improve the discriminatory performance of IVF predictive models.

Trial registration number: Not applicable.

P-380 Utility of three-dimensional ultrasound (3D-US) in screening for subtle septum in infertile women with arcuate uteri prior to IVF: a scenario economic analysis

A. Abdelmagied[1], M. Kamel[2], A. Abuelhasan[2], A. Nassr[2], A. Hamed[3], S. Shazly[4], A. Kamel[2], M. Makarem[2]
[1]*Assiut University, IVF center of Women Health Hospital, Obstetrics and Gynecology, Assiut, Egypt*
[2]*Women Health Hospital, Assiut University, Obstetrics and Gynecology, Assiut, Egypt*
[3]*Cambridge University Hospitals., Obstetrics and Gynecology, Cambridge, UK*
[4]*Mayo Clinic College of Medicine, Obstetrics and Gynecology, Rochester, MN, USA*

Study question: Is utility of 3D-US a cost-effective screening strategy for subtle septae in infertile women with hysterosalpingographic (HSG) diagnosis of arcuate uterus prior to IVF?

Summary answer: Prior to IVF, 3D-US screening for subtle uterine septae in infertile women with HSG diagnosis of arcuate uterus seems to be a cost-effective strategy.

What is known already: Current evidence suggests that, unlike arcuate uterus which has no effect on implantation, small and large uterine septae could be deleterious. Increase in live birth rate (LBR) has been reported after resection of uterine septae prior to IVF. Subtle septae have been reported by recent studies in women with HSG diagnosis of arcuate uterus who had prior failed IVF. These septae are diagnosed by office hysteroscopy after repeated IVF failure. Yet, no studies have addressed the value of 3D-US screening for subtle septum prior to first IVF cycle in this group of IVF women in terms of LBR and economics.

Study design, size, duration: A decision analysis model was constructed for a hypothetical cohort of 100 infertile women with HSG diagnosis of arcuate uterus scheduled for first IVF cycle, to compare the cost of 2 scenarios (strategies) over 2 successive IVF cycles; (1) Screening for subtle septum by 3D-US prior to IVF. (2) Proceeding to IVF without 3D-US screening. (No 3D-US strategy). Baseline input probabilities were derived by review of the published literature.

Participants/materials, setting, methods: Prevalence of misdiagnosed septate uterus in our hypothetical cohort, and the effect of hysteroscopic metroplasty on LBR were obtained from the available evidence in literature. Medicare National Fee Estimates were considered for costs assumptions. Study endpoints included cumulative LBR and the incremental cost-effectiveness ratio (ICER) after 2 IVF cycles. Costs were reported in 2015 US dollars. Sensitivity analysis was performed, to examine the effect of variation of the baseline inputs.

Main results and the role of chance: Screening for subtle uterine septum in women with hysterosaplingographic diagnosis of arcuate uterus prior to IVF was more cost effective than No 3D-US strategy. After 2 IVF cycles, 3D-US screening strategy resulted in cumulative LBR, costs per one LB and costs per infertile couple of 48%, $45,872 and $22,019, respectively compared to 33%, $73,310 and $24,192 in No 3D-US strategy. 3D-US implementation would cause initial extra-costs of $26.900; however, this would save extra-costs of $217,351 required by women with failed IVF for additional IVF cycles and additional office hysteroscopy evaluation of their uterine cavities to detect the missed septum as a cause of IVF failure. In No 3D-US strategy, the extra costs for achieving an additional LB; the ICER was $14,490. Sensitivity analyses were robust.

Limitations, reasons for caution: Hypothetical rather than actual estimates of cost present a limitation of this study**.**

Wider implications of the findings: Adoption of 3D-US, to reevaluate arcuate uteri initially diagnosed by HSG prior to IVF, could minimize the financial burden that infertile couple will suffer from failed cycle due to missed septum. This strategy may be helpful, since randomized controlled trials in IVF women face recruitment challenges.

Trial registration number: NA.

P-381 Iron and vitamin status in Italian female patients undergoing *in vitro* fertilization (IVF)

I. La Vecchia[1,2], M. Castiglioni[1,2], A. Paffoni[1], S. Ferrari[1], C. Ferraris Fusarini[3], N. Bettinardi[3], E. Somigliana[1], F. Parazzini[2]
[1]*Fondazione IRCCS Ca Granda Policlinico, Obstetrics and Gynecology, Milano, Italy*
[2]*Università degli Studi di Milano, Obstetrics and Gynecology, Milano, Italy*
[3]*Fondazione IRCCS Ca'Granda Policlinico, Central Laboratory, Milano, Italy*

Study question: To evaluate homocysteine and related B-vitamins, red-blood-cells (RBC) folate, vitamin A, vitamin E and iron status in a population of women undergoing *in vitro* fertilization.

Summary answer: A large proportion of women had RBC folate, vitamin B12, vitamin A deficiencies. Homocysteine was above adequate levels in less than one third of women.

What is known already: Biochemical indicators, including vitamins and iron-status indicators can be important to assess the health and nutrition status of specific populations. Nutrition deficiencies vary by age, gender or race/ethnicity and could be extremely relevant for certain population groups like childbearing women because they can influence the outcome of pregnancy and/or the health of the baby. Iron deficiency is the most common nutrient deficiency in the developed world and women of childbearing age are at greatest risk because of the effects of menstruation.

Women seeking a pregnancy are generally encouraged to receive adequate nutrition, and multivitaminic/multimineral supplementation.

Study design, size, duration: This is a cross-sectional study of 269 caucasian women aged 18–45 consecutively scheduled for IVF. Each identified subject was interviewed about her medical history and vitamin/mineral dietary supplements. Recruitment period lasted from March to December 2015.

Participants/materials, setting, methods: During routine blood sample examination before IVF treatment an additional amount of fasting venous blood

was drawn in order to measure: folate, RBC folate, homocysteine, vitamin B12, vitamin A, vitamin E, iron and ferritin. Samples were immediately taken to the laboratory to be processed within 2 h (vitamin B12, homocysteine, iron and ferritin) or stored at −20°C until assayed (serum folate, RBC folate, vitamin A and vitamin E).

Main results and the role of chance: The mean age of the enrolled women was 37 ± 4 (range 27–45) years; the mean BMI was 22.3 ± 4.3 (range 15.2–51.1 Kg/m^2). Percentages [95%CI] of women reaching concentration levels considered appropriate for the general population (reported between brackets) together with mean ± standard deviation values were: Serum folate (>6.6 ng/ml): 78% [72-83%]; 11.4 ± 5.4 ng/ml RBC folate (>225 ng/ml): 74%[69–79%]; 293 ± 91 ng/ml. Homocysteine (<10 mM/L): 69% [64–75%]; 9.4 ± 4.0 mM/L. Vitamin B12 (>474 pg/ml): 44% [38–50%]; 476 ± 216 pg/ml. Vitamin A (>0.4 mg/L): 44% [37–49%]; 0.40 ± 0.10 mg/L. Vitamin E (>5 mg/ml): 100% [99–100%]; 12.4 ± 2.3 mg/ml. Serum iron (>60 mcg/dl): 83% [78–88%]; 93.0 ± 36.5 mcg/dl Serum ferritin (20–200 mg/L): 82% [77–87%]; 53.0 ± 39.4 mg/L. When considering the RBC folate threshold suggested to achieve the greatest reduction of NTDs (400 ng/ml), the percentage of women with adequate levels dropped to 12% [8–16%]. The use of folate/vitamin supplements significantly (p = 0.001) increased the percentage of women with adequate levels of serum folate (94% [89–97%] versus 64% [55–72%]), RBC folate (22% [15–31%] versus 3% [1–7%]), homocysteine (83% [77–90%] versus 56% [48–65%]) in users compared to non users, respectively.

Limitations, reasons for caution: Reference values for most vitamins are matter of debate. We mainly refer to thresholds used in the Italian population. Different thresholds may significantly modify the scenario. Moreover, caution is needed for inferences to other contexts. Dietary habits influence biochemical indicators and differ according to social/medical conditions, ethnicity, region/country of provenance.

Wider implications of the findings: Our results highlight relevant deficiencies in iron and vitamin status of women initiating IVF. Of note, a small minority of women showed optimal RBC-folate levels. Given the role of folate in the prevention of important diseases, more effective public health strategies are needed to increase the use of dietary supplements.

Trial registration number: NA.

P-382 Type of gonadotropin does not affect either oocyte quality or follicular fluid endocrine profile during ovarian stimulation in oocyte donors

P. Alamá Faubel[1], M. Cruz[2], M. Muñoz[3], A. Pacheco[4], D. Collado[5], A. Requena[5]
[1]*IVICO & IVI Teaching Program Equipo IVI, Infertility, Valencia, Spain*
[2]*IVI Madrid, IVF Laboratory, Madrid, Spain*
[3]*IVI Alicante, Gynecology, Alicante, Spain*
[4]*IVI Madrid, Andrology, Madrid, Spain*
[5]*IVI Madrid, Gynecology, Madrid, Spain*

Study question: Is it possible to stimulate with any gonadotropin without affecting oocyte quality in a donor program?

Summary answer: Results from endocrine profile and apoptosis rate suggest that type of gonadotropin does not affect oocyte quality when stimulating a donor.

What is known already: Type of gonadotropin determines FSH levels in serum and follicular fluid, based in the proportion of acid residues in the FSH molecules. This should be considered due to gonadotropins are the main physiological regulatory hormones of follicular survival because of their anti-apoptotic properties; in addition, sex steroids act as an important regulators of intra-ovarian follicular atresia, meaning that an increased amount of estrogens are related to reduced apoptotic activity.

Study design, size, duration: A multicentre prospective randomized study was performed in 3 private clinics belonging to IVI group. Oocyte donors (n = 215) undergoing their first stimulation cycle were allocated to a stimulation group with recombinant FSH, highly-purified human menopausal gonadotropin HP-hMG or corifollitropin alfa. Blood samples were obtained on the day of hCG administration for estradiol (E2) analysis. Apoptosis rate was determined by flux cytometry in cumulus cells and hormonal profile in follicular fluid, both obtained at oocyte pick-up.

Participants/materials, setting, methods: Subjects were assigned to receive 100 µg of corifollitropin alfa which was potentially followed by daily administration of recombinant FSH (rFSH) from day 8 if instructed by the researcher (n = 67), or daily doses of 150 UI rFSH (n = 73) or 225 UI HP-hMG (n = 75). Daily doses of 0.25 mg GnRH antagonist were started on day 6 of stimulation in all groups. A single dose of GnRH agonist (0.2 mg) was administered for triggering final oocyte maturation.

Main results and the role of chance: According endocrine profile in follicular fluid, FSH concentration were significantly lower in the rFSH group (5.00 UI/L) vs. corifollitropin alfa (7.11 UI/L) or HP-hMG (7.15 UI/L), p = 0.05, while estradiol concentration were significantly higher in the HP-hMG group (1,885,545 pg/ml) compared to recombinant FSH (396,582 pg/ml) and corifollitropin alfa (597,398 pg/ml), p = 0.002. In serum, we found a significant higher estradiol concentration in the group stimulated with HP-hMG (3,643 pg/ml) compared with rFSH (1,542 pg/ml) and corifollitropin alfa (1,456 pg/ml), $p < 0.001$. Apoptosis rate in cumulus cells did not differ between all the study groups being the results as follows: 26.5% in the rFSH group, 26.2% in the corifollitropin alfa stimulation and 24.1% in the HP-hMG group, p = 0.840

Limitations, reasons for caution: This study has been performed in oocyte donors, which form a fairly homogeneous group in terms of age and ovarian response, so these results may not be extrapolated to other groups of women undergoing an assisted reproductive treatment.

Wider implications of the findings: Despite of the higher concentrations of FSH observed in follicular fluid from donors stimulated with HP.hMG or corifllitropin alfa, probably due to an acidic and longer half-life FSH, the absence of differences in apoptosis rate means the possibility of stimulating oocyte donors with any drug without compromising clinical results.

Trial registration number: NCT02213627

P-383 Effect of *in vitro* and *in vivo* acrylamide exposure on mouse oocyte

O. Cinar[1], D. Aras[1], Z. Cakar[1], S. Ozkavukcu[2], A. Can[1]
[1]*Ankara University School of Medicine, Histology–Embryology, Ankara, Turkey*
[2]*Ankara University, IVF Center, Ankara, Turkey*

Study question: Does acrylamide have harmful effects on *in vitro* and *in vivo* oocyte maturation?

Summary answer: Acrylamide blocks *in vivo* oocyte maturation by its metabolite, glycidamide, but it does not affect *in vitro* oocyte maturation.

What is known already: Acrylamide is a chemical that widely used in the treatment of wastewater, paper/pulp manufacturing, mining and scientific research. Processed foods such as roasted almonds, coated peanuts, dips, fried potato, biscuits, coffee, contain high levels of acrylamide. The consultation of the United Nations Food and Agricultural Organization and the World Health Organization on "Health Implications of Acrylamide in Food", indicated several important points such as; dietary habits in particular countries may lead to severe carcinogenic implications, as well as genotoxicity. Acrylamide effects on the oocyte maturation and meiotic spindle still need to be evaluated.

Study design, size, duration: BALB/c mice were used. *In vitro* and *in vivo* maturation kinetics of acrylamide treated oocytes (n = 182 and n = 133, respectively) were compared to control group (n = 77 and n = 102). *In vitro* maturation dynamics of glycidamide treated oocytes (n = 61) were compared to control oocytes (n = 24). Meiotic spindles were evaluated under a confocal microscope following fluorescently labeling the meiotic chromosomes and spindle microtubules.

Participants/materials, setting, methods: *In vitro* maturation kinetics of control oocytes were compared to 100, 500 or 1,000 µM of acrylamide treated ones. *In vivo* maturation analyses were performed following oocyte isolation from the animals that were intraperitoneally treated with either vehicle or 25 mg/kg/day of acrylamide for 7 days. To test whether *in vivo* effects of acrylamide resulted from its metabolite glycidamide or not, isolated oocytes were treated with 25 or 250 µM of glycidamide.

Main results and the role of chance: *In vitro* acrylamide exposure did not affect *in vitro* oocyte maturation and meiotic spindle. *In vivo* acrylamide

treatment caused an accumulation of oocytes at prometaphase-I (10.3% vs. 2.3% in controls, $p = 0.039$). Majority of the M-II stage oocytes from *in vivo* acrylamide treated group showed a decrease in the meiotic spindle mass and a misalignment of the chromosomes. This finding indicated that acrylamide might show its action via its metabolite glycidamide. Therefore, isolated GV-stage oocytes treated with 25 or 250 µM of glycidamide *in vitro*. All oocytes were degenerated after the culture period.
Limitations, reasons for caution: This study presents the outcomes of an animal model. It will be a good contribution if the effects of acrylamide or glycidamide were evaluated in human (discarded) oocytes that can be obtained from *in vitro* fertilization laboratories. Additionally, long and short terms reproductive effects of acrylamide need to be evaluated.
Wider implications of the findings: Dietary habits have been changing in parallel with the modern life. The finding, which acrylamide negatively affects oocyte maturation, suggests that it may reduce fertilization and implantation rates and could cause aneuploidy in higher doses, and thus implies that changing dietary habits must be reconsidered regarding female fertility.
Trial registration number: N/A.

P-384 The use of donor sperm in addition to donated oocytes after repeated implantation failure with donated oocytes does not improve live birth rates

A. Blazquez[1], D. Garcia[2], A. Rodriguez[1], R. Vassena[1], V. Vernaeve[1]
[1]*Clinica Eugin, Clínica Eugin, Barcelona, Spain*
[2]*Fundació EUGIN, Clínica Eugin, Barcelona, Spain*

Study question: Does switching to donor sperm in a subsequent cycle after repeated implantation failures in several cycles with donated oocytes increase the live birth rate?
Summary answer: Switching to donor sperm after several implantation failures in cycles with donated oocytes and partner sperm does not increase live birth rate.
What is known already: About 2% of patients receiving donated oocytes experience repeated implantation failures, despite normal anatomy of the uterine cavity and a diagnostic biopsy dismissing endometrial hyperplasia or endometritis, normal sperm characteristics, normal male karyotype, and a normal thrombophilia panel (antithrombin III activity, protein "S" coagulation inhibitory activity, anti-microsomal antibodies, antibody antitireoglobulin thyrotropin, lupus anticoagulants, protein "C" coagulation inhibitory activity, anticardiolipin IgM and IgG antibodies, resistance to activated protein C, homocysteine, prothrombine mutation 20,210). The ESHRE Capri Workshop Group indicates that donated semen can be offered after 3 failed cycles in order to improve reproductive outcomes, without evidence of male factor.
Study design, size, duration: Retrospective cohorts study including cycles with donated oocytes and either normozoospermic partner sperm (OD) or with donation of both oocyte and sperm (DD), performed following at least 3 oocyte reception cycles with implantation failure, performed between January 2011 and December 2014 in a large fertility center.
Participants/materials, setting, methods: The study included 228 cycles, 159 in OD group and 69 in DD group. The main outcome was live birth rates, analyzed with both a univariate and a multivariate approach, adjusted for the oocyte recipient's age and body mass index (BMI), day of embryo transfer, number of transferred embryos and embryo quality. Secondary outcomes were biochemical, clinical, and ongoing pregnancy rates.
Main results and the role of chance: There was no difference in live birth rate between the DD and OD groups (38.2% vs. 35.8%, $p = 0.73$), even after adjustment for confounding factors (OR 1.41, 95%CI 0.72, 2.75; $p = 0.31$). Rates of biochemical pregnancy (52.2% vs. 54.1%, $p = 0.79$), clinical pregnancy (41.2% vs. 45.9%, $p = 0.51$) and ongoing pregnancy (38.2% vs. 37.1%, $p = 0.87$) were similarly not different between the DD and the OD groups. The DD and OD groups were comparable at baseline in all demographic and cycle variables analyzed (recipient's BMI, number of transferred embryos and embryo quality) with exception of the recipient's age (42.3 in DD vs. 44.1 in OD), and day of embryo transfer (56.5% of DD and 83.6% of OD embryo transfers were performed on blastocyst stage); both variables were adjusted for in the multivariate analysis.
Limitations, reasons for caution: The main limitation of this study is its retrospective nature, and the lack of extensive molecular testing of sperm in normozoospermic patients. This last limitation is significantly attenuated by the lack of improvement in reproductive outcomes when changing partner semen for donor semen.
Wider implications of the findings: In cases of repeated implantation failure with donated oocyte and normozoospermic sperm, switching to donor sperm should not improve results. In disagreement with currently published guidelines, the physician should probably not offer the change to donor's sperm without a clinical indication of male factor infertility.
Trial registration number: NA.

P-385 Time from egg retrieval to embryo transfer does not affect live birth rates in a freeze-all strategy

K. Lattes[1], M.A. Checa[1], R. Vassena[2], M. Brassesco[1], V. Vernaeve[2]
[1]*CIRH BARCELONA, Medicina Reproductiva, Barcelona, Spain*
[2]*Clinica Eugin, Clínica Eugin, Barcelona, Spain*

Study question: Does time from ovum pick-up (OPU) to frozen embryo transfer (FET) affect live birth rates in a freeze-all strategy?
Summary answer: Performing FET on the first or subsequent menstrual cycles after OPU does not affect live birth rates (LBR) in a freeze-all strategy.
What is known already: Controlled ovarian stimulation (COH) leads to altered endometrial gene expression patterns, histological advancement, and decreased reproductive outcomes by affecting the embryo-endometrium synchrony. There's little information regarding the amount of time it takes for gene expression to return to its normal pattern. Moreover, delaying FET may have a significant emotional impact on patients, which adds up to the stress and anxiety that accompanies a standard IVF cycle. So far, there is no agreement on the best moment to perform a FET after freeze-all in order to maximize reproductive outcomes for the patient.
Study design, size, duration: Retrospective, cross-sectional study of 680 freeze-all cycles, corresponding to 649 women, performed between January 2012 and December 2014. COH was performed by either a GnRH-antagonist or a long GnRH-agonist protocol. Ovulation was triggered using either a GnRH-agonist ($n = 357$) or hCG ($n = 323$). Endometrial preparation was performed by either a modified natural ($n = 117$) or an artificial cycle ($n = 563$).
Participants/materials, setting, methods: Reproductive outcomes between FET who took place within the first menstrual cycle following OPU ($n = 324$) or afterwards ($n = 356$) were compared. Student's *t*-test for independent samples and Chi-square analysis were used as needed. A multivariate logistic regression analysis was performed adjusting for maternal age, drug used for ovulation trigger, number of retrieved oocytes, number of embryos obtained, day of embryonic development at transfer, and number of transferred embryos. Differences were considered significant if $p < 0.05$.
Main results and the role of chance: There was no difference in live birth rate between FET performed during the first menstrual cycle following OPU vs. subsequent menstrual cycles (36.4% vs. 32.3%, respectively; $p = 0.258$). Moreover, we found no difference in implantation rate (32.5% vs. 29.5%; $p = 0.289$), as well as biochemical pregnancy (49.7% vs. 48.3%; $p = 0.719$), clinical pregnancy (43.5% vs. 41.3%; $p = 0.555$), and pregnancy loss (13.3% vs. 15.7%; $p = 0.363$) between FET performed during the first menstrual cycle following OPU vs. subsequent menstrual cycles. A multivariate analysis found no impact of timing of elective FET on live birth rates (OR 0.87; 95% CI 0.62–1.21). The impact remained not significant after adjusting for drug used for ovulation trigger (hCG vs. GnRH agonist) and endometrial preparation protocol (natural vs. artificial). The factors that significantly affected live birth rates were, as expected, maternal age (OR 0.93, 95% CI 0.89–0.97), number of retrieved oocytes (OR 1.03, 95% CI 1.001–1.06), day of embryonic development at transfer (day + 3 vs. + 4; OR 1.53; 95% CI 1.02–2.29) and number of transferred embryos (OR 1.75, 95% CI 1.25–2.46).
Limitations, reasons for caution: The main limitation of our study is its retrospective nature. Although we adjusted our statistical analysis for a number of known and suspected confounders, we cannot exclude the possibility of residual confounding factors.
Wider implications of the findings: According to our results, clinicians do not need to wait more than one menstrual cycle before performing FET. This allows

us to reduce the psychological impact that delaying embryo transfer can have on our patients, without compromising reproductive outcomes.
Trial registration number: NA.

P-386 Concordance of vitamin D levels in the infertile couples' partners

A. Mangiarini[1], A. paffoni[2], L. restelli[2], S. ferrari[2], R. biancardi[2], E. somigliana[2], P. vigano'[3]
[1]*Fondazione Ca' Granda Ospedale Maggiore Policlinico, Milano, Italy*
[2]*Fondazione Ca' Granda Ospedale Maggiore Policlinico, Infertility Unit, Milano, Italy*
[3]*Ospedale vita e Salute San Raffaele, Infertility Unit, Milano, Italy*

Study question: Do vitamin D serum levels correlate in infertile couples' partners?
Summary answer: Serum Vitamin D levels highly correlate between the partners of infertile couples.
What is known already: There is emerging evidence suggesting a role of insufficient vitamin D in both male and female infertility. However, until now, available studies have focussed separately on the male or female partners. Given the crucial role of dietary and lifestyle habits in influencing peripheral levels of vitamin D, one may conversely hypothesize that levels may significantly correlate within couples' partners. In other words, vitamin D insufficiency may display its detrimental effects through both partners. However, evidence in favour of a correlation of vitamin D status between the partners of infertile couples is lacking in the literature.
Study design, size, duration: Between March and May 2014, couples referred to the Infertility Unit of the Fondazione Ca' Granda for IVF were consecutively considered for study entry. Initial selection criteria were as follows: female age 18–42 years and female body mass index (BMI) ≤25 Kg/m2. Exclusion criteria for both partners were a history of malignancy, hypertension, diabetes, multiple sclerosis, need for chronic medical treatments, autoimmune disorders and coronary, hepatic or renal diseases.
Participants/materials, setting, methods: Eligible couples accepting to participate provided a serum sample for 25-hydroxy-vitamin D [25(OH)D] measurement during the routine clinical assessment that preceded the initiation of an IVF cycle. The quantitative detection of total 25(OH)D levels was performed on fresh samples using a commercially available kit based on a chemiluminescence technology. Subjects were grouped according their serum levels of vitamin D, namely: "insufficient" when 25(OH)D was <20 ng/ml or "sufficient" when it was ≥20 ng/ml.
Main results and the role of chance: One hundred and three eligible couples were included. The mean ± SD 25(OH) levels were 16.4 ± 6.2 and 17.2 ± 6.0 ng/ml, in female and male partners, respectively ($p = 0.17$). They were significantly correlated, with a Pearson's r = 0.52 ($p = 0.001$). The number of women with 25(OH)D serum levels <20 ng/ml and ≥20 ng/ml were 73 (71%) and 30 (29%), respectively; similarly 77 (75%) men resulted insufficient for vitamin D level while 26 (25%) resulted sufficient. In 13 (13%) couples both partners showed sufficient vitamin D levels while in 60 (58%) couples both partners were classified as "insufficient"; on the contrary, 17 (16%) couples had "sufficient" female and "insufficient" male partner and 13 (13%) couples had male with 25(OH)D level ≥20 ng/ml and female <20 ng/ml. The contingency table highlighted an overall concordance rate equal to 73/103 (71%) compared to 30/103 (29%) couples showing discordance ($p = 0.007$). Comparing baseline characteristics between female with insufficient and sufficient vitamin D levels we did not found any differences with the exception for the presence of endometriosis, which is more frequent in the sufficient group. We failed to highlight any differences in sperm basal characteristics between men with sufficient and insufficient vitamin D levels.
Limitations, reasons for caution: The present study has been designed to describe vitamin D correlation between infertile requiring IVF. Data from the more general population of infertile couples is warranted. Moreover, the chances of pregnancy according to couple' vitamin D status were not investigated. Lastly, we did not investigate spousal concordance over time.
Wider implications of the findings: The study confirmed the high rate of vitamin D insufficiency in infertile patients and showed a high concordance between partners of IVF couples. Considering the possible effects of vitamin D on infertility, supplemental strategies involving both partners rather than only one may be wiser and deserve future investigations.
Trial registration number: Not applicable.

P-387 Expressions of aquaporin family in human luteinized granulosa cells and their correlations with IVF outcomes

H.J. Lee[1], B.C. Jee[2], K.C. Kim[3], W.Y. Paik[4], S.H. Kim[5]
[1]*CHA Fertility Center, Department of Obstetrics and Gynecology, Seoul, South Korea*
[2]*Seoul National University Bundang Hospital, Obstetrics and Gynecology, Seongnam, South Korea*
[3]*Hamchoon Women's Clinic, Obstetrics and Gynecology, Seoul, South Korea*
[4]*Gyeongsang National University Hospital, Obstetrics and Gynecology, Jinju, South Korea*
[5]*Seoul National University Hospital, Obstetrics and Gynecology, Seoul, South Korea*

Study question: Are mRNA for specific aquaporins (AQPs) expressed in human luteinized granulosa cells (GCs) and their expression levels correlated with *in vitro* fertilization (IVF) outcomes?
Summary answer: AQP1-7, 9, 11, and 12 was expressed in luteinized-GCs and AQP1 was negatively associated with retrieved-oocyte number and AQP7 was positively associated with fertilization rate.
What is known already: Currently, mRNA of AQP1–4 and AQP9 has been reported to be present in human GCs.
Study design, size, duration: Prospective observational study involving 111 women undergoing a stimulated IVF cycle.
Participants/materials, setting, methods: Luteinized GCs were obtained at the time of oocyte retrieval. The mRNA expressions of AQP0-12 were explored by RT-PCR in GCs from another 27 women, and mRNAs for AQP0, 8 and 10 were not detected. Real-time quantitative RT-PCR (qRT-PCR) was performed to quantify mRNA level of AQP1-7, 9, 11, and 12. The mRNA for luteinizing hormone receptor (LHR) and steroidogenic acute regulatory protein (StAR) were also quantified by qRT-PCR.
Main results and the role of chance: In samples from 111 women, retrieved oocyte number was negatively associated with the mRNA levels of AQP1, 4, 6, and 11 and LHR (r = –0.311, r = –0.233, r = –0.203, r = –0.194, and r = –0.202, respectively, $p < 0.05$ for each), however, after adjustment for woman's age and serum anti-müllerian hormone (AMH) levels, only correlation with AQP1 was found (r = –0.299, $p < 0.05$). Body mass index was negatively associated (after adjustment of age) with the mRNA level of AQP7 (r = –0.259, $p < 0.05$). Fertilization rate was positively associated with the mRNA level of AQP7 (r = 0.269, $p < 0.05$). The number or quality of embryos or clinical pregnancy was not associated with the mRNA levels of any of ten AQP subtypes. The mRNA levels for the ten AQP subtypes were correlated positively with LHR expression but negatively with StAR expression. Amongst high responders (oocyte number ≥14), the mRNA levels of AQP11 (1.4 ± 0.7 versus 1.7 ± 0.6) and LHR (1.3 ± 0.7 versus 1.7 ± 0.7) were significantly lower in the group with PCOS than in the non-PCOS group.
Limitations, reasons for caution: A relative small number of subjects in PCOS group would be the main limitation of our study.
Wider implications of the findings: AQP1 may be one of the factors that modulate individual ovarian response to exogenous gonadotropin. The mRNA level of AQP7 was positively associated with fertilization rate, which is a surrogate marker of oocyte competence, thus expression of AQP7 could be a marker for adequate folliculogenesis and healthy oocytes.
Trial registration number: No RCT.

P-388 Oocyte donation from a family-member

T. Shavit[1], T. Shaulov[2], J. Hasson[2], N. El-Ma'mary[2], S. Weon-Yong[2], W. Buckett[2], T. Tulandi[2]
[1]*MUHC Reproductive Center, McGill University, Montreal, QC, Canada*
[2]*MUHC Reproductive Center, McGill University, Obstetrics and Gynecology, Montreal, QC, Canada*

Study question: Does oocyte donation from a family-member improve success rates compared to that from an unrelated donor?
Summary answer: Oocyte donation from a family member or from an unrelated donor is associated with comparable rates of pregnancy and live birth.

What is known already: Oocyte donation is on the rise, mostly due to increasing number of older infertile women. In many countries, commercial oocyte donation is prohibited and paying the donor is illegal. Accordingly, recipients are required to find a donor to donate oocytes altruistically. Oocyte donation from a family member and especially from a sibling may be the most available option, and the ASRM ethics committee approves sister-to-sister oocyte donation. To date, there have been only several publications evaluating family member oocyte donation; they focused mainly on the psycho-social aspect and not on the clinical outcome.
Study design, size, duration: A retrospective cohort study performed at a single academic reproductive center.
Participants/materials, setting, methods: We compared the outcome of oocyte donation cycles from a family member (*n*: 123 cycles) and from an unrelated donor (298 cycles) conducted between 2010 and 2014. Subgroup analysis comparing the outcomes using sibling donor and unrelated donor was also performed.
Main results and the role of chance: Recipient basal FSH levels were lower in the family-member donor group (27.2 ± 27.1 IU/L) than in the unrelated donor group (38.0 ± 36.7 IU/L, *P*: 0.002, 95% CI −17.6; −4.1). More recipients in the non-family member group were menopausal (26.1% vs. 14.6%, $p = 0.01$ CI −0.2; −0.03). Family-member donors had higher previous parity (1.52 ± 1.55) than non-related donors (1.02 ± 1.14, $p = 0.02$ CI −0.6; −0.06). All other demographic characteristics as well as the cycle profiles were comparable. The rates of pregnancy, live birth and miscarriage rates were similar between the family member donor group and the unrelated donor group. There were 57 cycles of sibling donation (sister to sister). Sibling donors were older (33.9 ± 5.1 vs. 29.9 ± 5.3, $p < 0.0001$ CI 2.2;5.7) and had lower AFC (16.21 ± 10.2 vs. 21.1 ± 13.9, $p = 0.02$ CI −8.9; −0.8) than the unrelated donors, but the rates of pregnancy and live birth were not significantly different (42.9% and 22.8% in sibling-donor group vs. 50.3% and 22.8% in the non-related group).
Limitations, reasons for caution: Retrospective study.
Wider implications of the findings: Oocyte donation from sisters or other family members achieves comparable results compared to that from unrelated members. The former may be less expensive and more satisfying to the recipients. Oocyte donation from family members may be an acceptable option especially in countries where commercial donation is prohibited.
Trial registration number: N/A.

P-389 Oocyte cryopreservation for social reasons: a two-center study of the users' reproductive situations

G.C. Jou[1], K.H. Chao[1], H.H. Lai[2], H.H. Chou[2], M.Y. Wu[1], H.F. Chen[1], S.U. Chen[1], Y.S. Yang[1]
[1]*National Taiwan University Hospital, Obstetrics and Gynecology, Taipei, Taiwan R.O.C.*
[2]*Stork Fertility Center, IVF center, Hsin-Chu City, Taiwan R.O.C.*

Study question: With more women seeking oocyte cryopreservation (OC) for delaying childbearing (social reasons), little is known related to their reproductive situations after the procedure.
Summary answer: Only one fifth of the users attempted pregnancy after OC and only 8% of the users ever returned to use their frozen oocytes.
What is known already: A small number of studies from the USA and Europe have provided some data on the profile and characteristics of women who have undergone OC for social reasons. However, information about these users' later-on reproductive situations and the outcome of the cryopreserved oocytes were limited.
Study design, size, duration: This is a retrospective cohort study, analyzing the reproductive situations of the women having undergone social OC after at least one year follow-up. Totally 235 women underwent social OC from 2002 to 2014. They were contacted by phone to evaluate their reproductive situation by a senior staff in the Stork Fertility Center or by a senior fellow in National Taiwan University Hospital. Women who were not reached or who refused to respond were excluded.
Participants/materials, setting, methods: There were 178 women going through the interview completely. The response rate was 75.7%. Their reproductive situations were categorized to four subgroups: (1) women attempting pregnancy naturally (2) or from frozen-thawed oocytes, (3) women who did not try to conceive despite there's a stable relationship (4) or because they were single/without stable relationship. Their demographic data and the clinical results of the frozen-thawed oocytes were analyzed.
Main results and the role of chance: Among those who underwent the interview completely, the mean age at social OC was 38.3 ± 3.7 years old with a mean of 10.2 ± 7.6 oocytes frozen per person. The majority were women who did not attempt pregnancy (138 women, 77.5%), 106 (59.6%) women were single or without stable relationship while 32 (18%) women had stable relationship. Only 25 (14.0%) women attempted pregnancy naturally, and 14 women (7.9%) returned to thaw their oocytes. One woman conceived from fresh IVF/ET instead of using cryopreserved oocytes for personal favor. Women who did not attempt pregnancy despite there's a stable relationship tended to stored their oocytes earlier than other subgroups, and even significantly earlier than women who were single or without stable relationship (36.4 ± 4.4 vs. 38.8 ± 3.4 years old, $P = 0.002$). Whereas women who attempted pregnancy naturally tended to be younger than those from frozen-thawed eggs in the aspects of the age at OC (38.4 ± 4.0 vs. 39.5 ± 4.1 years old) and the age with ongoing pregnancy (37.3 ± 3.0 vs. 39.2 ± 4.8 years old). The ongoing pregnancy rates of frozen-thawed oocytes from different ages at OC (≤35 years old: 100%, 36~39 years old: 50%, ≥40 years old: 25%) seemed similar to those of fresh oocytes in our fertility centers.
Limitations, reasons for caution: At least one year follow-up may be too short to evaluate the reproductive situations for some users. The population who thawed their oocytes is not big enough for a more convincing pregnancy outcome. There might be some information bias as a result of the retrospective aspect.
Wider implications of the findings: The value of social OC for fertility preservation remained unclear. We noted only 21.9% of the users ever attempted pregnancy, and 7.9% returned to use the frozen oocytes. Hope more study with longer follow up will be reported.
Trial registration number: Nil.

P-390 Lack of association between smoking habit at the time of treatment and live birth in recipients of oocyte donation cycles

P. Massart[1], T. Freour[1], D. Garcia[2], A. Rodriguez[3], R. Vassena[2], V. Vernaeve[3]
[1]*CHU Nantes, Médecine de la reproduction, Nantes, France*
[2]*Clinica Eugin, Research Department, Barcelona, Spain*
[3]*Clinica Eugin, ART Department, Barcelona, Spain*

Study question: Is smoking habit in donors, recipients, and male partners associated with live birth in oocyte donation cycle?
Summary answer: Smoking is not associated with a compromised oocyte quality or uterine receptiveness in oocyte donation cycles, as live birth rate remains unaffected by smoking.
What is known already: Smoking has been shown several times to have deleterious effects on female fertility and on autologous *in vitro* fertilization (IVF) outcome, but very little is known on its respective impact on oocyte quality and uterine receptiveness. A single previous investigation in oocyte donation cycles has suggested that smoking in recipients was associated with lower pregnancy rate in heavy smokers than in non-heavy smokers.
Study design, size, duration: This is a retrospective cohort study encompassing oocyte donation cycles with partner sperm performed between 2010 and 2014 in a large fertility center. A total of 7,470 donors and 9,747 recipients undergoing 12,121 oocyte donation cycles were included.
Participants/materials, setting, methods: Smoking habit was categorized for each party as follows: Non-smokers (NS), light smokers (LS; 1–10 cigarettes/day) and Heavy smokers (HS; >10 cigarettes/day). The main outcome of the study was live birth, which was analyzed by univariate and multivariate analysis, adjusted for education level, working status, day of embryo transfer, number of transferred embryos, and embryo quality. Secondary outcomes were biochemical, clinical, and ongoing pregnancy.
Main results and the role of chance: Live birth rates were not affected by degree of smoking in either donor (OR 1.1 [0.99–1.24] and 1.1 [0.96–1.25] in LS and HS, respectively), recipient (OR 0.99 [0.85–1.16] and 1.0 [0.79–1.31] in LS and HS, respectively) or recipients' partner (OR 1.0 [0.86–1.16] and 1.1

[0.95–1.32] in LS and HS, respectively). Biochemical, clinical, and ongoing pregnancy rates were similarly not affected by any of the three parties smoking habits at the time of ART treatment. Furthermore, the analysis of interactions between each party smoking status (passive smoking) did not yield statistically significant results.
Limitations, reasons for caution: Smoking habit at the time of treatment was self-reported, increasing the risk of under reporting.
Wider implications of the findings: Our results question the concept of tobacco-induced alteration of uterine receptiveness, and suggest that smoking habits at the time of the treatment might not be the most relevant parameter to evaluate in order to decipher the potential smoking induced alteration of oocyte quality. Length of exposure could be relevant.
Trial registration number: Not applicable.

P-391 Progestin-primed ovarian stimulation in combination with clomiphene citrate in normalovulatory women undergoing IVF/ICSI treatments: a prospective randomized controlled trial

Y. Liu[1], Q. Chen[1], S. YU[1], Q. Lyu[1], A. AI[1], K. Kuang[1]
[1]*Shanghai 9th People's Hospital, Department of Assisted Reproduction, Shanghai, China*

Study question: Whether Progestin-primed ovarian stimulation(PPOS) in combination with clomiphene citrate can reduce Gn dosage and how endocrine hormones change during Controlled ovarian hyperstimulation(COH).
Summary answer: Clomiphene citrate co-treatment with PPOS decrease gonadotropin dosage and improve LH level, without changing the number of oocytes retrieved and viable embryos compared with PPOS.
What is known already: Progesterone, whether exogenous applied in the follicular phases or endogenous generated in the luteal phases can effectively prevent premature LH surge. The Gn dosage and the duration of Gn administration are higher and LH concentrations are lower in the PPOS than in the short protocol. Clomiphene citrate has been proved effective in decreasing Gn dosage in GnRH-antagonist protocol, while no relevant investigations were reported in PPOS.
Study design, size, duration: A prospective randomized controlled trial was performed in 242 patients with normal ovarian reserve between June 2015 to October 2015. They were allocated into two groups by simple randomization: HMG+MPA+CC (group A, $n = 121$) or HMGMPA (group B, $n = 121$).
Participants/materials, setting, methods: In group A, clomiphene citrate (50 mg/d) in combination with hMG (150 IU) and MPA (10 mg/d) were applied simultaneously from cycle day 3. Equal starting doses of hMG and MPA were administered for group B. Ovulation was co-triggered by a GnRH agonist (0.1 mg) and hCG (1,000 IU) when dominant follicles matured and viable embryos were cryopreserved for later transfer in both protocols. The primary outcome measure for this study was the number of oocytes retrieved.
Main results and the role of chance: No statistically difference was found in the number of oocytes retrieved (9.1 ± 5.8 vs. 9.8 ± 8.1, $p > 0.05$) and viable embryos (3.6 ± 2.7 vs. 3.6 ± 3.4, $p > 0.05$) between the two groups. Group A received significantly lower Gn dose (1,349.4 ± 189.4 IU vs. 1,463.4 ± 364.6 IU, $p < 0.01$), and shorter Gn duration (8.9 ± 1.0 days vs. 9.3 ± 1.9 days, $p < 0.05$). In group A, LH value on the trigger day was higher than in group B (3.7 ± 1.8 IU/L vs. 1.6 ± 1.2 IU/L, $P < 0.01$). *P* value and E2 value on the trigger day were higher in group A than group B. Other parameters such as the number of mature oocyte, fertilization, cleavage were similar ($p > 0.05$). During the following up of FET, a total of 140 women completed 152 FET cycles, no significant difference was found in the clinical pregnancy rate (62.5% (45/72) vs. 63.8% (51/80), $p > 0.05$) and implantation rate (45.9% (61/133) vs. 47.9% (69/144), $p > 0.05$) between the two groups.
Limitations, reasons for caution: This study was for normal ovarian reserved women, more researches are still needed to testify whether it was applicable for different kinds of patients such as PCOS and DOR.
Wider implications of the findings: The co-treatment of clomiphene Citrate with PPOS can effectively prevent premature LH surge and decrease Gn dosage as well as its duration, without adversely affecting the pregnancy outcome. This protocol will be promising in combination with freeze-all policy.
Trial registration number: The trial was registered with the Chinese Clinical Trial Registry (ChiCTR-IPR-15006521)

P-392 The role of Clomiphene Citrate (CC) co-treatment with Progesterone-Primed Ovarian Stimulation (PPOS) protocol in subfertility women with PCOS undergoing IVF treatment: a randomized controlled trial

H. Ye[1], Q. Chen[1], Y. Fu[1], R. Cai[1], W. Chai[1], Y. Wang[1], Q. Hong[1], Y. Kuang[1]
[1]*Shanghai ninth hospital affiliated to jiaotong University, Assisted Reproductive, Shanghai, China*

Study question: What is the role of CC co-treatment with PPOS based on the freeze-all strategy during controlled ovarian stimulation (COH) in women with polycystic ovarian syndrome (PCOS)?
Summary answer: CC co-treatment with PPOS is effective to improve the LH level without LH surge, shorten the stimulation duration without adversely affecting the pregnancy outcome meanwhie.
What is known already: Our previous study indicated that progesterone could prevent premature LH surge in the luteal-phase ovarian stimulation and follicular-phase ovarian stimulation in PCOS patients. However, due to the persistent *P´* suppression to the pituitary, there is a decreasing trend in serum LH values during the simulation, it needs more Gn dose to stimulate the follicular development in the PPOS protocol compared with the short protocol. Therefore, we conducted a prospective study of CC co-treatment in the PPOS, to evaluate the endocrine characteristics and the clinical outcomes in PCOS patients undergoing IVF/ICSI treatment.
Study design, size, duration: In the prospective study, a total of 220 PCOS patients undergoing PPOS treatment were recruited between April 2014 and November 2015 and randomized allocated into two groups: hMG and MPA combined with CC (the study group, $n = 110$) or hMG and MPA (the control group, $n = 110$).
Participants/materials, setting, methods: In the study group, the initiating dose of hMG (150 IU) and MPA (10 mg/d)combined with CC (50 mg) were administered beginning on menstrual cycle day 3, while the starting dose of hMG (225 IU) and MPA (10 mg/d) were administered for the control group. The hMG dose could be adjusted depending on ovarian response. Ovulation was co-triggered by GnRH agonist (0.1 mg) and hCG (1,000 IU) when dominant follicles matured. Viable embryos were cryopreserved for later transfer in both protocols.
Main results and the role of chance: The study group was characterized by a shortened stimulation duration (9.14 ± 1.3 vs. 11.07 ± 1.24, $P < 0.05$) and lower stimulation dose of hMG (1,486.34 ± 360.36 IU vs.1,930 ± 377.72 IU, $P < 0.05$). The number of oocyte retrieved, MII oocytes, the fertilized oocytes and the cryopreserved embryos in the study group were lower than the control group ($P < 0.05$). The LH levels in the study group showed a slightly rise initially, then a downward trend, and average LH values on the trigger day was significantly higher than the control group (4.49 ± 2.49 vs. 2.52 ± 2.09 $P < 0.05$), moreover, no LH surge was found in the two groups. The pregnancy outcomes in FET cycles including implantation rate(51.09% vs. 45.04%), clinical pregnancy (72.86% vs. 62.09%)and ongoing pregnancy (62.86% vs. 54.8%) were comparable between the two groups, which indicated that the embryos originating from MPA and hMG co-treatment CC regimen had similar developmental potential. There were twenty three cases presenting LH levels higher than 10 IU/L in the two groups, and 16 out of 23 patients achieved ongoing pregnancy. The cycle cancellation rate due to no viable embryos was not different between the two groups (4.55% vs. 2.73%, $P > 0.05$). The incidence of OHSS was low between the two groups with no significant difference ($P > 0.05$).
Limitations, reasons for caution: The main limitation of this work is the absence of the live-birth outcomes following PPOS. Furthermore, questions for long-term safety of off-spring in PPOS remain.
Wider implications of the findings: This is the first trial to establish a novel regimen of CC in combination with PPOS in patients with PCOS undergoing IVF, Further studies will be performed to optimize and individualize the selection of the dose of progestin, clomiphene citrate and hMG initiating.
Trial registration number: ChiCTR-IIR-16007770

P-393 A randomized comparison of live birth rates following hormone replacement regimens for thawed blastocyst transfer

S. Taguchi[1], M. Funabiki[1], Y. Nakamura[1]
[1]*Oak Clinic Inc., Infertility Center, Osaka, Japan*

Study question: Does the hormone replacement protocols used in thawed blastocyst transfer affect the live birth rate ?

Summary answer: Our data indicate the hormone replacement protocols produced significantly different live birth rates after thawed blastocyst transfer.
What is known already: There are no randomized controlled trials evaluating the live birth rates after thawed blastocyst transfers in patients treated with various hormone replacement regimens.
Study design, size, duration: A prospective randomized controlled trial was conducted in patients. We evaluated the live birth rates of two different hormone replacement regimens used for thawed blastocyst transfers. This study enrolled 300 women (median age 37.3 years) undergoing *In vitro* Fertilization (IVF) at our clinic in Japan from July 2014 to December 2015.
Participants/materials, setting, methods: The participants were randomized using a computer-generated randomization. There were two study groups; a Julina (®) group (n = 150; 4 mg/day) and an Estrana tape® group (n = 150; 0.72 mg, 4 pieces per 2 days).
Main results and the role of chance: On the 12th cycle day, the endometrium thickness was 8.86 ± 1.23 mm in the Julina ® group and 7.71 ± 0.23 mm (mean ± SD) in the Estrana tape® group. The endometrium thickness in the Julina® group was significantly higher than in the Estrana tape® group (P < 0.001). The serum estradiol (E2) levels were 279.86 ± 156.83 pg/ml in the Julina® group and 462.53 ± 296.0 pg/ml in the Estrana tape® group. The serum E2 levels in the Estrana tape® group were significantly higher than those in the Julina ® group (P < 0.001). The live birth rate in the Estrana tape® group was higher than that in the Julina® group (39.3% versus 28.0%, P = 0.038, odds ratio 1.67, 95% confidence interval: 1.03–2.70). The regimens were well-tolerated, and there was no difference in serious adverse events.
Limitations, reasons for caution: The conclusions of this study are limited to the two hormone replacement regimens examined in our patient population.
Wider implications of the findings: The serum E2 levels are correlated with differences in the live birth rate. The Estrana tape® hormone replacement protocol led to a higher live birth rate following the thawed blastocyst transfer procedures.
Trial registration number: UMIN000015488

P-394 Association of untreated subclinical hypothyroidism with live birth rates following *in vitro* fertilisation: a cohort study

D. Listijono[1], C. Venetis[1], D. Garrett[2], S. Kilani[1], S. Cooke[3], M. Chapman[1]
[1]*University of New South Wales, School of Women's and Children's Health, Sydney, NSW, Australia*
[2]*IVFAustralia, Department of Andrology, Sydney, NSW, Australia*
[3]*IVFAustralia, Department of Embryology, Sydney, NSW, Australia*

Study question: Is untreated subclinical hypothyroidism (SCH), defined as thyroid-stimulating hormone (TSH) values of 2.5–4 mIU/L in the presence of normal free thyroxine (FT4) levels, associated with live-birth rates (LBR) after *in vitro* fertilisation?
Summary answer: Untreated pre-cycle SCH, defined as TSH values of 2.5–4 mIU/L with normal FT4 levels, is not associated with LBR after *in vitro* fertilisation (IVF).
What is known already: Overt hypothyroidism has been implicated in poor reproductive, obstetric and foetal outcomes. However, the evidence surrounding the impact of SCH in the sub-fertile patient undergoing assisted reproductive technology (ART) remains controversial, particularly in the setting of moderately elevated TSH. Whilst some studies have suggested an increased prevalence of SCH in infertile women compared with the general female population, it remains unclear whether SCH adversely impact IVF success, thereby causing considerable debate on the need for treatment. Intriguingly, there have also been suggestions of a possible correlation between SCH and diminished ovarian reserve (DOR), however this too remains inconclusive.
Study design, size, duration: A retrospective analysis of IVF outcomes of untreated SCH patients compared to age-matched euthyroid controls. The primary end-point was LBR. Secondary end-point was clinical pregnancy rates (CPR). The antimüllerian hormone (AMH) test was used as surrogate measure for ovarian reserve. For a 10% difference in LBR, assuming two-tailed outcomes with ∝ minus error probability of 0.05 and power level of 0.8, a sample size of 203 is required for the study group.
Participants/materials, setting, methods: All fresh IVF cycles of women <38 years of age between 2011 and 2015 were retrieved from the IVFAustralia database. Only those patients who had underwent Thyroid Function Tests (TFTs) were included. Differences in proportions of categorical variables were evaluated with Chi-squared test. Unpaired Student's t-tests and single-factor analysis of variance were used to analyse continuous variables. The level of significance was set at two-tailed p-values of <0.05.
Main results and the role of chance: A total of 207 SCH patients were included in this study and were compared against 621 age-matched euthyroid controls, with a mean age of 34.1 years. The study group had a significantly elevated TSH compared to the control group (2.97 vs. 1.60, p < 0.01) with comparable FT4 levels (14.2 vs. 14.5, p = NS). The average number of oocytes retrieved (11.5 vs. 10.3) and fertilisation rates (59.7% vs. 60.0%) were similar in both groups. There was no significant difference in the LBR (27.1% vs. 25.4%) and CPR (30.0% vs. 28.8%) between the SCH and control groups (p = NS). No statistically significant difference was present in AMH levels between patients with and without SCH (27.6 vs. 31.1, p = NS).
Limitations, reasons for caution: Although the two groups were age-matched, the retrospective nature of the study might have allowed for the presence of other sources of bias. In addition, the total sample size of both cohorts may be inadequately powered to detect the difference observed in the above outcomes.
Wider implications of the findings: Our findings support current literature which recommends, in patients with marginally elevated TSH between 2.5–4 mIU/L, the option of monitoring TSH levels and treating when levels 4 mIU/L as alternative to commencing treatment to maintain TSH <2.5 mIU/L.
Trial registration number: Not applicable.

P-395 Gene expression differences in human pre-ovulatory granulosa cells derived from large and small follicles

I. Bouba[1], A. Galidi[1], L. Lazaros[1], S. Bellou[2], C. Kostoulas[1], P. Sakaloglou[1], C. Kitsou[1], K. Zikopoulos[3], I. Georgiou[3], E. Hatzi[4]
[1]*University of Ioannina, Medical School, Laboratory of Medical Genetics and Human Reproduction, Ioannina, Greece*
[2]*University of Western Macedonia, Department of Informatics and Telecommunications Engineering, Kozani, Greece*
[3]*University of Ioannina, Medical School, Department of Obstetrics and Gynecology, Genetics and IVF Unit, Ioannina, Greece*
[4]*University Hospital of Ioannina, Department of Obstetrics and Gynecology, Genetics and IVF Unit, Ioannina, Greece*

Study question: Is there a difference in the gene expression profile of human preovulatory granulosa cells derived from large and small follicles?
Summary answer: 44 genes were up-regulated while only 5 genes were down-regulated in granulosa cells from large follicles compared to those from small follicles.
What is known already: Human granulosa cells play crucial role in folliculogenesis, oocyte maturation and ovulation. Gene expression microarray analysis has been performed in order to find candidate genes responsible for the modulation of follicular development and oocyte quality. To our knowledge, there are no data concerning human preovulatory granulosa cells regarding the follicle size.
Study design, size, duration: The study population consisted of 32 women with tubal and/or male-factor infertility who underwent controlled ovarian stimulation for IVF/ICSI, for a period of one year. The follicles were categorized into small follicles with diameter <12 mm (from 16 women) and large follicles with diameter >18 mm (from 16 women) and granulosa cells were collected after their aspiration. Granulosa cell culture and RNA isolation was performed and further analyzed by microarrays and qRT-PCR.
Participants/materials, setting, methods: Granulosa cells originated from large and small follicles were cultured for 2 days, harvested and RNA extraction was performed. RNA quality and integrity was determined by Agilent 20,100 bioanalyzer and DNA contamination by RT-PCR. Equal

amounts (400 ng) of total RNA from each woman were pooled prior to microarray analysis (Affymetrix HG-U133 Plus 2.0). Q-RT PCR was performed to verify the results in the pooled RNA samples as well as in other individual samples.
Main results and the role of chance: Analysis of the microarray data demonstrated an up-regulation of 44 genes (3 fold-up) and a down-regulation of only 5 genes (3 fold-down) in granulosa cells from large pre-ovulatory follicles compared to those from small follicles. qRT-PCR was performed in the 5 down-regulated genes (SOX4, NPY1R, NCAM1, MLLT10, SLC27AC) as well as in ADAMS28, SSP1 and ITGAM up-regulated genes in the pooled RNA sample and in additional individual samples derived from several women. NCAM1 and SLC27A6 were found to be down-regulated in granulosa cells from large follicles. However, the different expression of SOX4, NPY1R and MLLT10 between large and small follicles was not confirmed. Our results provide a basis for the identification of genes involved in the oocyte maturation and ovulation during the IVF procedure.
Limitations, reasons for caution: In order to confirm the results, more samples need to be tested. Additionally, a bioinformatic analysis should be performed in order to analyse the transcriptome and define the genes implicated in specific pathways for further analysis.
Wider implications of the findings: The oocyte maturation process as well as the quality of the oocyte, mainly controlled by granulosa cells, play a key role in IVF-outcome. Therefore, the study of granulosa cell transcriptome could reveal new regulatory molecules and provide new tools that could be used to improve the quality of the oocyte.
Trial registration number: –

P-396 Effect of regular exercise on reproductive function of aged female mice

K.S. Lee[1], S. Kim[1], B. Park[1], J. Joo[1], J. Son[2], B. Joo[3]
[1]*Pusan National University School of Medicine, Department of Obstetrics and Gynecology, Pusan, South Korea*
[2]*Miraro Hospital, Department of Obstetrics and Gynecology, Pusan, South Korea*
[3]*Pusan National, University, Supercomputing Center, Pusan, South Korea*

Study question: Can regular exercise improve the expression of ovarian anigogenic factors, oocyte quality and fertility potential in aged female mice.
Summary answer: Regular exercise induced by illumination with incandescent lights in aged mice improves their reproductive outcomes by improving ovarian function and oocytes quality.
What is known already: Some studies have reported the relation between exercise and angiogenesis (Gustafsson et al., 2001; Prior et al., 2004). Previously it has been reported that a single bout of moderately intense treadmill running upregulates VEGF expression of skeletal muscle in rat (Breen EC et al., 1996) and upregulation of VEGF mRNA also occurs during exercise in humans in both normal healthy individuals (Gustafsson et al., 1999; Richardson et al., 1999) and patients with heart failure (Gustafsson et al., 2001).
Study design, size, duration: Forty female mice of 30–32 weeks were divided into the two groups. One group (n = 20) were induced to stimulate exercise (physical activity) by illuminating incandescent lights (60 Watts, 220 V), placed on the top of the cage, starting at 11:00 a.m. for 30 min daily. The other group (n = 20) were served as control without the induction of exercise.
Participants/materials, setting, methods: C57BL inbred mice were used and purchased from Korea Experimental Animal Center (Daegu, South Korea). Mice were maintained on a light-dark cycle, with light on at 5:00 AM and off at 7:00 PM, and with food and water available ad libitum.
Main results and the role of chance: The total number of pregnant mice was 15 (75%) in the exercise group, which was significantly higher than 5 (25%) in the control group ($P < 0.05$). The mean number of offspring was also significantly higher in the exercise group (9.2) than the control group (6.3) ($P < 0.05$). The mean number of one-cell embryos retrieved and blastocyst formation rate were 12.6 and 43.8% in the exercise group and 10.8 and 8.1% in the control group with a significant difference ($P < 0.05$). Ovarian VEGF and eNOS expression was increased, but ovarian apoptosis was decreased in the exercise group.
Limitations, reasons for caution: First, this study did not use a general exercise equipment, such as treadmill. Second, this study did not examine the effect of exercise on implantation because a lot of studies have shown that physical activity can affect implantation of endometrium.
Wider implications of the findings: This study did not clearly elucidate the mechanism that exercise treatment results to improve ovarian function and oocyte quality. However, this study showed the increased ovarian VEGF and eNOS expression and decreased ovarian apoptosis.
Trial registration number: None.

P-397 The role of three-dimensional transvaginal ultrasonography as a predictor of endometrial receptivity in *in vitro* fertilization

L. Borges[1,2], J. Souza[1], C. Souza[1], T. Bonetti[2], E. Motta[2]
[1]*Jules White Reproductive Medicine, Clinical, Vitória, Espírito Santo, Brazil*
[2]*Universidade Federal de São Paulo, Escola Paulista de Medicina UNIFESP-EPM, Departamento de Ginecologia, Disciplina de Ginecologia Endocrinológica, São Paulo, Brazil*

Study question: Is the three-dimensional ultrasound (3D-US) with power doppler better than two-dimensional ultrasound (2D-US) to endometrium analysis of infertile women undergoing *in vitro* fertilization (IVF)?
Summary answer: Endometrial volume evaluated by 3D-US is a stronger predictive factor of pregnancy in IVF cycles with transfer of fresh embryos than 2D-US endometrial thickness.
What is known already: The endometrial receptivity is influenced by biological mechanisms, hormone secretion, proteins expression and a favorable endometrial milieu is extremely important for the success of IVF cycles, presenting a relative contribution of 31–64% for pregnancy. What determines such endometrial receptivity remains controversial and 2D-US has been routinely used in IVF clinical practice to evaluate the endometrial characteristics to embryo transfers. However, the endometrium is a three-dimensional, volumetric and non-planar structure, thus endometrial volume may be supposed to be more reliable than thickness to functional assessment, and it can be assessed by 3D-US in the IVF cycles.
Study design, size, duration: This prospective observational study included 123 women undergoing standard protocols for ovulation induction to fresh embryo transfers at a private Assisted Reproduction Center, between 2012 and 2015. Participants were split into two groups according with the clinical results of treatment: pregnancy and no-pregnancy. The variables were compared between groups and a multivariate logistic regression model was used to evaluate the association of ultrasound variables on the outcome of clinical pregnancy, adjusted for variables possibly involved.
Participants/materials, setting, methods: All patients underwent 2D-US to endometrium thickness measurements and 3D-US for assessment of endometrial volume and vascularization (VI, FI, VFI), using equipment ACCUVIX XQ (Medison, Seoul, Korea) at follicle final maturation trigger day. All 2D-US and 3D-US were performed by the same professional. The VOCAL® instrument was the imaging program used to calculate the volume and vasculature index in 12 outlines endometrial plans to cover 180°.
Main results and the role of chance: The demographic characteristics were similar between pregnancy and non-pregnancy groups (age: 33.8 ± 4.0 and 35.2 ± 4.7, p = 0.114; antral follicle count: 8.1 ± 3.8 and 7.2 ± 3.5, p = 0.223; FSH dose administered: 1,897 ± 663 and 2,105 ± 699, p = 0.119). However, pregnancy group had higher number of MII oocytes collected (8.2 ± 4.7 and 6.4 ± 3.5, p = 0.020) and good embryos transferred (1.8 ± 0.8 and 1.5 ± 0.9, p = 0.036). Pregnancy rate was 31.7%. The endometrial thickness was marginally higher in pregnancy than no-pregnancy group (9.9 ± 2.7 and 9.1 ± 2.2, p = 0.09), while the endometrial volume presented significantly higher in the patients who become pregnant (4.8 ± 2.1 and 3.7 ± 1.8, p = 0.003). The parameters of endometrial vascularization (VI, FI and VFI) were similar. The multiple logistic regression analysis showed the endometrial volume was a predictive factor of pregnancy (OR: 1.41, p = 0.003), wherein the endometrial volume increased the pregnancy rate in about 40% adjusted for confounders as age, antral follicle count, FSH dose, number of MII oocytes collected and good embryo transferred. The endometrial thickness was a weaker predictor of pregnancy (OR: 1.20, p = 0.05),

also adjusted for confounders. The ROC curve analysis showed that an endometrial volume of 2.0 cm^2 is a predictor of pregnancy ($p = 0.002$) with sensibility of 95% and specificity of 82%.
Limitations, reasons for caution: This is a prospective observational study evaluating the endometrial characteristics by 2D-US and 3D-US to estimate endometrial receptivity and it influence in conception. Ovarian stimulation response and embryo quality were not similar between pregnant and no-pregnant, but the multiple regression analysis were carried out to adjust for those confounders.
Wider implications of the findings: 3D-US is an accurate measurement of endometrial receptivity. In addition, it is non-invasive, relatively inexpensive, and, most importantly, has a high reproducibility intra and inter observer. Our findings support that 3D-US is a better predictor of pregnancy chance than 2D-US and can be used for routine in IVF cycles.
Trial registration number: Not applicable.

P-398 Ovarian stimulation in oocyte donors is associated with high expression of mRNA coding for apoptotic markers in cumulus cells

R. Nunez – Calonge[1], S. Cortes[1], L. Rancan[2], L. Ortega[1], E. Vara[2], A. Guijarro[3], P. Caballero[1], J. Fernández-Tresguerres[2]
[1]*Clinica Quirurgica Tambre, Reproduction Unit, Madrid, Spain*
[2]*Universidad Complutense Madrid, Bioquímica, Madrid, Spain*
[3]*Hospital Virgen de la Luz, Ginecologia, Cuenca, Spain*

Study question: Are there similar levels of apoptotic markers in cumulus (CC) and granulose cells (GC) of periovulatory follicles from fertile oocyte donors undergoing gonadotropic stimulation?
Summary answer: We found that ovarian stimulation to IVF in fertile women is associated with higher mRNA expression of apoptotic markers in cumulus cells, specifically caspase 3
What is known already: We have recently demonstrated that oxidative stress (OS) is involved in apoptosis of cumulus and granulose cells. The quality of a follicle and an oocyte has been estimated in terms of the incidence of apoptosis in granulosa cells in the patients involved in *in vitro* fertilization (IVF) treatment. On the other hand, we now know that GCs apoptosis is an important event in follicular atresia even though our understanding of the mechanisms that regulates GCs and CCs apoptosis is limited, and scarce knowledge exists about how CCs and GCs might be affected by ovarian stimulation in fertile women.
Study design, size, duration: This observational, prospective study compared the expression of mRNA coding for apoptotic markers in 185 oocyte-cumulus and 114 oocyte-granulose complexes retrieved from 18 healthy fertile oocyte donors <35 years, undergoing *in vitro* fertilization (IVF) during the period of June to November 2015. Written informed consent was obtained from the participants, and the local ethics committee approved the study. Only donors with at least a previous cycle with pregnancy were included.
Participants/materials, setting, methods: Donors were stimulated with the same protocol (FSHr and triggering with GnRH analogues). After collection of GC and CC cells from each donor, the samples were processed for mRNA levels of apoptotic markers: BcL-2, Bax, caspase-3 and caspase- 9 were assessed carrying out using real-time polymerase chain reaction (RT-PCR) analysis on the day of oocyte retrieval. The relative expressions of mRNAs of apoptotic markers in cumulus and granulose cells removed from individual oocytes were compared.
Main results and the role of chance: Results obtained from comparative RT-PCR analysis revealed that the mean relative levels of mRNA coding for caspase-3 were significantly increased ($p < 0.001$) in CCs (1.009 ± 0.12), from oocyte donors compared with CGs (0.343 ± 0.01) from the same women. The mean relative levels of mRNA coding for caspase-9 were also increased in CCs (1.05 ± 0.06), from oocyte donors compared with CGs (0.81 ± 0.06) although without statistically significant differences ($p = 0{,}069$).

No significant difference between groups was observed in mRNA coding for BcL-2 (CCs: 1.36 ± 0.05; CGs: 1.47 ± 0.02; $p = 0.39$), and BAX (CCs: 1.26 ± 0.06; CGs: 1.19 ± 0.01; $p = 0.139$)
Limitations, reasons for caution: Although it has been shown different levels of caspase 3 and 9 in CCs and GCs in fertile women undergoing ovarian stimulation to IVF, its implication in ovarian controlled hyper stimulation needs to be addressed in further studies on a larger sample of women.
Wider implications of the findings: These results indicate that CCs from fertile women subjected to ovarian stimulation, might suffer apoptosis in greater degree than CGs and are taken as an evidence for reduced defence against reactive oxygen species (ROS) in CCs during reproductive treatment.
Trial registration number: No clinical trial.

P-399 Expression of substance P, hemokinin-1 and the tachykinin NK1 receptor in human granulosa and cumulus cells

J. García-Ortega[1], F.M. Pinto[2], V. Blasco[1], N. Prados[1], L. Candenas[2], M. Fernández-Sánchez[1]
[1]*IVI Sevilla, IVF, Seville, Spain*
[2]*Instituto de Investigaciones Químicas, CSIC, Biological Chemistry, Seville, Spain*

Study question: Are substance P (SP), hemokinin-1 (HK-1) and NK1 receptor (NK1R) expressed in human ovarian cells?
Summary answer: SP, HK-1 and NK1R are expressed and act in coordination with kisspeptin in ovarian granulosa cells.
What is known already: The neurokinin B (NKB)/NK3 receptor (NK3R) and kisspeptin (KISS1)/kisspeptin receptor (KISS1R), two systems which are essential for reproduction, are expressed in human granulosa cells and contribute to the control of fertility by acting directly on the gonads. However, little is known about the presence and role of other members of the tachykinin family in human granulosa and cumulus cells.
Study design, size, duration: Samples were provided by 33 oocyte donors undergoing controlled ovarian stimulation at the clinic IVI Sevilla (Seville, Spain) between January 2012 and December 2013. Follicular fluid samples containing mural granulosa cells (MGCs) and cumulus-oocyte complexes (COCs) were collected after transvaginal ultrasound-guided oocyte retrieval. Cumulus cells (CCs) surrounding the oocyte were removed by using cutting needles, by subsequent treatment of COCs with Hyaluronidase and by carefully removing the CCs of the *corona radiata* with denudation pipettes.
Participants/materials, setting, methods: RT-PCR, quantitative real-time PCR, immunocytochemistry and western blot were used to investigate the pattern of expression of SP, HK-1 and NK1R mRNAs and proteins in MGCs and CCs. Intracellular free Ca^{2+} levels and $[Ca^{2+}]i$ in MGCs after exposure to SP or kisspeptin in the presence of SP, in the presence or not of tachykinin receptor antagonists, were also measured.
Main results and the role of chance: SP, HK-1 and NK1R were all expressed, at the mRNA and protein levels, in MGCs and CCs. Regarding NK1R, only the truncated isoform, NK1R-T, was detected. SP and HK-1 mRNA levels were similar in MGCs and CCs while NK1R-T mRNA was higher in MGCs, in comparison with CCs from the same donor. SP failed to induce any change in $[Ca^{2+}]i$ but reduced the $[Ca^{2+}]i$ increase produced by exposure to kisspeptin and the inhibitory effect of SP was suppressed in the presence of a cocktail of antagonists selective for the three known tachykinin receptors.
Limitations, reasons for caution: MGCs and CCs were obtained from oocyte donors undergoing ovarian stimulation which in comparison with natural cycles, may have affected gene and protein expression in granulosa cells.
Wider implications of the findings: Our data demonstrate that, in addition to NKB, other members of the tachykinin system are expressed and act coordinately with kisspeptin to regulate granulosa cell function in the human ovary.
Trial registration number: This is not a clinical trial.

P-400 Comprehensive analysis of body mass index effects on *in vitro* fertilization outcomes

L. Privitera[1], V. Sarais[1], L. Pagliardini[1], V.S. Vanni[1], P. Giardina[1], M.T. Potenza[1], L. De Santis[1], A. Alteri[1], P. Monehar[1], P. Vigano'[1], M. Candiani[1], E. Papaleo[1]

[1]IRCCS San Raffaele Hospital, Obstetrics and Gynecology, Milano, Italy

Study question: What is the effect of body mass index on retrieved oocytes number and oocytes quality among couples undergoing *In vitro* Fertilization in an Italian population?
Summary answer: Results show a significantly reduced percentage of mature oocytes when comparing obese (BMI ≥30 kg/m^2) and normal-weight patients (BMI = 18.50–24.99 kg/m^2).
What is known already: Conflicting evidence exists with regard to the effects of a raised body mass index on the outcome of ART. Even less clear is whether BMI acts with a potential detrimental effect on IVF outcomes via a deleterious effect on innate quality of oocytes or on the environmental milieu within the uterus.
Study design, size, duration: Data from 1,602 women (aged 20–45 years) treated at San Raffaele Hospital, a large university-affiliated infertility center, undergoing their first IVF/ICSI cycle, were analyzed retrospectively. Data were collected from January 2012 to December 2014.
Participants/materials, setting, methods: Patients were divided into four BMI categories. Baseline characteristics of the four BMI groups were compared with the use of Pearson chi-square test for variables categories and one-way analysis of variance for continuous variables, using Tukey's post hoc test for multiple comparisons. Outcomes of cycles were compared between BMI groups with the use of logistic regression to calculate the odds ratio, with their 95% confidential interval.
Main results and the role of chance: A significantly reduced percentage of mature oocytes was reported when comparing obese and normal-weight patients, (respectively 67.24 ± 30.65 and 76.9 ± 24.8, p = 0,005), resulting in a significant lower number of oocytes used for IVF procedures (in obese and normal-weight women respectively: 4.2 ± 3.4 and 6.0 ± 4.1, p = 0.003). Nevertheless, after adjusting for maternal age and other confounders, pregnancy rate was similar across different BMI categories. No statistically significant differences were observed neither for miscarriage nor for live birth rate. However a significant increased OR could be reported for miscarriage if all patients with BMI ≥25 were grouped.
Limitations, reasons for caution: Results are limited by the retrospective nature of the study; data have been obtained from a single institute. We considered only first ART cycles to minimize potential confounders by multiple failed cycles, but this might confer a potential limitation.
Wider implications of the findings: Appropriate counselling to encourage weight loss may help these patients but this strategy might be very time consuming. Number and quality of embryo are not severely affected by an high BMI while the maintenance of pregnancy seems to represent an important issue in these women.
Trial registration number: NA.

P-401 Ovarian rejuvenation and folliculogenesis reactivation in peri-menopausal women after autologous platelet-rich plasma treatment

K. Pantos[1], N. Nitsos[1], G. Kokkali[1], T. Vaxevanoglou[1], C. Markomichali[1], A. Pantou[1], M. Grammatis[1], L. Lazaros[1], K. Sfakianoudis[1]
[1]Genesis Athens Hospital, Centre for Human Reproduction, Chalandri, Athens, Greece

Study question: To explore whether autologous ovarian platelet-rich plasma (PRP) treatment could result in ovarian rejuvenation and subsequent folliculogenesis reactivation in peri-menopausal women.
Summary answer: Our data show, for the first time, the successful temporary ovarian activity restoration in peri-menopausal women after an autologous ovarian platelet-rich plasma treatment.
What is known already: PRP constitutes a concentrated source of growth factors and cytokines. Numerous studies in various medical fields have demonstrated the beneficial effects of PRP on tissue and angiogenesis regeneration. PRP treatment has been shown to improve vascularization and quality of an implant in an autologous ovarian transplantation, while when administered intrauterinely PRP has been shown to promote endometrial growth in cases with poor endometrial quality. The study of an ischemia/reperfusion injury rat model has shown that PRP treatment diminishes the oxidative stress and the ovarian histopathology caused by the bilateral adnexal torsion, while it increases the peritoneal vascular endothelial growth factor.
Study design, size, duration: Eight peri-menopausal women undergoing PRP treatment constituted the study population. All subjects, aged 45.13 ± 4.42 years, had absence of menstrual cycle for 4.88 ± 1.13 months. The FSH, LH, E_2 and AMH levels were determined before the PRP treatment and at monthly intervals after the PRP treatment in order to monitor the ovarian function. The presence of developing follicles was confirmed by ultrasound scan.
Participants/materials, setting, methods: PRP was prepared using the RegenACR®-C Kit and was infused into the ovaries using a transvaginal ultrasound-guided injection. All patients underwent natural cycle IVF without any ovarian stimulation or GnRH antagonist supplementation. When a follicle of >16 mm was observed, ovulation triggering was achieved with 5000 IU of hCG and follicle aspiration was performed 32 h later by the transvaginal route. The follicular size, the follicle and oocyte numbers were recorded during oocyte retrieval.
Main results and the role of chance: The successful ovarian rejuvenation was confirmed by the menstrual cycle restoration 1–3 months after the ovarian PRP treatment. The oocyte retrieval was successful in all cases, resulting in 2.50 ± 0.71 follicles of 15.20 ± 2.05 mm diameter, 1.50 ± 0.71 oocytes and 1.50 ± 0.71 MII oocytes. All mature oocytes were inseminated by ICSI and the 1.50 ± 0.71 resultant embryos were cryopreserved at 2pn stage until transfer. To date, no embryo transfer has been performed. Given the highly angiogenic ovarian structure and the critical role of various platelet derived factors for the vascular activation and stabilization, we could assume that PRP infusion probably enriched the dysfunctional, peri-menopausal ovarian tissue with the essential factors for angiogenesis and normal vascular function leading to tissue regeneration. As far as the observed folliculogenesis is concerned, many peri-menopausal women may maintain a restricted amount of inactive primordial follicles, that could be activated by the PRP growth factors or the subsequent ovarian tissue regeneration and maturate into preantral and antral follicles. Indeed, platelet-derived growth factors (PDGFs), regulating cell growth and division, have been shown to enhance blood vessel formation and growth. PDGFs have been localized in human oocytes and granulosa cells, while their receptors in granulosa cells, suggesting a potential association with primordial follicle activation.
Limitations, reasons for caution: Our investigation was based on eight women of advanced maternal age undergoing PRP treatment and subsequent natural cycle IVF during their transition to menopause. Further studies in larger population groups, analyzing both peri- and post-menopausal women are needed to verify our findings.
Wider implications of the findings: After the verification of our preliminary results in larger population groups, PRP could be used as a first line treatment for the ovarian regeneration and the folliculogenesis reactivation of peri-menopausal women. PRP therapy may extend the fertility potential of peri-menopausal women, rendering oocyte donation IVF cycles as an ultimate option.
Trial registration number: N/A

P-402 Profile of the patient with low oocyte yield: predictors of the oocyte recovery

E. Santamaría[1], D. Galliano[2], F. Cruz[3], M. Fernández-Sánchez[4], N. Prados[1]
[1]IVI Sevilla, IVF Laboratory, Seville, Spain
[2]IVI Roma, Reproductive Medicine Unit, Rome, Italy
[3]IVI Valencia, Reproductive Medicine Unit, Valencia, Spain
[4]IVI Sevilla, Reproductive Medicine Unit, Seville, Spain

Study question: Could we predict the number of oocytes obtained the day of the oocyte pick-up (OPU) and the risk of a low yield?
Summary answer: Number of follicles higher than 12 mm the day of the induction seems to be the best single predictor of the number of oocyte retrieved.
What is known already: Serum estradiol levels and follicular number and size by ultrasound scan the day of the induction are commonly used to predict the number of retrieved oocytes. But there is variability in the number obtained and, in approximately 1 to 5% of the retrievals, no oocyte is found (EFS; empty follicle syndrome). This syndrome is sometimes related to a human error or wrong drug administration. Other times no abnormal treatment or response has been described even in recurrent cases.

Study design, size, duration: We analyzed retrospectively 24434 OPU cycles from patients and donors undergoing ovarian stimulation between January 2011 and December 2013 in four clinics (IVI Valencia, IVI Barcelona and IVI Sevilla).
Participants/materials, setting, methods: We analysed different stimulation and patient variables. Simple and multiple linear regressions were used.

Using the number of follicles equal or higher than 12 mm as the best predictor, we have compared 4 models of low oocyte yield retrievals. We define a low yield when less than 1, 1.25, 1.5 or 2 standard deviations from the average were obtained. Multiple logistic regressions were used to build and compare the models.
Main results and the role of chance: The best single predictor is the number of follicles equal or higher than 12 mm (R^2 = 88.9%, $p < 0.001$), followed by the number of follicle equal or higher than 10 mm (R^2=88.5%, $p < 0.001$). Estradiol levels is the other good predictor predictor (R^2=78.3%; $p < 0.001$). With a R^2 between 35% and 5% we found the clinic, induction method, age, etiology, stimulation method, basal FSH and progesterone at induction and with less than 5%: type of patient, total gonadotropin dose, duration of stimulation, use of contraceptives, body mass index (BMI), stimulation protocol and other endocrine levels. No combination of variables showed a relevant improvement over the use of the number of follicles as the single predictor.
Some variables are found significantly in the four models: induction type, days of stimulation and BMI. Some variables are only found in the less restrictive models: the clinic, oral contraceptive use, basal estradiol or stimulation protocol. Progesterone level only appears in the most restrictive model. The less restrictive models are more related to the local clinical management of the patients. The most restrictive model is the one that points to the intrinsic patient characteristics that correlates to the low oocyte yield.
Limitations, reasons for caution: This is a retrospective study and would be necessary to test this model in a prospective study and confirm these findings.
Wider implications of the findings: Though the number of follicles over 10 or 12 mm is enough to predict the number of retrieved oocytes, there is no good predictor of a low yield. Nevertheless, the risk of obtaining a low yield is related to the progesterone level at induction, age and ovarian reserve.
Trial registration number: Not applicable.

P-403 Apoptosis and pAKT levels in cumulus cells of patients undergoing *in vitro* fertilization program with specific polymorphisms of gonadotropins and their receptors: a case-control study

L. Bosco[1], M.C. Roccheri[1], A. Paffoni[2], P. Piomboni[3], D. Valerio[4], E. Sarcina[5], M. Lispi[6], G. Ruvolo[7]

[5]*Centro Medico San Luca, Centro Medico San Luca, Bari, Italy*
[6]*Merck Serono S.p.A, Roma, Italy*
[7]*Centro di Biologia della Riproduzione, Palermo, Italy*

Study question: Is there a difference in oocyte competence among patients with different gonadotrophin polymorphisms, after ovarian stimulation with r-FSH?
Summary answer: Higher DNA Fragmentation Index and cleaved caspase-3 related to lower level of pAKT has been observed in patients with specific gonadotrophin polymorphism (FSHR and LHB).
What is known already: In our experience, the DFI, the percentage of cleaved caspase-3 and the pAKT on cumulus cells can be used as molecular markers of oocyte competence; The polymorphic variant of LHB is characterized by an extra glycosylation signal into the β subunit. This molecular variation influences the pharmacokinetic properties of v-betaLH, showing an elevated bioactivity *in vitro*, but a significantly shorter half-life in circulation if compared with the wild type LH. These patients show sub-optimal ovarian response after pharmacological ovarian stimulation with r-FSH; We know that FSH receptor (FSHR) variants, Thr307/Asn680 and Ala307/Ser680, are involved in the response to ovarian stimulation.
Study design, size, duration: The aim of the study was to determine the apoptosis levels (in terms of percentage of DNA fragmentation and percentage of cleaved caspase-3) and the pAKT levels as potential markers of oocyte competence in the cumulus cells of individual patients with specific FSHR and LHB polymorphisms. It was a retrospective study. It was included 36 patients. The duration of the study was 12 months.
Participants/materials, setting, methods: Patients were normo-responder patients with a normal basic level of FSH (<12 IU/mL), body mass index <28, aged <38 years old, with a minimum of 3 MII oocytes collected. The patients were treated with a GnRH agonist and r-FSH. Cumulus cells were collected after treatment with a hyaluronidase solution. SNPs of FSHR and LHB gene will be amplified by PCR in different tubes, using different primers.
Main results and the role of chance: In this study population we found the following phenotypes:

- for FSHR: A/T – S/N (n = 18); A/A S/S (n = 6); T/T N/N (n = 12)
- for LHB: W/W I/I (n = 23); W/R I/T (n = 13)

A higher level of apoptosis in terms of DFI and amount of active protein caspase-3 ($p < 0.05$ vs. all other combinations) has been observed in patients with phenotype A/TS/N associated with W/RI/T (double heterozygous), correlating with an inverse proportion of survival factor pAKT. The analysis of clinical data between the double heterozygous and other combinations showed that there are no statistically significant differences in terms of total number of oocytes, oocytes in Metaphase I, zygotes, high quality embryos. No statistical difference was found also in the pregnancy rate (25% in double heterozygous compared to 30% in other combinations).
Limitations, reasons for caution: The main limitations could be the low number of patients with polymorphic variants among the cohort of patients included in the study.
Wider implications of the findings: We expect that patients with double polymorphism for LHB and FSHR will produce oocytes with a limited competence after ovarian stimulation with r-FSH. So, it will be possible to personalize the ovarian stimulation according to polymorphic condition of the individual patient.
Trial registration number: The trial is an observational study and no registration is needed.

P-404 Dual trigger with GnRH-a and hCG compared with a standard dose of hCG in patients with few follicles in IVF – pilot randomized case control study

N.B. Fraire[1], A.L. Torno[1], G. Rey Valzacchi[1], E. Salama[1], L. Blanco[1], C. Carrere[1], A. Divita[1], S. Bertolozzi[1], A. Sdrigotti[1], M. Rodriguez Kubrusli[1], L. Ferle[1], E. Szlit de Feldman[1]
[1]*PROCREARTE, Reproductive Medicine, Buenos Aires, Argentina*

Study question: To evaluate if dual trigger with GnRh-a and hCG improves the outcome in patients with low number of preovulatory follicles, compared with hCG alone.
Summary answer: Dual trigger improved the outcomes regarding cancellation, fertilization and pregnancy rates, although the number of total and MII oocytes was similar.
What is known already: The combination of GnRH-a plus hCG for final oocyte maturation have been previously studied in normo and high responder patients in order to decrease the incidence of severe ovarian hyperstimulation syndrome and increase pregnancy rate. More recently it was reported the successful use of "dual trigger" in a patient showing repetitive immature oocytes and empty follicle syndrome.

Pregnancy and live-birth rates have been improved with dual trigger in normo-responder patients.

To our knowledge this is the first prospective study in order to investigate the effect of dual trigger in patients with low response to gonadotropin stimulation for IVF.
Study design, size, duration: This is a Randomized Case Control Study in which 96 patients with low response to controlled ovarian hyperstimulation undergoing IVF-ICSI were included from January to December 2015. Patients were randomized with sealed envelopes into two groups: Group 1 (Dual Trigger): received r-hCG 250 μg plus triptorelin 0.1 mg and Group 2 (control): received r-hCG 250 μg alone. The oocyte pick-up was performed 35–36 h after.

Demographic data, cycle characteristics of ovarian stimulation and final outcomes were studied.

Participants/materials, setting, methods: We analyzed 96 women undergoing IVF-ICSI in a GnrH antagonist protocol who presented ≤5 follicles ≥16 mm during transvaginal ultrasound performed the day of final trigger. All patients received a maximum dose of either recombinant or urinary gonadotropin of 300 UI/day. They were divided into two groups according to the triggering agent used: Group 1 (Dual Trigger): $n = 48$ patients and Group 2 (Control): $n = 48$ patients.

Main results and the role of chance: Both groups were demographically comparable in terms of age, FSH/LH, HAM, number of previous cycles, infertility cause, days of stimulation and total dose of gonadotropins used.

The total number of oocytes retrieved and maturity rate were similar in both groups. In Group 1 cancellation rate was statistically significantly lower, the fertilization rate was higher although it didn't reach statistical significance, the number of embryos cleaved was statistically significantly higher. PR per started cycle was higher, even though it didn't reach statistical significance.

	Dual Trigger	Control Group	*p* Value
OOCYTES RETRIEVED, No. (±SD)	3.34 (1.8)	2.75 (1.61)	NS
MATURITY RATE, % (±SD)	82 (24)	84 (24)	NS
FERTILIZATION RATE, % (±SD)	74 (25)	57 (35)	0.07
EMBRYOS TRANSFERRED per patient No. (±SD)	1.44 (0.85)	1.06 (0.9)	NS
EMBRYOS CLEAVED, No. (±SD)	2.96 (1.05)	1.7 (0.83)	0.01
GOOD QUALITY EMBRYOS, % (±SD)	82 (33)	84 (32)	NS
CANCELLATION RATE, % (*n*)	6.25 (3/48)	29 (14/48)	0.03
PR per started cycle, % (*n*)	29 (14/48)	10 (5/48)	0.058
PR per ET, % (*n*)	43 (13/30)	16 (5/31)	0.08

Limitations, reasons for caution: There was a tendency of better results regarding fertilization and pregnancy rates in dual trigger group but it wasn't statistically significant, possibly due to the small number of patients included. Currently synchronization between nuclear-cytoplasmatic maturation is impossible to be checked in live oocytes.

Wider implications of the findings: Dual trigger can improve outcome in patients with low response. The benefit may be related to more synchronic cytoplasmatic-nuclear maturation which could have decreased cancellation rate, increased the number of cleaved embryos and pregnancy rate. These promising results have to be confirmed by a larger number of patients.

Trial registration number: –

P-405 Effect of recipient's female age on clinical outcomes in oocyte donation cycles

V. Casciani[1], E. Iovine[1], R. Polese[1], F. Scarselli[1], A. Ruberti[1], A.M. Lobascio[1], S. Muzzì[1], G. Nastri[1], T. Riccio[1], V. Zazzaro[1], M.T. Varricchio[1], C. Mencacci[1], M.G. Minasi[1], E. Greco[1]

[1]*European Hospital, Centre for Reproductive Medicine, Rome, Italy*

Study question: Does maternal recipient's age affect cumulative clinical outcomes in oocyte donation cycles with frozen oocytes?

Summary answer: A trend towards a reduction in cumulative positive betaHCG, clinical pregnancy and implantation rates was observed in the group of patients with higher maternal age

What is known already: In analyzing the outcomes of oocyte donation cycles, most attention has been focused on comparing results between fresh and vitrified oocytes, on the efficiency of vitrification protocols and on the effect of oocyte storage time/method on survival rate. Surely, the oocytes status is essential to the outcome of donation cycles, especially when frozen oocytes are concerned. However, successful implantation depends also on endometrial receptivity. It has been proposed that uterine age may play a role in endometrial response at a molecular level. However, existing reports on this issue are conflicting and many of them indicate no effect of uterine age.

Study design, size, duration: In Italy, egg donation was reintroduced with the last Constitutional Court sentence in April 2014. Vitrified oocytes were either imported from a foreign bank or obtained from our own bank. Oocytes were thawed and all inseminated by ICSI after 2 h incubation at 37°C, 5% O_2 and 6% CO_2. Retrospective analysis of cumulative pregnancy and implantation rates in our population is presented here. Data analysis was performed with Fisher's exact test. Data are expressed as mean ± SD.

Participants/materials, setting, methods: Our population was divided into 3 groups based on maternal age of the recipient at the time of transfer: group 1) $N = 17$, age 28–38 (35.4 ± 2.77); group 2) $N = 80$, age 39–44 (42.8 ± 1.55); group 3) $N = 49$, age 45–50 (47.0 ± 1.16). Patients were prepared with GnRH agonist and increasing doses of oestrogens. With advanced maternal age (>38) and/or amenorrhoea, additional treatment with oestrogens and progesterone was provided (days 1–7: 4 mg oestrogens; days 8–14: 6 mg oestrogens; days 15–21: 6 mg oestrogens+progesterone).

Main results and the role of chance: 976 oocytes were thawed (average/patient 6.1 ± 1.15); survival rate was 86.2% (841/976); donor's mean age was 27.1 ± 3.87; fertilization rate was 64.9% (546/841). Out of 162 cycles, 13 were cancelled for oocyte degeneration ($N = 2$) or null embryo development; 146 cycles underwent fresh ET whereas in 3 cycles embryos were all frozen. Out of 146 cycles with fresh transfer, in 52 (35.6%) no supernumerary embryos were frozen whereas in 94 cycles, 1–6 embryos were vitrified (average/cycle 2.2 ± 1.18). Cumulative positive betaHCG, clinical pregnancy and implantation rates on 173 transfer cycles (146 fresh, 27 frozen) were, respectively, 60.0% (12/20), 50.0% (10/20) and 30.6% (11/36) in group 1; 54.4% (49/90), 42.2% (38/90) and 30.0% (51/170) in group 2; 42.2% (27/64), 35.9% (23/64) and 24.3% (27/111) in group 3 (NS). This result was not significant probably for the low number of cycles. In our overall population the cumulative abortion rate per clinical pregnancy was 25.4% (18/71). This value could be underestimated since 35 pregnancies are still ongoing; 18 pregnancies gave birth to 20 healthy babies (delivered at 32–38 weeks of gestational age): 5 females and 15 males

Limitations, reasons for caution: Data presented here derive from cycles still ongoing and not all frozen embryos have been thawed, therefore it was not possible to estimate weather an average of 6.1 oocyte/cycle was adequate to give birth. Complete information on abortion rate in relation to maternal age is not yet available.

Wider implications of the findings: The success of oocyte donation relates not only to oocytes, donor's age, freezing and storing methods. An altered uterine receptivity with advanced age could imply a lower implantation or higher miscarriage. We hypothesize that the number of starting frozen oocyte needed in donation cycles should change according to maternal age.

Trial registration number: Not applicable

P-406 Long term outcomes in IVF: a systematic review and meta-analytical estimate of cumulative live birth and dropout rates

O. Pirrello[1], P. Arvis[2], I. Parneix[3], L. Fresneau[4], P. Lehert[5], C. Avril[6], F. Lesourd[7], G. CQFD[4]

[5]*University of Melbourne, Faculty of Medicine, Melbourne, Australia*
[6]*Clinique Mathilde, Assisted Reproductive Technology, Rouen, France*
[7]*Hôpital Paule de Viguier, Department of Assisted Reproductive Technology, Toulouse, France*

Study question: Although constituting the main endpoint of IVF, few studies estimate Cumulative Live Birth Rate (CLBR) and dropout rate (DOR), or compare countries or centers.

Summary answer: Point estimates and credible 95% $C_r I$ of CLBR or DOR are 41.6% [24.3–75.6] and 49.5% [21.3, 63.8] respectively, both strongly influenced by patient mix, country and center performance.

What is known already: CLBR and DOR are difficult to estimate, mainly due to missing data and switches between centers. No systematic review or meta-analysis was conducted on this question. Important differences are suspected among countries, centers, initial patient's selection, rate of cancellation, used ART and freezing techniques, number of embryos per transfer, items selected for statistics, and a possible trend of center performance in time. Moreover, the definitions of CLBR and DOR, and the statistical

techniques are heterogeneous between the studies, making the comparison difficult.

Study design, size, duration: We conducted a systematic review and meta-analysis on literature findings. The main endpoint was long term IVF outcome. All studies published from 1995 to 2015 and reporting estimates of CLBR or DOR were included. For each study, we additionally collected the year of publication, country, number of centers, duration of follow-up, and inclusion conditions. For studies reporting subgroups, CLB and DOR were documented for each category of age, indication, and rank of attempts.

Participants/materials, setting, methods: A literature search of peer reviewed papers was conducted, using keywords as dropout, long term, IVF, CLBR, excluding abstracts. CLBR estimate was the main endpoint, CLBR dispersion estimated by the credibility interval (defined as containing 95% of the studies). Our primary analysis was a random Model, illustrated by a Forest plot and measurement of between study effects measured by I^2 statistics. Secondary analyses included meta-regressive models using age, publication year, type of study as meta-variates.

Main results and the role of chance: 34 studies were found during 1995–2015 period, over 15 countries. 9 were prospective studies, 17 were multicenter studies. The mean follow-up duration was 60 ± 33 months. The methodological quality index varied within [0.51, 0.87]. The median number of patients and cycles per study were 1001 [IQ: 550, 3011], and 2367 [1328, 5310]. The overall estimate and credible 95% C_rI of CLBR are 41.6% [24.3–75.6], this value was heterogeneous by country (SD = 0.036), and center within country (SD = 0.061). An inverse U-curve quadratic effect of age and a linear positive trend in time (0.008/year [0.002, 0.014], $p < 0.001$) were identified. The adjusted CLBR for the population of reference (30 years old, study in 2015) was 47.9% [37.5, 58.4]. The overall DOR was 49.5% 95% C_rI [21.3, 63.8], found very heterogeneous by country (SD = 0.083), and center within country (SD = 0.092). A strong increasing linear effect of age (0.019/year, [0.015; 0.023], $p < 0.001$) but no positive trend in time were identified. The adjusted DOR for the population of reference (30 years old, study in 2015) was 39.1% [22.1, 56.4].

Limitations, reasons for caution: Major endpoint in IVF, CLBR is poorly known and very seldom evaluated. Important differences were observed on definition of CLBR and dropout. In particular, for some studies, the possible switch of patients to other centers was not reported or considered as missing.

Wider implications of the findings: This first international meta-analytical estimate provides evidence of a positive trend of CLBR with time, but a strong heterogeneity of the performance among the centers. The DOR is even more heterogeneous among centers and does not decrease with time. Collaboration among centers is needed to optimize Center performance.

Trial registration number: NO Trial registration number

P-407 A randomized trial comparing the efficacy and safety of rFSH+rLH vs. rFSH alone and hMG to induce ovulation in cycles for low complexity techniques

D. Bejarano Velázquez[1], L.O. De la O Pérez[2], J.D. Treviño Báez[2], O.A. Gonzalez Díaz[2]
[1]*Monterrey, Mexico*
[2]*Instituto Mexicano del Seguro Social, Unidad Medica de Alta Especialidad NO.23, Biology of Human Reproduction, Monterrey, Mexico*

Study question: What is the efficacy and safety of rFSH+rLH stimulation scheme compared with rFSH alone and hMG in cycles for intrauterine insemination or programmed intercourse?

Summary answer: Stimulation with rFSH+rLH shown a significantly higher number of developing follicles with fewer stimulation days and similar safety parameters compared with hMG and rFSH alone

What is known already: Ovarian stimulation and programed intercourse are considered the initial treatment of anovulatory infertility and/or idiopathic. The most used drugs to induce ovulation are clomiphene citrate, recombinant follicle stimulating hormone (rFSH) and menotropins (hMG), reporting ovulation rates of about 80%; while pregnancy rates are up to 30%. Nonetheless, recombinant luteinizing hormone (rLH) supplementation has been used for treatment of high complexity patients with hypogonadism-hypogonadotropic, over 35 years or poor responders, which have reported improved pregnancy rates. This stimulation scheme also could benefit to younger patients undergoing low complexity; however, it is necessary to demonstrate the efficacy and safety of the treatment

Study design, size, duration: A randomized clinical trial, open label, comparing three schemes of ovulation induction. The sample size calculated included 152 cycles as followed: Group A, (rFSH+rLH) 51 cycles, Group B (rFSH) 53 cycles, Group C (hMG) 48 cycles; from January to December 2015, obtained by probabilistic sampling for intrauterine insemination or programmed intercourse

Participants/materials, setting, methods: Women aged ≤35 years attended at Reproductive Medicine Department, with unexplained infertility or anovulation. Patients were requested to have a BMI ≤30 kg/m^2, unilateral or bilateral tubal permeability, normal thyroid function, baseline serum FSH level ≤10 UI/l. They were randomized into 3 groups. Ultrasound and estradiol level until at least one follicle reaches to 18–23 mm, hCG triggering and intrauterine insemination or timed intercourse were performed

Main results and the role of chance: Demographic characteristics were similar in 3 groups. Baseline levels of FSH, LH, estradiol and TSH were comparable in all patients. The efficacy was significantly higher in the hMG and rFSH+rLH groups with percentages of response of 96% and 98% of ovulatory cycles respectively, compared with rFSH alone group with 85% ($p = 0.02$). The canceled cycles were more frequent with rFSH treatment ($p = 0.009$). It also was observed that rFSH+rLH treatment has a significantly higher number of follicles of 18–23 mm ($p = 0.01$), estradiol levels on day 10 ($p = 0.001$), fewer days of stimulation ($p = 0.010$) and fewer total units administered ($p \leq 0.001$) compared with the other treatments. hMG and rFSH+rLH treatments were significant in endometrial morphology ($p = 0.01$), the number of patients with hCG triggering ($p = 0.02$) and intrauterine insemination ($p = 0.004$). The pregnancy rate was higher but not significant in rFSH+rLH group ($p = 0.37$). There were no serious adverse events reported in any studied group

Limitations, reasons for caution: The development of more randomized trials in our population is necessary to obtain more clinical evidence and statistical significance. Also should be important to include a greater number of cycles in multicentre future trials

Wider implications of the findings: The rFSH+rLH stimulation scheme is an effective and safe treatment for infertile women in cycles for low complexity, that can be considered as first-line treatment for younger patients with anovulation or unexplained infertility, based on fewer days of doses and stimulation with similar rates compared to other schemes already used

Trial registration number: IMSS: R-2015-1905-10

P-408 Subcutaneous aqueous versus vaginal progesterone gel for luteal phase support in intrauterine insemination cycles: a pilot randomized, controlled trial

R. Venturella[1], R. Mocciaro[1], D. Lico[1], M. Rocca[1], A. Di Cello[1], F. Piccione[1], P. D'Alessandro[1], M. Morelli[1], F. Zullo[1]
[1]*University Magna Graecia, Chair of Obstetrics and Gynecology, Catanzaro, Italy*

Study question: Is pregnancy rate with subcutaneous progesterone similar to vaginal progesterone gel when used for luteal phase support in controlled ovarian stimulation (COH)-intrauterine insemination (IUI) cycles?

Summary answer: The clinical pregnancy rates are comparable between subcutaneous and vaginal gel progesterone, with a difference between groups consistent with the non-inferiority of subcutaneous formulation.

What is known already: Luteal phase support has been demonstrated to increase pregnancy rates among women undergoing IUI when receiving gonadotropins for ovulation induction. No significant differences in clinical pregnancy rates have been reported between vaginal progesterone gel and other vaginal or intramuscular progesterone products by authors, but no study have been conducted on the effect of the new subcutaneous formulation in women undergoing COH-IUI cycles.

Study design, size, duration: This open-label, prospective randomized, controlled, parallel-group, two-arm, non-inferiority pilot study was performed between December 2014 and January 2016. A total of 246 patients who underwent urinary follicle stimulating hormone (FSH) preparation (Fostimon)-stimulated

IUI cycles were prospectively randomized into 2 groups for luteal phase support. The study group (n = 120) received aqueous subcutaneous progesterone (Pleyris), and the control group (n = 126) received vaginal progesterone gel (Crinone 8) supplementation.

Participants/materials, setting, methods: In total, 246 women 18–38 years old, with either primary or secondary infertility for at least 1 years, body mass index between 19 and 30 kg/m^2, Day 2 serum FSH <15 IU/ml, normal serum prolactin level, normal uterine cavity on hysterosalpingography or hysteroscopy undergoing COH-IUI were randomized to an aqueous preparation of progesterone administered subcutaneously (25 mg daily) or vaginal progesterone gel (90 mg daily).

Main results and the role of chance: Using a PP analysis, which included all patients who received IUI (Pleyris =120; Crinone 8 =126), the ongoing pregnancy rate per cycle for subcutaneous versus vaginal progesterone was 12.7 versus 11.9%, with a difference between groups of −0.8% (95% CI −3.4, 2.8), consistent with the non-inferiority of subcutaneous progesterone for luteal phase support. In addition, rates of initial positive β-hCG (14.4% subcutaneous versus 14.0% vaginal) and clinical intrauterine pregnancy with fetal cardiac activity (13.8 versus 12.9%) were comparable. Both formulations were well tolerated, with no difference in serious adverse events. The result in tolerability of the drugs was measured using a satisfaction score ranging from 0 to 10 and the satisfaction among patients receiving subcutaneous was similar to vaginal gel (7.8 ± 3.1 subcutaneous versus 7.1 ± 2.9 vaginal; p = 0.126). By rotating the sites of injections with each dose (abdomen, arm, thigh, or buttocks) women randomized to Pleyris significantly reduced skin irritation and pain and increased their satisfaction with the new formulation. Possibility of self-administration, no need for special "confidence" with lower genital tract, no vaginal side effects, no interference with sexual activity and improvement of menstrual pain in women with endometriosis were also reported as advantages of subcutaneous progesterone administration by patients.

Limitations, reasons for caution: The conclusions are limited to the progesterone dosing regimen studied and duration of treatment for the patient population examined in this study. Data on live-birth rates are still ongoing and the study was not powered to detect differences in term of patients' satisfaction with drugs

Wider implications of the findings: Subcutaneous progesterone is a new option for luteal phase support in women undergoing assisted reproduction cycles (both IUI or IVF) who for are not confident with their genital tract or prefer not to use a vaginal preparation or who wish to avoid the side effects of vaginal routes of administration.

Trial registration number: NCT02316626.

P-409 The influence of initiation of progesterone supplementation in IVF-ET outcome-a prospective, randomized, controlled trial

J. Gao[1], F. Gu[1], B.Y. Miao[1], C. Zhou[1], Y. Xu[1]
[1]*The First Affiliated Hospital, Sun Yat-Sen University, Reproductive Center, Guang Zhou, China*

Study question: What is the optimal time for initiation of luteal phase support (LPS) in in-vitro fertilization and embryo transfer (IVF-ET) cycles

Summary answer: Initiation of progesterone supplementation on day +1 of oocyte retrieval did not decreased clinical pregnancy rate and implantation rate

What is known already: There is a consensus in the literature that LPS is necessary for IVF cycles. There has been significant debate regarding timing, dose, and routes of P administration. With regard to the timing of P initiation, it has been proposed that early P administration may be of benefit for ET by relaxing effect of P on the uterus. Conversely, ART cycles may be associated with advancement of the endometrium leading to embryo-to-endometrial asynchrony and implantation failure. Too early administration of P may further expand this asynchrony. In China most centers start P administration on the day of oocyte retrieval.

Study design, size, duration: This prospective randomized control study was conducted on 187 patients who underwent long-protocol treatment from 1 Oct 2014 to 31 Jan 2015 at our hospital.

Participants/materials, setting, methods: A computer-base randomization divided the recipients into two groups when HCG trigger. The first group (group A) started progesterone supplementation 1 day after oocyte retrieval; the second group (group B) started progesterone supplementation on the day of oocyte retrieval. Both of them receive embryo transfer 72 h to 120 h after oocyte retrieval.

Main results and the role of chance: Two groups were equal in COH protocol and causes of infertility. There were no significant differences with regard to the serum estrogen and progesterone level on the day of HCG trigger, oocyte retrieval and embryo transfer. The clinical pregnancy rate (group A 54.3% vs. group B 50.5%), implantation rate (group A 37.6% vs. group B 37.0%), and early pregnancy loss rate (group A 6.0% vs. group B 2.1%) were similar between the two groups.

Limitations, reasons for caution: In this paper we study the initiation time of i.m progesterone. It suggest that different routs of P administration may have influence on LPS initiation point. Addition randomized clinical trials are needed to better define P start time for luteal support for vaginal P, which is our future research direction.

Wider implications of the findings: We found that postpone the initiation of LPS to 1 day after oocyte retrieval would not result in insufficient of progesterone level on embryo transfer day and decrease the clinical pregnancy rate in ART. Besides that postpone the initiation of LPS would relieve patient's pains of intramuscular injection.

Trial registration number: Our study has registered in Chinese Clinical Trial Registry and the registration number is ChiCTR-IPR-14005293

P-410 A retrospective cohort study to investigate AMH-tailored optimisation of controlled ovarian stimulation in IVF cycles

O. Rustamov[1], J. Wilkinson[2], C. Fitzgerald[3], S. Roberts[2]
[1]*Central Manchester University Hospital NHS Foundation Trust, Department of Reproductive Medicine, Manchester, UK*
[2]*University of Manchester, Centre for Biostatistics, Institute of Population Health, Manchester Academic Health Science Centre (MAHSC), Manchester, UK*
[3]*Central Manchester University Hospital NHS Foundation Trust, Manchester Academic Health Science Centre (MAHSC), Department of Reproductive Medicine, Manchester, UK*

Study question: Which pituitary desensitisation regime and initial dose of gonadotropins should be used in controlled ovarian stimulation (COS) for patients with different anti-mullerian hormone (AMH) levels?

Summary answer: We did not find effect of increasing gonadotropin doseon oocyte yeild Consequently, it may not be possible to optimise dose and regime according to AMH.

What is known already: Tailoring COS protocols according to AMH is believed to be an effective strategy for optimising ovarian response, and has been widely advocated.

Study design, size, duration: Retrospective cohort study covering the period 1st October 2008 to 8th August 2012. 1851 treatment cycles undertaken by 1430 patients were included. The study was not subject to attrition, as cancelled cycles were included in the analysis.

Participants/materials, setting, methods: Women of 21–43 years of age undergoing ovarian stimulation for IVF (possibly with ICSI) using their own eggs at the Reproductive Medicine Department of St Mary's Hospital. Regime (GnRH long agonist or GnRH antagonist) and initial gonadotropin dose was selected on the basis of AMH. Patients received doses of 75–150 IU (n = 297), 187–250 IU (n = 484), 300 IU (n = 919), 375 IU (n = 62) or 450 IU (n = 89).

Main results and the role of chance: Compared to 75–150 IU in a GnRH long agonist cycle, yield ratios (95% CIs) corresponding to number of oocytes retrieved per cycle were, in GnRH antagonist cycles: 0.76 (0.67 to 0.86) for 75–150 IU, 1.08 (0.90 to 1.30) for 187–250 IU, 1.04 (0.91 to 1.18) for 300 IU, 1.11 (0.90 to 1.37) for 375 IU and 0.94 (0.76 to 1.17) for 450 IU. In GnRH long agonist cycles, adjusted rate ratios (95% CIs) were 1.12 (1.01 to 1.25) for 187–250 IU, 1.17 (1.03 to 1.33) for 300 IU, 1.18 (0.92 to 1.51) for 375 IU and 1.07 (0.87 to 1.33) for 450 IU. There was no evidence to suggest that dose effects varied according to AMH (p = 0.60).

Limitations, reasons for caution: This was a retrospective, observational study where COS treatment was selected on the basis of AMH. Although we have adjusted for a large number of plausible confounders, confounding due to unmeasured factors remains a concern. The possibility of a dose-response was not completely ruled out by 95% CIs.

Wider implications of the findings: If there is no effect of increasing dose on stimulation response, then optimisation of COS according to AMH may not be feasible. Existing evidence for AMH-tailored COS has limitations, and an AMH-stratified RCT using clinical doses of gonadotropin in different pituitary desensitisation regimes is needed.
Trial registration number: Non applicable.

P-411 How low can you go? – cutoff limit for IUI in mill/ml

L. Zierau[1], S. Lindenberg[1]
[1]*Copenhagen Fertility Center, Copenhagen Fertility Center, Copenhagen, Nordvest, Denmark*

Study question: How low is the cutoff concentration of motile semen in IUI to get a pregnancy rate of 5%?
Summary answer: Between the age of 17–39 a clear cutoff at 2 mill/ml motile semen cells were needed to achieve a minimum pregnancy rate of 5%.
What is known already: IUI is widely used in couples with unexplained infertility or mild to moderate male infertility. Despite the extensive literature in the area, the effectiveness of the IUI is still questioned.

IUI is known to increase the gamete density at the site of fertilization and thereby increase the pregnancy rate. Through literature, no consensus of the minimum concentration of motile semen, needed to achieve a pregnancy rate of 5%, is found. The correlation between the age of the women inseminated, the semen concentration and the pregnancy rate is also yet to be defined.
Study design, size, duration: In a retrospective study from 2012–2015, data of 4.322 IUI cycles was consecutively collected in a private clinical setting (Copenhagen Fertility Center, Denmark).
Participants/materials, setting, methods: All IUI cycles with use of homologous semen were included. The mean age of the women were 35 years. The mean motile semen concentration after washing was 30 mill/ml. All women were grouped into age brackets of: 17–29, 30–34, 35–39, >40 years of age. All inseminations were grouped according to motile sperm concentration count after washing: <2, 2–7.9, 8–49.9 and >50 mill/ml.
Main results and the role of chance: In all age groups, a pregnancy rate of less than 5% was seen when inseminated with <2 mill/ml. In the 17–29 bracket group a significant increase in pregnancy rate of 23% was seen when inseminated with >50 mill/ml compared to the women inseminated with <2 mill/ml (23% increase in pregnancy rate) 2–7.9 and 8–49.9 mill/ml ($p < 0.01$). In the 30–34 bracket a significant increase in pregnancy rate of 15% was seen comparing women inseminated with <2 mill/ml to women inseminated with >50 mill/ml ($p < 0.01$). Among the 35–39 bracket a significant increase in pregnancy rate of 13% was seen comparing women inseminated with <2 mill/ml with women inseminated with >50 mill/ml ($p < 0.05$). In the >40 bracket no pregnancies was found when inseminated with <2 mill/ml. No significant increase in pregnancy rate was seen when comparing the different semen concentration groups. The respective pregnancy rates was according to the semen concentration: 2–7.9 mill/ml = 6%, 8–49.9 mill/ml = 6% and >50 mill/ml = 5%.
Limitations, reasons for caution: This study includes only patients attending a private fertility clinic in Denmark, situated in Copenhagen. Therefore, the patients are selected from their geographic location. The next study in line could include patients outside the capital**.**
Wider implications of the findings: This large population study demonstrates the importance of a clear cutoff at 2 mill/ml for IUI treatment to achieve a minimum pregnancy rate of 5%. The low pregnancy rates in IUI treatment among women aged >40 underlines the importance of sufficient stimulation and fast conversion to IVF when needed.
Trial registration number: N/A

P-412 New findings on acute immunomodulatory changes during controlled-ovarian-stimulation

M. Noventa[1], A. Vitagliano[1], S. Borgato[1], F. Esposito[1], M.V. Di Giovanni[1], M. Gangemi[1], M. Quaranta[2], H. Al Hussain[2], F. Khalid[2], S. Gizzo[1]
[1]*University of Padua, Woman and Child Health, Padova, Italy*
[2]*NHS Trust, Northampton General Hospital, Obstetrics and Gynecology, Northampton, UK*

Study question: May estradiol raise exert an immunomodulatory effect in women undergoing COS?
Summary answer: The acute increase of E2 during COS for infertility treatment does not seem to have a major impact on the immune system.
What is known already: The higher incidence of B-cell mediated autoimmune diseases in women of childbearing age have been imputed to the oestrogens power to promote a shift from Th1 to Th2 immune response. At this regard, experimental murine studies have recently demonstrated that the upregulation of E2 (17β-Estradiol) is capable to influence B cell development, selection, and activation, thus leading to a loss of B cell tolerance, and the promotion of B cell autoreactivity, lymphoproliferation, hypergammaglobulinemia, and autoimmunity.
Study design, size, duration: We conducted a prospective study on idiopathic infertile women aged between 18–43 years, scheduled for fresh non-donor IVF treatment between January 2011 and March 2014. All patients were defined normo-responders according to biochemical and sonografical features (Group_A: treatment group). We also recruited a cohort of normo-ovulatory age-matched healthy women (Group_B: control group) who spontaneously adhered to the aim of the study. Their serum samples were used for time-matched comparison with Group_A.
Participants/materials, setting, methods: In the setting of the Infertility Center of University of Padua, we enrolled 63 infertile normo-responder women (Group_A) undergoing COS and 39 normo-ovulatory healthy women (Group_B). We analyze for all patients serum levels of E2 and BAFF (B cell-activating factor), BAFF/E2 ratio, circulating IgM, IgG and IgA, ANA (anti-nuclear antibodies) and peripheral B-cell phenotype according the subsequent timing: T0 (hypothalamic-suppression), T1 (ovulation-induction) and T2 (βhCG-test) in Group_A; T0 (2nd day of spontaneous menstrual cycle), T1 (14th day) and T2 (21th day) in Group_B.
Main results and the role of chance: At T0, the comparison between women in Group_A versus Group_B showed no significant differences in terms of absolute value of E2 as well as absolute value of BAFF. Also considering the BAFF/E2 ratio, no significant difference was observed between Group_A and Group_B. At T1, a significant difference in absolute values of E2 between Group_A and Group_B was recorded ($p < 0.0001$), without any difference in terms of absolute value of BAFF and the BAFF/E2 ratio. Of the 63 women in Group_A, 15 became pregnant. Concerning the absolute values of BAFF, the comparison between the non-pregnant women of Group_A and Group_B showed no differences as well as the comparison between the non-pregnant versus the pregnant women of Group_A. Considering only Group_A patients, a correlation was observed between BAFF levels at T0 and IgM at T0 (rho= 0.401; $p = 0.009$), T1 (rho=0.496; $p = 0.002$) and at T2 (rho= 0.406; $p = 0.061$). Concerning the peripheral B cell subpopulation status in Group_A, a tendency was observed toward an expansion of the mature marginal zone CD19+ CD27+ IgD+ of memory B cells at T1 in comparison with T0 ($p = 0.083$), whereas the proportion of immature B-transitional-type 2 B cells CD19+ CD27 − IgDhiCD21hi was lower at T1 than at T0 ($p = 0.074$).
Limitations, reasons for caution: The small sample size, the fact that all infertile patients were affected by unexplained infertility, the relatively low pregnancy rate, the absence of evidences regarding the effects of different COS protocols, and the lack of data regarding pregnancy after spontaneous cycle represent potential bias of our study.
Wider implications of the findings: If our results will be confirmed, COS may be considered as a medical procedure with safe short-term effects on women immunological profile.
Trial registration number: N/A

P-413 Intra uterine insemination pregnancy outcome is not affected by a longer time interval between semen processing and insemination

C.H.J.R. Jansen[1], L.M. Dijksman[2], M.G.L.M. Elisen[1], C.W. Leenstra[1], E.M. Kaaijk[1], K. van Stralen[3], H.R. Verhoeve[1]
[1]*OLVG, Fertility, Amsterdam, Netherlands*
[2]*OLVG, Epidemiology, Amsterdam, Netherlands*
[3]*Spaarne Gasthuis, Epidemiology, Hoofddorp, Netherlands*

Study question: Is the pregnancy outcome of intrauterine insemination (IUI) affected by a longer time interval between semen processing and insemination?
Summary answer: There is no difference in on-going pregnancy rate between insemination directly after semen processing compared to insemination 24 h after semen processing.

What is known already: IUI outcome depends on multiple factors such as patient characteristics, timing of ovulation and semen-quality. Semen processing is essential since spermatozoa have limited survival capacity and other constituents in semen, such as leucocytes and dead spermatozoa, produce oxygen radicals that negatively influence the ability to fertilize the egg. Previous data suggest that IUI pregnancy outcome is enhanced by a short time interval between semen collection and semen processing before IUI. It has also been suggested that pregnancy outcome after IUI is enhanced by shortening the time interval between processed sperm and IUI, but the evidence for this is lacking.
Study design, size, duration: Historically in our clinic, if ovulation takes place on a Saturday, sperm is collected and processed on the Friday before. Several unpublished analyses in the past showed no negative effect on pregnancy outcome but a systematic evaluation of this policy was never performed. This is a single-centre, retrospective cohort study including 2154 IUI cycles in 1135 couples. To avoid duplicates we analysed only the last IUI. Data were collected between November 2005 and April 2015.
Participants/materials, setting, methods: patients in whom ovulation and insemination took place on Saturdays and semen was collected and processed on Friday for logistical reasons (delayed insemination) were compared to patients where processing of sperm and insemination took place on Friday (immediate insemination). Depending on the subfertility diagnosis, IUI-cycles were either with or without controlled ovarian hyperstimulation. Baseline characteristics and cycle specific information were collected. For statistical analysis independent T-test and Chi-square contingency test were performed.
Main results and the role of chance: In total 1135 couples were analysed. In 13% of the couples pregnancy occurred after immediate insemination (77/588) and 14% of the couples were pregnant after delayed insemination (77/547). Both groups had similar clinical characteristics, with all P values >0.05. After adjustment for female age, male age, type of subfertility, indication of IUI, type of stimulation and total motile count, there was no difference in on-going pregnancy rate after immediate or delayed insemination, odds ratio 0.89 (95% CI: 0.63 to 1.25).
Limitations, reasons for caution: This is a single centre, retrospective cohort study. Therefore, the level of evidence is moderate. We might have overestimated the overall pregnancy rate since we only evaluated the last IUI cycle of every couple.
Wider implications of the findings: This study suggests that there is no negative effect on on-going pregnancy rates when IUI with processed sperm is delayed. This approach allows additional flexibility for couples if the partner is not available on the day of ovulation. Also, semen processing on Fridays reduces the laboratory workload in the week-end.
Trial registration number: WO 15.111

P-414 "Operative complications and results after laparoscopic removal and transplantation of ovarian tissue: own experience in comparison with the literature"

S. Findeklee[1], L. Lotz[1], I. Hoffmann[1], R. Dittrich[1], M.W. Beckmann[1]
[1]*Universitätsklinikum Erlangen Frauenklinik, OB/GYN, Erlangen, Germany*

Study question: What is the frequency of surgical complications and the pregnancy rate occurring in laparoscopic removal and transplantation of ovarian tissue for fertility preservation in cancer?
Summary answer: Laparoscopic removal and subsequent transplantation of ovarian tissue is a procedure with a very low complication rate and a chance for pregnancy of about 15–30%.
What is known already: Fertility preserving techniques in oncological treatments are gaining an increasing weight. Long-term survival in cancer could have been prolonged and the fulfilling of the wish for a child is being shifted in later periods of life. At the same time, the gonadotoxic potential of oncological therapy did not decrease. A fertility-preserving option in oncological patients becoming more and more popular is the laparoscopic removal of ovarian tissue before and its transplantation after treatment. Until today, operative complications and pregnancy rates within this procedure have not been investigated very well.
Study design, size, duration: We performed a selective research of the literature yet being published in MEDLINE about operative complications and pregnancies in the context of removal and transplantation of ovarian tissue to preserve fertility. Altogether 16 publications about the removal and 15 publications about the transplantation of ovarian tissue were detected.
Participants/materials, setting, methods: Afterwards, we compared the results retrospectively with those of 29 patients treated at our centre between May 2007 and November 2014. So we combined the systematic review of the published literature with a retrospective analysis of operative and pregnancy outcome during the procedure of laparoscopic removal and transplantation of ovarian tissue.
Main results and the role of chance: Laparoscopic removal and transplantation of ovarian tissue are operative procedures with a low risk for complications. Potential risks such as post-operative haemorrhage or wound infection occur with a frequency of <1%. In most cases there is no complication at all. More than 60 children already have been born after removal and transplantation of ovarian tissue. This number is raising. In the 29 patients treated at our centre we did not observe any operative complication. There were 9 pregnancies with 5 live births in 7 different patients. The pregnancy rate of 24% at our centre is comparable with the frequency of pregnancies reported in literature of about 15–30%.
Limitations, reasons for caution: The evidence about complication rates of removal and transplantation found in literature is very limited. There are no prospective randomized controlled trials evaluating this field at all. The patient collective of our single centre is small and we performed a retrospective analysis.
Wider implications of the findings: In our eyes-due to the results-laparoscopic removal and transplantation of ovarian tissue should be regarded as a standard surgical procedure as any other laparoscopy else and it should be offered to every premenopausal woman with cancer and potential future wish for a child undergoing oncologic therapy.
Trial registration number: none

P-415 Initial trial of a serum diagnostic profile to predict outcome of embryo transfer

T. Edgell[1], L. Rombauts[2], B. Vollenhoven[2], L. Salamonsen[1]
[1]*Hudson Institute for Medical Research, Centre for Reproductive Health, Clayton, VIC, Australia*
[2]*Monash University, Department of Obstetrics and Gynaecology, Clayton, VIC, Australia*

Study question: Can a serum diagnostic profile at hCG+2 predict the outcome of a same cycle embryo transfer?
Summary answer: A serum biomarker panel shows promise as a same cycle prognostic test for embryo transfer outcome.
What is known already: Successful IVF requires both a quality embryo and a receptive endometrium. Currently there is no diagnostic test available to assess the quality of the maternal endometrium during an embryo transfer cycle. Previous studies focussed on gene or protein profiling of tissue and uterine secretions during the anticipated receptive period. However these approaches have limited utility within an embryo transfer cycle, due to tissue damage potentially compromising implantation and time constraints of sample collection and assay prior to embryo transfer. A serum assay performed at oocyte retrieval would overcome these limitations, informing of likelihood of successful transfer, and increase success rates.
Study design, size, duration: Serum was collected with informed consent at the time of oocyte retrieval from 397 women over an 18 month period. Of these women 280 (aged 23–46 years) underwent embryo transfer in the same cycle and are included in this analysis. Logistic modelling was performed and performance assessed by ROC analysis.
Participants/materials, setting, methods: Serum was assayed for Colony Stimulating factor-3 (CSF3), Interleukin-8 (IL8), Interleukin-6 (IL6), vascular endothelial growth factor (VEGF) and Interleukin-17A (IL17A) using Milliplex bead-based ELISA. C-reactive protein (CRP) was determined using Randox high sensitivity assay. Additional parameters, e.g., peak estradiol, progesterone, embryo quality, age, BMI, etiology, endometrial thickness, etc., were collected. Outcome of embryo transfer was determined as a confirmed pregnancy by ultrasound; biochemical pregnancies, Any not confirmed by ultrasound were excluded.
Main results and the role of chance: Logistic models combining the six biomarkers along with other parameters showed significance in predicting the outcome of embryo transfer for the women with confirmed pregnancy or no pregnancy outcomes. Four markers (CSF3, IL17A, VEGF and IL8) showed strong discrimination of pregnancy and no pregnancy outcomes, as did a number of ratio combinations of the six.

In logistic regression models, criterion values in ROC analysis were assigned to ensure prediction of successful pregnancies was as close to 100% as possible, at the expense of poorer detection of failed pregnancy.

For day 2/3 transfers (n = 100) ROC curve analysis gave AUC = 1.000 with significance $p < 0.0001$, thus 100% correct predictions, PPV of 100 and NPV of 100 were achieved. The major factors used in the analysis were, age, Il6, CRP, IL8, P4, E2, and endometrial thickness.

For day 5/6 transfers (n = 162) ROC analysis gave AUC = 0.873 with significance $p < 0.0001$, with a sensitivity of 97.8 and specificity of 47.0, NPV = 98.2 and PPV = 41.5.

The major parameters used were; age, IL6, IL8, VEGF, CRP, CSF3, IL17A, P4, E2.

Limitations, reasons for caution: This is a single site preliminary trial of a new diagnostic for receptivity. Numbers are limited and a second test data set to evaluate the true diagnostic performance is required.

Wider implications of the findings: The use of serum as opposed to invasive uterine tissue or fluid is negated. Potential identification of further biomarkers including those to identify specific risk factors, best therapy options and combination with embryo quality testing may provide a path to cycle monitoring and individualised therapy.

Trial registration number: Not applicable

P-416 A new approach for egg collection, using a thin egg-collecting needle in a natural cycle, that produces multiple mature eggs from each follicle

M. Ochi[1], S. Watanabe[1], R. Matsunaga[1], N. Yamanaka[1], M. Kamihata[1], H. Miyamura[1], A. Kuwahata[1], T. Fujii[2], T. Horiuchi[3]
[1]*Ochi Yume Clinic Nagoya, ART Laboratory, Nagoya, Japan*
[2]*Fujita Health University, Department of Obstetrics and Gynecology, Toyoake, Japan*
[3]*Prefectural University of Hiroshima, Faculty of Life and Environmental Sciences, Shobara, Japan*

Study question: We collected eggs from every follicle produced during a natural cycle, including the dominant follicle, and examined whether multiple mature eggs could be produced.

Summary answer: Overall, 2 mature eggs were obtained from 37% of natural cycles. The eggs collected demonstrated high developmental potency and fertility.

What is known already: Although previous reports indicates that multiple mature eggs can be obtained from every follicle, including small ones, in a letrozole stimulated cycle, there are few reports on egg collection from every follicle as part of a natural cycle.

Study design, size, duration: We collected eggs during a natural cycle from 247 women (age: 37 years or younger, treatment cycle: 251) between January 2014 and April 2015.

Participants/materials, setting, methods: We collected eggs from every follicle during a natural cycle (down to those measuring 5 mm in diameter). Thirty-four hours after treatment with a gonadotropin releasing hormone agonist nasal spray the dominant follicle reached 17 mm or more in diameter. Puncturing of small follicles was carried out using a thin egg-collecting needle (KITAZATO, 22 or 23 G). We performed single embryo transfer and, in cases in which the embryo remained, offered blastocyst culture.

Main results and the role of chance: The average number of punctured follicles was 4.8. The total number of mature eggs obtained from follicles was 372 (1.5-egg per cycle). At least 1 mature egg was collected after 205 cycles (82%), and 2 mature eggs or more were obtained after 92 cycles (37%). The maximum number of mature eggs was 8. Single embryo transfer pregnancy rates were 42% (66/158). Blastocyst development rate of the remaining embryos was 32% (32/100). Blastocysts were vitrified. Women who failed embryo transfer underwent freeze-thaw blastocyst transfer during the next cycle after the failed transfer. Their pregnancy rate was 46% (6/13).

Limitations, reasons for caution: Not available.

Wider implications of the findings: Egg collection during a natural cycle has no risk of ovarian hyperstimulation syndrome and is less stressful for patients because they require less medication. Although a thin needle is used, multiple mature eggs can potentially be obtained from every follicle. Pregnancy rates increased when using the remaining embryos.

Trial registration number: Not available.

P-417 When is enough enough? Pregnancy rate and cost-effectiveness of three cycles homologous intrauterine insemination (IUI) vs. one cycle mild ovarian stimulation *in vitro* fertilization (IVF)

A. Cissé[1], L. Zierau[1], S. Lindenberg[1]
[1]*Copenhagen Fertility Center, Infertility, Copenhagen, Nordvest, Denmark*

Study question: Is the pregnancy rate by one mild ovarian stimulation IVF cycle higher than by three IUI cycles?

Summary answer: Mild ovarian stimulation for IVF provides a higher pregnancy rate as well as being cost effective when compared to three IUI cycles

What is known already: IUI is a widely used treatment because of the low costs and minimal risks. IUI is often repeated more than three times before converting to IVF. In IUI, cycles with Clomiphene Citrate stimulation, the pregnancy rate is 10–15% per cycles in women under the age of 35, with open tubes and a normal semen sample. After three IUI cycles the pregnancy rate drops to 5%. In contrast, mild ovarian stimulation for IVF has a pregnancy rate of 35–37% pr cycle. It's cost-effective and patient-friendly regimens optimize the balance of outcome and risks of treatment

Study design, size, duration: In a retrospective study data from 2010–2015, in a Danish private fertility clinic, was collected. In all 897 IUI, cycles and 53 IVF cycles were included. Only IUI cycles with homologous insemination and only IVF cycles with mild ovarian stimulation were included. Pregnancy rate was measured as positive hCG per cycle

Participants/materials, setting, methods: In the IUI group the mean age was 33. All were treated for three cycles with 50–100 IU Clomiphene Citrate, low dose follicle stimulating hormone (FSH) or no treatment. In the IVF group, the mean age was 34. They were treated with either 20–40 mg Tamoxifen or 50–100 IU Clomiphene Citrate daily, supplemented with FSH 150 IU injections every other day. Transfer of only one good quality embryo was performed between days 2–3 from aspiration

Main results and the role of chance: In the IUI group of 897, 109 of the women had a positive hCG after the third IUI cycle. In the group of mild ovarian stimulation for IVF, 16 of the 53 women had a positive hCG. This showed a significant difference in positive hCG between the IUI group and the IVF group (12% vs. 30%; $P < 0.001$). There was no significant difference in patients' age group

Limitations, reasons for caution: The number of patients in the IVF group was 53. In a future study, a larger group of patients should be included

Wider implications of the findings: This study shows how the pregnancy rate of one mild ovarian stimulation for IVF (30%) is more than the double as effective as three cycles homologous IUI insemination (12%). This underlines the importance of a discussion of a faster conversion in treatment from IUI to IVF

Trial registration number: N/A

P-418 Evaluation of dose depended protective effect of resveratrol at cisplatin induced ovarian damage

Y. Bayoglu Tekin[1], N. Çetin[2], Y. Kalkan[3], B. Süleyman[2], T. Mercantepe[3], Ü. Mete Ural[1], E.S. GüvendağGüven[4]
[1]*Recep Tayyip Erdogan University, Gynecology and Obstetrics, Rize, Turkey*
[2]*Erzincan University, Pharmacology, Erzincan, Turkey*
[3]*Recep Tayyip Erdogan University, Histology and Embriology, Rize, Turkey*
[4]*Black Sea Technical University, Gynecology and Obstetrics, Trabzon, Turkey*

Study question: Does Resveratrol have protective effect against cisplatin induced ovarian damage and is this effect dose depended.

Summary answer: Resveratrol has a protective effect against chemotherapy induced ovarian damage and this protective effect strengthens with the increasing dosages of Resveratrol

What is known already: Cisplatin is one of the most effective chemotherapy agent for several kinds of solid organ cancers. However it has adverse effects on reproductive capacity and ovarian functions. Many researches were carried out to restorate these side effects of cisplatin and prevent ovarian functions in women at reproductive ages with cancer. Resveratrol is a polyphenol found in grapes and red wine and has antioxidant, anticancer, antiangiogenic and anti-inflammatory activity. Recently it was shown that resveratrol has a role

at chemosensitizing and protective at cisplatin induced nephrotoxicity and ototoxicity.

Study design, size, duration: This study was conducted in a University Surgical Research Center. Twenty four Sprague-Dawley rats were randomly divided into four groups. Group 1, 2 and 3 were injected 5 mg/kg cisplatin for 7 days, additionally group 2 was administered 10 mg/kg and group 3 was administered 100 mg/kg Resveratrol 24 h before and during cisplatin injection period. Group 4 was vehicle. Rats were sacrificed at the end of the experiment and their ovarian tissue were excised.

Participants/materials, setting, methods: Ovarian damage was evaluated by vascular congestion, edema, follicular degeneration and vacuolization at hematoxylin and eosin staining and apoptosis was evaluated immunohistochemically with anti-Caspase 3 antibody.

Main results and the role of chance: Vascular congestion, edema, follicular degeneration and vacuolization were severe and significantly increased in Cisplatin group ($p < 0.001$). The protective effect of Resveratrol was observed in both low and high dosages ($p = 0.006$ and 0.001 respectively) but the ameliorative affect was most striking in high dosage group ($p < 0.005$) as decreased congestion, edema, vacuolization and follicular degeneration. Anti-Caspase 3 staining was significantly higher and prominent in group 1 ($p = 0.031$). There were significantly lower anti-Caspase 3 staining in group 2 and 3 in comparison to group 1 ($p = 0.048$ for each group).

Limitations, reasons for caution: Confirmation of the results with the human tissues would be required in the future.

Wider implications of the findings: Our results are proved that Resveratrol is a potential agent for ovary preservation from chemotherapy induced toxicity and the protective affect is enhanced dose depended.

Trial registration number: Project number: 2015.106.02.3.

P-419 Individual fertility assessment and counselling predicts prolonged time to pregnancy – a prospective two year follow-up study of 519 women

K. Birch Petersen[1], T. Maltesen[2], J.L. Forman[2], H.W. Hvidman[1], R. Sylvest[1], A. Pinborg[3], H.S. Nielsen[1], E.C. Larsen[1], K.T. Macklon[1], A.N. Andersen[1]
[1]Copenhagen University Hospital Rigshospitalet, Fertility Clinic, Copenhagen, Denmark
[2]Copenhagen University, Department of Biostatistics, Copenhagen, Denmark
[3]Copenhagen University Hospital Hvidovre Hospital, Department of Gynecology/Obstetrics, Copenhagen, Denmark

Study question: What is the predictive value of individual fertility assessment and counselling in terms of subsequent time to pregnancy?

Summary answer: The chance of achieving a spontaneous pregnancy within 12 months was reduced in women with at least one high risk score (OR 0.25, 95% CI 0.12–0.52).

What is known already: The reproductive patterns have changed substantially in the past decades. Several factors has led to increased demand for pro-fertility consultations: 1) postponement of family formation due to increased female education, 2) the option of single motherhood by donor insemination, 3) introduction of oocyte vitrification for non-medical reasons, and 4) the possible concealment of long-term oral contraceptive use on the ovarian reserve (Birch Petersen et al., 2015). The Fertility Assessment and Counselling Clinic (FACC) was initiated to provide individual assessment of infertility risk factors and ovarian reserve to help women fulfil their reproductive life-plan (Hvidman et al., 2015).

Study design, size, duration: Longitudinal cohort study including the first 570 women aged 20–43 who consulted the FACC at Rigshospitalet, Copenhagen University Hospital from 2011 to 2013. The study aimed to validate the risk assessment score from the initial consultation to identify the main female predictors of prolonged time to pregnancy after two years of follow-up.

Participants/materials, setting, methods: The women answered a baseline questionnaire (demography, health behaviour, gynaecological/reproductive history). A fertility specialist completed a risk assessment score sheet with items on infertility risk factors, AMH and ultrasound measurement of AFC, ovarian volume and pathology. For each parameter the risk score was categorized as green/yellow (low), orange (medium) and red (high) (Hvidman et al., 2015). After two years an email-based questionnaire was distributed regarding subsequent pregnancies, time to pregnancy (TTP), births, failed pregnancy attempts, other health-related or relationship changes.

Main results and the role of chance: A total of 570 women attended the FACC of which 519 (91.1%) answered the follow-up questionnaire. The mean female age was 35 years (SD 4.6), 38% were singles and 75% had an educational length of more than three years. The majority (67.8%, 352/519) tried to conceive within two years, of which 73.6% (259/352) achieved a pregnancy, 21% (74/352) were still trying and 5.4% (19/259) had given up trying. Almost one third (83/259) of the pregnancies were achieved after fertility treatment with IUI-H as the most frequently used procedure among couples (20/49) and IUI-D among singles (19/34). Of the remaining 167 women, 30% wished for a pregnancy at the time of follow-up, but were not actively trying. The women who had tried to conceive ($n = 352$) were similar to the women without any pregnancy attempts regarding age ($P = 0.49$), AMH ($P = 0.28$), AFC ($P = 0.08$), previous pregnancies ($P = 0.87$) and health behaviour. Two thirds of the women with only low risk scores ($n = 62$) conceived spontaneously within 12 months (65.6%), while this figure was only 28% for women with at least one high risk score ($n = 82$). Accordingly, presence of at least one high risk score reduced the odds of achieving a pregnancy within 12 months by 75% (OR 0.25, 95% CI 0.12–0.52).

Limitations, reasons for caution: The women attending the FACC are concerned about their ovarian reserve and reproductive time-span, which could imply a potential selection bias. The homogeneity of the included women and the relatively short follow-up period of two years may impede the predictive value of the continuous variables in the risk assessment.

Wider implications of the findings: The FACC was initiated to provide women information about their current fertility status to prevent involuntary childlessness, infertility and smaller families than desired. Based on these findings the new FACC concept seems usable and offers a tool for fertility experts to guide women on how to fulfil their reproductive life-plan.

Trial registration number: Establishment of the Bio Bank is approved by the Scientific Ethical Committee (nr: H-1-2011-081). Permission to store data was granted by the Data Protection Agency (30-0728).

P-420 Effects on the level of hormone in micro-environment of follicular fluid from advanced oxidation protein products

J. Liu[1], Y.L. Song[1], D.H. Chen[1], C. Luo[1], Z.L. Qiu[1], X.P. Yang[1], L.N. Li[1], S. Quan[1], W. Cao[2]
[1]NanFang Hospital, Reproductive Technology Center, Guangzhou-Guangdong, China
[2]NanFang Hospital, Department of Nephrology, Guangzhou-Guangdong, China

Study question: To detect the AOPP level in follicular fluid of women with infetility, and its correlation with estradiol (E_2) level, progesterone (P4) level in follicular fluid.

Summary answer: The follicular fluid AOPP level with different pathogeny was different, higher AOPP level caused lower P concentration in follicular fluid and worse outcome of IVF.

What is known already: Advanced oxidation protein products (AOPP) were the products and mediator of oxidative stress reaction. Its role as a novel marker to investigate oxidation stress has performed in many fields. The AOPP level in body fluid of women with polycystic ovarian syndrome (PCOS) or endometriosis (EMs) were found both higher than health women. In our previous research, AOPP level in follicular fluid presented negative correlations with the proportion of mature oocytes, cleavage rate, fertilization rate, good embryo rate.

Study design, size, duration: 139 women with infertility, including 20 EMs (average age: 33.3 ± 3.9 y; average BMI: 22.27 ± 3.23 kg/m^2), 76 pelvic and tubal factors (average age: 31.8 ± 4.6 y; average BMI: 21.11 ± 2.87 kg/m^2) and 17 PCOS (average age: 28.7 ± 3.0 y; average BMI: 21.98 ± 2.59 kg/m^2) were enrolled. 26 healthy women (average age: 30.6 ± 3.7 y; BMI: 21.02 ± 3.30 kg/m^2) coming to our reproductive technology center because of male factors were recruited as control group.

Participants/materials, setting, methods: Follicular fluid samples were obtained from all groups to measure the levels of AOPP, E2 and P4, and all data about clinical IVF prognosis was collected for analysis. The determination of AOPP was based on the spectrophotometric method. The concentration of A2, E2 and P4 in follicular fluid were determined with the use of commercial Iodine [125I] Radioimmunoassay Kit according to the manufacturer's instructions. Pearson correlation and One-Way ANOVA were applied to analyse data.

Main results and the role of chance: The difference of average AOPP level among groups was significant (PCOS group vs. EMs group: 65.25 ± 25.69 μmol/L vs. 45.73 ± 22.55 μmol/L, $p = 0.021$; PCOS group vs. pelvic and tubal factors group: 65.25 ± 25.69 μmol l/L vs. 51.97 ± 26.08 μmol/L, $p = 0.012$). The correlation between AOPP level and P4 level in follicular fluid was significantly inverse ($r = –0.176$, $p = 0.038$). As well, in pelvic and tubal factors group, AOPP level was negatively correlated with blastocyst rate ($r = –0.294$, $p = 0.032$). In addition, the number of dominant follicles (diameter>14 mm) was positively correlated with the serum P4 level at the time of hCG administration ($r = –0.268$, $p = 0.001$), and significantly negatively correlated with age ($r = –0.377$, $p = 0.000$).
Limitations, reasons for caution: In the future research, the sample size should be amplified further. And the number of samples in different groups is not the same, maybe the results could be influenced by one pathogeny.
Wider implications of the findings: The AOPP in follicular fluid may disturb the endocrine function of granular cells, and lower P4 concentration in follicular fluid. Then high AOPP level in follicular fluid would bring adverse effects on the development and maturity of oocytes.
Trial registration number: This is a basic research.

P-421 ART outcomes for fresh versus differed frozen-thawed day-2 embryo transfer: a matched cohort study

M. bourdon[1], P. Santulli[1], V. Gayet[1], L. marcellin[1], K. Pocate-Cheriet[2], S. cheniere[1], A. kim[1], R. callec[1], C. Maignein[1], V. blanchet[1], J. gonnot[1], C. Chapron[1]
[1]*Centre Hospitalier Universitaire CHU Cochin-Port Royal, Assistance Publique-Hôpitaux de Paris AP-HP Université Paris Descartes, Faculté de Médecine, Department of Gynaecology Obstetrics II and Reproductive Medicine, Paris, France*
[2]*Centre Hospitalier Universitaire CHU Cochin-Port Royal, Assistance Publique-Hôpitaux de Paris AP-HP Université Paris Descartes, Faculté de Médecine, Department of Histology-Embryology-Biology of Reproduction, paris, France*

Study question: To compare assisted-reproductive-technology (ART) outcomes between fresh day-2 embryo transfer (ET) versus differed frozen-thawed day-2 embryo transfer (dif-ET).
Summary answer: ART outcomes were similar for day-2 fresh versus day-2 differed frozen-thawed embryo-transfers.
What is known already: Controlled ovarian stimulation (COS) could potentially have an adverse impact on endometrial receptivity, thereby reducing ART success rates by adversely affecting the implantation step. To address this concern, one emerging strategy is the "freeze-all" approach. Compelling results have been presented that indicate that differed frozen-thawed embryo transfer (dif-ET) is the most suitable method for several sub-populations of ART patients. There nonetheless remains a degree of controversy in this regard. Furthermore, since most of studies have focused on blastocyst transfers, knowledge regarding differed frozen-thawed day-2 embryo transfers has remained quite limited to date.
Study design, size, duration: This cohort study conducted in a tertiary care university hospital, analysed all first transfer/cycles between 01/10/2012 and 31/12/2014. For this study, main inclusion criterias were a day-2 ET and having obtained fewer than 7 zygotes.

Of the initial cohort of 3,116 ART procedures scheduled during the study period, 325 day-2 dif-ET cycles and 1,296 day-2 fresh ET cycles were eligible for matching. The main outcome measure was ongoing-pregnancy rates.
Participants/materials, setting, methods: Fresh and frozen-thawed ET were matched by age and the number of previous ART cycles. Two groups were compared: a group made up of "exposed" women (dif-ET group) who received differed ET using frozen-thawed day-2 ET and an "unexposed" control group (fresh ET group), comprised of women who received fresh day-2 ET. Statistical analyses were conducted using univariate and multivariate logistic regression models.
Main results and the role of chance: A total of 650 cycles were included in the analysis: 325 in the fresh ET group and 325 in the dif-ET group. No significant differences were found between fresh and frozen-thawed ET cycles in terms of clinical pregnancy rates [98/325 (30.15%) vs. 85/325 (26.15%)] and ongoing pregnancy rates [71/325 (21.85%) vs. 60/325 (18.46%)]. In addition, the number of 2PN embryos (3.41 ± 1.58 vs. 3.56 ± 1.72) and the implantation rates (0.20 ± 0.33 and 0.17 ± 0.31) were not significantly different between both groups. Independent predictors for ongoing pregnancy after a multiple logistic regression analysis were the women's age (OR=0.92; 95% CI: 0.87–0.96), BMI (OR=0.94; 95% CI: 0.89–0.99), and the number of 2PN embryos (OR=1.23; 95% CI: 1.08–1.40).
Limitations, reasons for caution: In our center, in fresh ET protocol, day-2 ET was the standard of care; In differed-ET protocol, day-2 ET was done only when less than seven 2PN were obtained. To avoid selection bias, we studied for both groups only day-2 ET derived from ART cycles with less than seven 2PN.
Wider implications of the findings: Embryo-endometrium interaction after a day-2 ET did not appear to be impaired by COS. Given that we performed a broad-based analysis of deferred-ET in this study, further investigation may be required to determine for which specific subgroups of infertile patients deferred-ET may be more efficient and appropriate for ensuring increased-PRs.

P-422 Start of ovarian stimulation on day three versus luteal phase of the menstrual cycle in the same oocyte donor. A prospective observational study

C. Alvarez Pinochet[1], A. Flores Gornés[1], J. Sánchez Rosas[1], A. Pérez Garrido[1], M. Lara Lara[1], I. Alonso Muriel[1], M. Martínez Moya[1]
[1]*URE Centro Gutenberg, Reproduction Unit, Malaga, Spain*

Study question: Assess ovarian response (oocytes) after ovarian stimulation starting on day 3 or luteal phase of the menstrual cycle in the same oocyte donor.
Summary answer: In the same oocyte donor, the ovarian response is similar when the stimulation is started on day 3 or on the luteal phase of cycle.
What is known already: To optimize the IVF process and obtain sufficient mature oocytes, controlled ovarian hyperstimulation (COH) is needed. Usually, COH is performed from the beginning of the follicular phase on day 2 or 3 of the menstrual cycle. Current findings have described the presence of multiple waves of follicular recruitment within a single ovulatory period. There are publications describing that is possible to obtain mature oocytes starting the COH on luteal phase of cycle. This is an important tool to consider for oncologic patients who want to preserve their fertility and for the programs oocyte donors.
Study design, size, duration: Prospective observational study on a group of 8 oocyte donors from our oocyte donation program between January 2015 and December 2015. Donors who meet the legal requirements and agreed to participate in the study were recruited. Donors were subjected to two cycles of COH, one cycle of conventional COH starting on day 3 (Classical COH) and another on luteal phase after confirming ovulation with ultrasound (Luteal COH), in a 3–5 month interval.
Participants/materials, setting, methods: In the two cycles of stimulation, COH was performed with recombinant FSH at doses of 150–225 IU/day. Administration of GnRH antagonist was started whit a follicle measuring >14 mm. A GnRH agonist was used to trigger ovulation and oocyte retrieval was performed 36 h later. We evaluated count of follicles >10 mm on day 5 of stimulation, follicles >15 mm and estradiol levels on day of agonist GnRH, oocytes and mature oocytes retrieved.
Main results and the role of chance: A total of eight stimulation cycles on Classical COH and eight stimulation cycles on Luteal COH were performed on eight oocyte donors (age 23.38 ± 2.45 years) a 3–5 month interval. No statistically significant differences were found in the COH donors' responses between the Classical COH and Luteal COH starts. The count of follicles >10 mm on day 5 of stimulation was 9.50 ± 3.58 vs. 10.13 ± 2.16, the follicles >15 mm on day agonist GnRH 17.13 ± 7.24 vs. 16.63 ± 5.58, estradiol level (pg/mL) on day agonist GnRH 2,312 ± 1,081 vs. 2,463 ± 954, total days of stimulation 10.25 ± 1.98 vs. 10.25 ± 0.88, total doses of gonadotropin 1959.37 ± 442.38 vs. 1950.00 ± 198.20, oocytes retrieved 23.00 ± 13.09 vs. 19.38 ± 6.11, mature oocytes 21.50 ± 12.37 vs. 17.00 ± 5.37
Limitations, reasons for caution: The limitation of our study could be the small sample size. The study was performed on healthy young women (<35 years), so the results could not be extrapolated to other clinical conditions such as low ovarian reserve, older women, etc.
Wider implications of the findings: The ovarian response in donors is similar when the COH start on early follicular phase or on luteal phase. These results demonstrate that the ovarian stimulation starting in the luteal phase could be useful in patients that want to preserve oocytes o preserve fertility for cancer o social reasons.
Trial registration number: Not applicable

P-423 Incidence of successful pregnancy after weight loss interventions in infertile women: a systematic review and meta-analysis of the literature

L.M. Sosa Fernandez[1], M. Milone[2], L.V. Sosa Fernandez[1], G. De Placido[3]
[1]*Embryos, Reproductive Medicine, Battipaglia, Italy*
[2]*University of Naples "Federico II", Public Health, Naples, Italy*
[3]*University of Naples "Federico II", Neuroscience-Reproductive Mecicine-Odontostomatology, Naples, Italy*

Study question: The impact of weight loss surgery on pregnancy rate.
Summary answer: Our results showed an impressive high incidence (58%) of infertile women who become spontaneously pregnant after surgery.
What is known already: The relationship between obesity and infertility is well established. Increasingly, bariatric surgery is used to treat morbid obesity in women of reproductive age, and data suggest that surgery may have a beneficial influence on fertility. Some studies reported about infertile women who become pregnant after bariatric surgery. However, little is known about the impact of weight loss surgery on pregnancy rate.
Study design, size, duration: A systematic review with meta-analysis of literature has been performed to evaluate the incidence of successful pregnancy after bariatric interventions in infertile women. The primary analysis was the assessment of the incidence of successful pregnancy, which was defined as live birth. Moreover, the impact of major clinical and demographic characteristics on the effect size has been evaluated.
Participants/materials, setting, methods: All studies reporting on the pregnancy rate of infertile women undergoing bariatric surgery were included.

All studies reporting on the pregnancy rate of infertile women undergoing bariatric surgery were included.

To be included in the analysis, a study had to provide the incidence of successful pregnancy in infertile women undergoing bariatric interventions. For each study, data regarding sample size, major clinical and demographic variables, and type of bariatric surgery has been extracted.
Main results and the role of chance: By pooling together data from 589 infertile obese women, we have been able to provide an aggregate estimation of successful pregnancy after weight loss interventions. Our results showed an impressive high incidence (58%) of infertile women who become spontaneously pregnant after surgery. A meta-regression approach showed an inverse association between baseline Body Mass Index (BMI) values and the weighted mean incidence of successful pregnancy after bariatric surgery (Z-score − 3.27, p = 0.001). In addition, an inverse association was found between BMI reduction after surgery and the Weight Mean Incidence (WMI) of successful pregnancy (Z-score − 2.96, p = 0.003).
Limitations, reasons for caution: Conclusion drawn from the current literature must be interpreted with caution owning to the quality of the original data provided by included studies: over 60% of the conclusions originated from a single series, time to pregnancy was not reported, and only mean post-operative weight loss was informed.
Wider implications of the findings: Based on our results, bariatric surgery has been found to be associated with a high incidence of successful pregnancy in infertile women, providing the rationale to guide clinical practice for this challenging problem and direct future basic science and translational research.
Trial registration number: Not required

P-424 Effect of female body mass index on oocyte quantity: treatment cycle number is a possible effect modifier

M.W. Christensen[1], H.J. Ingerslev[1], B. Degn[1], U. Kesmodel[2]
[1]*Aarhus University Hospital, Fertility Clinic, Aarhus N, Denmark*
[2]*Herlev and Gentofte Hospital, Gyneacology and Obstetrics, Herlev, Denmark*

Study question: Does treatment cycle number influence the outcome when investigating the effect of female body mass index on oocyte quantity in IVF?
Summary answer: The association between female BMI and oocyte outcome may be modified by cycle number, BMI having an adverse effect in first but not subsequent cycles.
What is known already: The literature regarding obesity and the impact on oocyte outcome is conflicting and it varies studies between whether they report on several treatment cycles per women or only on first treatment cycle. Overweight and obese women may require higher doses of gonadotropin when undergoing IVF. Consequently one may expect a sub-optimal oocyte retrieval in the first treatment cycle and thus a larger compensation in gonadotropin-dose in the following treatment-cycles and a more favorable outcome.
Study design, size, duration: Historical cohort study on 5,342 ART- cycles performed at the Fertility Clinic, Aarhus University Hospital during the period 1999–2009.
Participants/materials, setting, methods: Women were included in the study if they were receiving either *in vitro* Fertilization (IVF) or Intra Cytoplasmatic Sperm Injection (ICSI) treatment. Exclusion criteria were missing information on BMI or treatment type. Further, women were excluded if they had ovulated before oocyte retrieval. According to baseline BMI, women were divided into four categories following the WHO standards. Multiple linear regressions analyses were performed accounting for the non-independence of ≥2 cycles in a woman.
Main results and the role of chance: No statistically significant differences were observed in oocyte yield for underweight, overweight and obesity compared to normal weight women when analyzing all treatment cycles. Overweight women had significantly fewer mature (MII) oocytes (p = 0.009) than normal weight women, whereas no differences was observed for underweight and obese women. Stratifying according to cycle number revealed a more sub-optimal outcome in first treatment cycles than in the following cycles, suggesting a possible interaction or effect modification from cycle number or a factor related to cycle number. The median dose of total FSH given to the four BMI groups could not straight forwardly explain the less optimal oocyte outcome observed in first treatment cycles.
Limitations, reasons for caution: A relative large number of cycles were excluded due to lack of information regarding either BMI or treatment type. Though, one might assume that the lack of information in the excluded cycles was due to chance, it is not possible to assess whether this could have influenced the results.
Wider implications of the findings: The findings of our study indicate that cycle number may be a possible effect modifier for the association of BMI and oocytes. This could have implications for future studies on BMI and the chance of achieving pregnancy.
Trial registration number: Not applicable

P-425 Saline infusion sonohysterography is required for the initial workup of infertility

K. Shlush[1,2], W.L. Zhou[1], I. Gat[1], C. Librach[1], P. Sharma[1]
[1]*CReATe Fertility Centre, Department of obsterics and gynecology University of Toronto, Tornoto, ON, Canada*
[2]*Rambam Healthcare campus, Department of obsterics and gynecology, Haifa, Israel*

Study question: The aim of this retrospective study was to accurately assess the diagnostic accuracy of Transvaginal sonography (TVS), and Saline infusion sonohysterography (SIS).
Summary answer: As long as hysteroscopy is not feasible for every patient the addition of SIS to TVS reduces both false positive and false negative of TVS.
What is known already: The assessment of the uterine cavity is one of the early steps in infertility workup. The gold standard for diagnosis is hysteroscopy, however currently it is still not feasible to offer this procedure to all patients. In order to reduce hysteroscopy burden different centers have used the following strategies: 1) some centers offer Transvaginal sonography (TVS), and if abnormal followed by Saline infusion sonohysterography (SIS). Based on the results of SIS a decision regarding hysteroscopy is made. 2) Others perform hysteroscopy directly after abnormal TVS. Current data provide conflicting results regarding the sensitivity and specificity of TVS an SIS.
Study design, size, duration: In the current study we assessed retrospectively whether the addition of SIS provides any diagnostic advantages to TVS. We assessed 564 women who underwent TVS, SIS and hysteroscopy between January 2009–July 2015. Mean age was 37.5 years (range 23–51)
Participants/materials, setting, methods: Using the Quality Assessment of Diagnostic Accuracy Studies (QUADAS tool) we aimed to compare accuracy between procedures done in the follicular vs. ovulatory/luteal menstrual phases, as well as to evaluate the diagnostic accuracy variance with time interval, using hysteroscopy as the gold standard, in the diagnosis of uterine cavity abnormalities and malformations in a population of sub-fertile female patients.

Main results and the role of chance: Our results provide evidence that SIS is more accurate than TVS (accuracy SIS=0.8 TVS=0.56 $p < 0.01$). Specifically the sensitivity of SIS to diagnose polyps and intrauterine adhesion (IUA) was statistically significant higher. The accuracy of SIS for diagnosing IUA and polyps decreased as the time from SIS to hysteroscopy increased.
Limitations, reasons for caution: The study was retrospective, and since there were no clear guidelines in our clinic to perform all tests to all patients not all patients in our clinic underwent all three studies. Accordingly a selection bias for patients undergoing all workup might have occurred.
Wider implications of the findings: Hysteroscopy is still expensive and requires experienced physicians. Our results provide evidence to the usefulness of SIS in the setting of lack of resources for hysteroscopy. These results can change the standard of care in many places over the world.
Trial registration number: N/A

P-426 Are extremely high progesterone levels still an issue in IVF?

V.S. Vanni[1], L. Pagliardini[2], S. Girardelli[1], A. Alteri[1], L. Quaranta[1], M. Molgora[1], D. Delprato[1], E. Rabellotti[1], E. Giacomini[2], P. Vigano'[2], E. Papaleo[1]
[1]*San Raffaele Biomedical Science Park, IVF Unit Department Obstetrics and Gynaecology, Milano, Italy*
[2]*San Raffaele Biomedical Science Park, Reproductive Sciences Laboratory, Division of Genetics and Cell Biology, Milano, Italy*

Study question: with advances in freezing/thawing techniques, the "freeze-all" strategy might overcome detrimental effects of extremely high progesterone (P) levels during Controlled Ovarian Stimulation (COS).
Summary answer: results support the "freeze-all" strategy in cases of extremely high P levels during COS. Cycle cancellation due to premature luteinization should therefore be avoided.
What is known already: the "freeze-all" strategy – where the entire cohort of embryos/blastocysts is cryopreserved for subsequent Frozen-thawed Embryo-Transfer (FET) – is already considered the preferred method for management of subtle P elevation during COS. However, published studies have never focused on extremely high P levels. While slight P elevation relates to ovarian response to COS, extremely high P represents the occurrence of premature luteinization. The scant available literature suggests that cycle cancellation is still the preferred method of dealing with extremely high P levels as caused by accidental ovulation. With advances in freezing/thawing techniques, however, cycle cancellation might be avoided.
Study design, size, duration: the study is a non interventional, retrospective, case-control, single-center trial conducted on COS cycles complicated by extremely high P levels. All patients underwent a "freeze-all" program at the blastocyst stage between January 2012 and September 2014. Controls ($n = 67$) were matched to cases ($n = 42$) for age, BMI, basal FSH and duration of infertility. Data on clinical/ongoing pregnancy rates and cumulative clinical/ongoing pregnancy rates were obtained from all FETs performed up to November 2015.
Participants/materials, setting, methods: patients undergoing a "freeze-all" program due to premature luteinization during COS – identified by extremely high P levels at induction (P levels ≥3.0 ng/ml and/or P/Estradiol ratio ≥1) – were compared to controls undergoing a "freeze-all" program with P at induction <1.5 ng/ml. After blastocyst culture, FET was performed (maximum 2 blastocysts transferred per attempt). Power analysis was used to have 80% power to detect a 50% difference in blastulation rates.
Main results and the role of chance: Number of oocytes retrieved was similar between Cases and Controls (12.6 ± 6.5 vs. 15.0 ± 6.8 respectively, Mean ± SD, $p = 0.06$) and so was percentage of mature oocytes (Metaphase two or MII oocytes, 71.6% ± 21.6% vs. 69.7% ± 20.6% respectively, Mean ± SD, $p = 0.20$). Also blastulation rate was not decreased in patients with premature luteinization compared to controls (48.1% ± 20.5% in Cases vs. 52.3% ± 24.9% in Controls, $p = 0.36$) and the proportion of top-quality blastocysts was as well comparable between cases and controls (14.3 ± 25.2 vs. 12.7 ± 21.4 respectively, Mean ± SD, $p = 0.72$). Ongoing pregnancy rates after the first FET (38.1% in Cases and 41.0% in Controls, $p = 0.83$) and cumulative ongoing pregnancy rates after three FET cycles (40.5% in Cases vs. 47.8% in Controls, $p = 0.55$) were as well similar. Based on this, COS cycle cancellation – which is likely the most frequently used method for management of extremely high P levels during COS- currently represents a clinical misconduct.
Limitations, reasons for caution: the relatively small number of patients included represents a limitation of our study and further validation in larger multicenter trials would be warranted. Also, a "freeze-all" strategy as suggested by our study should only be undertaken by centers with the appropriate freezing/thawing facilities and expertise.
Wider implications of the findings: premature luteinization doesn't have consequences at oocyte/embryo level in a "freeze-all" strategy. Cycle cancellation in case of very high P levels before induction, at present, represents a malpractice. This also supports the "random start" in COS for fertility cryopreservation and suggests that P assessment might be useless in segmented cycles.
Trial registration number: n/a

P-427 The impact of premature progesterone rise on the outcome of intrauterine insemination cycles with controlled ovarian hyperstimulation in unexplained infertility

M. Erdem[1], M.F. Mutlu[2], A. Erdem[1], I. Mutlu[3], I. Guler[1]
[1]*Gazi University Faculty of Medicine, Obstetrics and Gynecology, Ankara, Turkey*
[2]*Yuksek Ihtisas University, Faculty of Medicine, Obstetrics and Gynecology, Ankara, Turkey*
[3]*Novaart IVF Center, IVF Clinic, Ankara, Turkey*

Study question: What is the impact of premature progesterone rise on the day of hCG administration on cycle outcomes in terms of live birth in COH-IUI cycles?
Summary answer: Premature progesterone is a frequent feature of COH-IUI cycles and associated with decreased live birth rates.
What is known already: Addition of COH to IUI increases the number of oocytes available for fertilization and the risk of premature progesterone rise. Most of the data with regard to the impact of premature P rise were acquired from COH cycles in IVF and it was shown that different cutoff levels of premature P rise ranging between 1–1.5 ng/mL on the day of hCG has detrimental effect of IVF outcome. However, there were a few studies which investigate the incidence and the impact of early P rise in COH-IUI cycles.
Study design, size, duration: Six hundred forty two cycles of 460 couples with unexplained infertility having COH-IUI treatment between 2008–2013 in an university-based tertiary infertility clinic were enrolled in this prospective study.
Participants/materials, setting, methods: Couples with unexplained infertility having COH-IUI treatment with a starting dose of 75 IU recombinant FSH were enrolled. Serum P levels were determined on the day of hCG trigger. Premature P rise was defined as progesterone ≥1 ng/ml. The primary outcome measure was live birth per cycle with regard to P levels of ≥1 ng/mL and ≥1.5 ng/mL. Secondary outcome measures were cycle characteristics associated with P rise.
Main results and the role of chance: The incidence of premature P rise was 18.0%. P levels on hCG day were significantly lower in cycles with live birth as compared to cycles without live birth 0.48 ± 0.50 vs. 0.64 ± 0.72. Live birth rates were significantly lower in cycles with hCG day P levels ≥1.0 ng/dL (7% vs. 16.2%) and ≥1.5 (5.7% vs. 15.4%). It was found that P levels on the day of hCG trigger was the only significant variable to predict live birth on multivariate analysis in comparison to age, number of dominant follicles, estradiol, LH levels on the day of hCG trigger. The number of dominant follicles on hCG day and premature LH surge were the only significant variables related with premature P rise.
Limitations, reasons for caution: There has also been no exact strategy to prevent P rise in COH cycle; so screening of hormone levels should not been recommended as a standard practice in COH- IUI cycles.
Wider implications of the findings: The negative effect of progesterone levels of both 1 ng/mL and 1.5 ng/mL on the day of hCG was observed in COH-IUI cycles. COH-IUI outcomes might be improved by avoiding LH surge and excess follicular development.
Trial registration number: Absent

P-428 Maternal serum bile acid composition at conception is related to birth weight of offspring

R. Nagy[1,2], A. van Montfoort[1,3], A. Dikkers[2], J. van Echten-Arends[1], I. Homminga[1], A. Hoek[1], U. Tietge[2]
[1]*University Medical Centre Groningen, University of Groningen, Department of Obstetrics and Gynaecology, Groningen, Netherlands*
[2]*University Medical Centre Groningen, University of Groningen, Department of Paediatrics, Groningen, Netherlands*
[3]*Maastricht University Medical Centre, Department of Obstetrics and Gynaecology, Maastricht, Netherlands*

Study question: Does the bile acid (BA) composition of maternal serum and follicular fluid (FF) of women undergoing IVF relate to birth weight of the offspring?
Summary answer: There is an association between serum levels, but not FF levels, of primary BA and ursodeoxycholic acid (UDCA) at conception and offspring birth weight.
What is known already: We have previously reported the presence of BA in FF of human ovaries and the relationship between FF BA and embryo development, suggesting a role of BA in fertility. Furthermore, it has been described that human offspring who encountered a cholestatic condition during their fetal development may have an increased incidence of preterm birth and low birth weight. These offspring may also show metabolic syndrome related phenotypes during adolescence. The influence of the maternal serum and FF BA pool at the moment of conception on characteristics of offspring at birth has yet to be explored.
Study design, size, duration: In our retrospective cohort study, FF and serum samples collected in the setting of a study on the effectiveness of modified natural cycle-IVF (MNC-IVF) (January 2001 to June 2004) were used. Only samples from cycles in which one oocyte was obtained were included, assuring that the FF BA level was related to the embryo that was transferred. Furthermore, only samples from IVF patients who achieved a singleton live birth were used.
Participants/materials, setting, methods: Total BA and BA subspecies were measured in serum and FF samples by enzymatic fluorimetric assay and liquid chromatography-mass spectrometry, respectively. The association of total BA and BA species with birth weight was analysed and, in a regression analysis, corrected for offspring gender, gestational age at birth, BMI of mother, parity and maternal smoking during pregnancy.
Main results and the role of chance: Serum was available from 51 patients fulfilling the inclusion criteria and FF from 34. Serum levels of the primary BA chenodeoxycholic acid (CDCA) and cholic acid (CA) and of the BA UDCA were significantly correlated with birth weight ($r = -0.395$, $P = 0.004$; $r = -0.311$, $P = 0.026$; $r = -0.319$, $P = 0.023$, respectively). Neither the secondary BA deoxycholic acid and lithocholic acid, nor total BA levels were correlated with birth weight. After correction for possible confounders, CDCA, CA and UDCA were still significant predictors of birth weight ($P = 0.002$, $P = 0.004$ and $P = 0.048$, respectively), while total and secondary BA remained unrelated. For FF total BA and BA species no significant correlation with birth weight was found. Taken together, these novel data suggest that even in non-cholestatic individuals maternal serum BA levels are related to fetal growth. As the serum BA levels remain stable during pregnancy and within the normal pre-conceptional range, the effect on fetal growth is probably induced during pregnancy.
Limitations, reasons for caution: Despite the limited number of investigated samples and participants, we believe that the robustness of the correlation even after correction makes these data worth reporting.
Wider implications of the findings: Metabolic (programming) effects of BA are an emerging topic supported by a variety of data. Further steps should be taken to unravel the biological mechanism of BA in oocyte and foetal development.
Trial registration number: N/A

P-429 Effect of cancer and its treatment on reproductive function markers in long-term female survivors of childhood cancer: results of the Dutch nationwide DCOG LATER-VEVO study

Study question: Which chemotherapeutic agents and radiation sites are dose-dependently associated with reproductive function markers in female childhood cancer survivors (CCSs)?
Summary answer: Cyclophosphamide, procarbazine, etoposide and vincristine as well as ovarian radiation dose were associated with low AMH levels and antral follicle counts in a dose-dependent manner.
What is known already: Late effects of childhood cancer treatment have emerged as a growing concern, since survival has dramatically increased. Adverse late effects on the reproductive system may not become apparent until many years later. Anti-cancer treatment, often consisting of a combination of radiotherapy and chemotherapy, may reduce the fertile life span and induce premature menopause, as therapy may deplete the non-renewable pool of primordial follicles in the ovaries. Alkylating agents and procarbazine have been associated convincingly with gonadotoxicity. The effect of dose, as well as the effects of age at time of treatment and the time since treatment, is less well known.
Study design, size, duration: The study is part of the DCOG LATER-VEVO study, a nationwide retrospective cohort study on female fertility of Dutch CCSs. The control group consisted of sisters of survivors and females from the general population. Data collection took place between January 2008 and May 2014.
Participants/materials, setting, methods: The study population consisted of female 5-year CCSs who were treated between 1963 and 2002 in the Netherlands, and who were at least 18 years at inclusion. Of the 1,166 CCSs and 836 controls who participated in the study, 629 (54%) and 432 (52%), respectively, provided a blood sample and/or underwent ultrasonic evaluation of the ovaries. Both multivariate linear and logistic regression analyses were performed.
Main results and the role of chance: CCSs appeared to be at increased risk of having low (<0.5 µg/l) AMH levels and low number of antral follicles (≤5 follicles) (OR (95% CI) 12.4 (3.7–41.5) and 3.7 (1.2–11.3), respectively) compared to healthy controls. Results show that having been treated before menarche in general seemed less damaging compared to being treated during and after menarche, with AMH and AFC levels being higher when treated before menarche. In a multivariate model, corrected for age, BMI, use of contraceptive therapy and time since treatment, there was a statistically significant inverse dose-effect relation of cyclophosphamide ($p = 0.001$), procarbazine ($p < 0.001$), vincristine ($p = 0.003$) and etoposide ($p = 0.01$) on AMH levels. In addition, increasing radiation doses on the abdomen or pelvis ($p < 0.001$) or total body ($p < 0.001$) was associated with low AMH levels. Furthermore, increasing doses of cyclophosphamide ($p = 0.001$), procarbazine, ($p < 0.001$) and higher dose of radiotherapy to the abdomen or pelvis ($p < 0.001$) and total body irradiation ($p < 0.001$) were significantly associated with lower AFCs.
Limitations, reasons for caution: AMH and AFCs are considered reliable markers for ovarian reserve, however their predictive value for pregnancy remains questionable. Premature menopause would be better outcome to assess this research question. However, as the median attained age of the study

population was 28–30 years, the cumulative incidence of premature menopause was low.
Wider implications of the findings: The results of the study improve the physician's ability to counsel female CCSs on family planning. In addition, females who are about to undergo gonadotoxic cancer therapy may benefit since proven high risk populations can be offered clinical interventions aimed at preserving a women's reproductive function.
Trial registration number: NTR2922 http://www.trialregister.nl/trialreg/admin/rctview.asp?TC=2922

P-430 Outcomes of blastocyst transfer program resulting from vitrified donor oocytes

S. Seshadri[1], W. Saab[1], M. Davies[1], H. Exeter[1], E. Drew[1], A. Doshi[1], P. Serhal[1]
[1]CRGH, Assisted Conception Unit, London, UK

Study question: What is the clinical pregnancy rate and live birth rates per warmed oocyte used in an egg recipient program compared to the use of fresh autologous oocytes? Is there a difference in the obstetrical outcomes between the two groups?
Summary answer: Blastocysts from vitrified oocytes have good implantation potential resulting in a live birth rate comparable to fresh oocytes with no difference in neonatal outcomes.
What is known already: Oocyte donation is a successful and well-established treatment of age-related female infertility, where the oocyte and subsequent embryo qualities are optimized by donated oocytes from young women resulting in high pregnancy rates. Since the introduction of vitrification, the use of vitrified donor oocytes enables the clinician better coordination for treatment of the egg recipients. The clinical pregnancy rates using vitrified donor oocytes is comparable to the use of fresh oocytes.
Study design, size, duration: A prospective case control study comprising of 220 patients from January 2010 to April 2015. 1127 oocytes were vitrified from 110 egg donors at the Centre of Reproductive and Genetic Health (CRGH) clinic. The control group were age matched controls who underwent ICSI treatment with their own oocytes ($n = 1165$).
Participants/materials, setting, methods: 110 egg donors went through a stimulation cycle at CRGH resulting in 1127 vitrified oocytes. The control group consisted of age matched controls, who underwent ICSI with fresh oocytes. The clinical and obstetrical outcomes were compared in both the groups. Summary data were obtained and logistic regression analysis performed using SPSS Version 23 and Stata 2015. Case and control percentages were compared by Fisher's exact test. A significance level of 5% was adopted throughout.
Main results and the role of chance: The survival rate of vitrified oocytes was 74.1% (95% CI: 71.5–76.6). The clinical pregnancy rate (per embryo transfer) using vitrified oocytes was found to be 48.4% compared to 47.3% in the control group. The live birth rate per warmed oocyte was found to be 6.8%. The live birth rate per embryo transfer in the vitrified oocyte group was 41.5% (95% CI 29.3–54.9) compared to 42.9% (95% CI 31.9–54.5) in the control group. There was no difference in the gestational age of the infants in both the groups [39 weeks (95% CI 33–42) vs. 40 weeks (29–42), $p = 0.27$]. There was no difference in the gestational weight at birth in both the groups (3175 grams (1616–4480) vs. 3289 (1502–4337) $p = 0.35$).
Limitations, reasons for caution: There was no relation between the number of allocated donor eggs with livebirth rate. Larger studies are required to establish the safety and efficacy of oocyte cryopreservation in women requesting social freezing.
Wider implications of the findings: This study reiterates the safety and efficacy of using vitrified donor oocytes in a recipient program and demonstrates no difference of obstetrical outcomes in both groups. The findings of this study could be extrapolated to women opting for egg freezing due to reasons like underlying malignancy or social reasons.
Trial registration number: Not applicable

P-431 Alteration in ovarian expression of bone morphogenetic protein 15, growth differentiation factor 9, and c-kit according to female aging in mice

B.S. JOO[1], P. Min Jung[1], K. Cheol Min[1], L. Kyu Sup[2], K. Sun Sook[2], J. Jong Kil[2]
[1]Pusan National University, Research Center for Anti-Aging Technology Development, Busan, South Korea
[2]Pusan National University, OB/GYN-School of Medicine, Busan, South Korea

Study question: Can ovarian expression of bone morphogenetic protein 15, growth differentiation factor 9, and c-kit be a new standard marker for the objective evaluation of ovarian aging resulted from female aging?
Summary answer: The ovarian expression of bone morphogenetic protein 15, growth differentiation factor 9, and c-kit can be a standard marker of ovarian aging.
What is known already: Although many studies have showed that antral follicle count (AFC) and anti-Müllerian hormone (AMH) has been suggested as good predictors of ovarian reserve, more researches are needed to standardize these threshold values universally. It has been well known that bone morphogenetic protein 15 (BMP15), growth differentiation factor 9 (GDF9) are oocyte-secreted growth factor required for ovarian follicle development and ovulation in mammals. c-Kit has been also known to play an important role in follicle growth as a close coordinator secreted by granulosa cells. However, the alteration in ovarian expression of these factors according to the ovarian aging is not determined yet.
Study design, size, duration: The ovarian expression of BMP15, GDG9 and c-kit were evaluated according to the female aging (10, 20, 30, and 40 weeks-old) by RT-PCR, real-time PCR, western blot and immunohistochemistry. In addition, follicle count, such as primordial, primary and secondary follicle, and the oocyte developmental competency were also examined as a traditional marker for ovarian aging.
Participants/materials, setting, methods: Ovaries of differently aged C57BL female mice (from 10 to 40 weeks-old) were provided in the evaluation of follicle count and expression of BMP15, GDF9, and c-kit. Also these aged mice were superovulated with PMSG and hCG, and then immediately mated with an individual male. Zygotes were obtained and cultured for 5 days. The number of oocytes ovulated and the developmental rate to blastocyst were investigated.
Main results and the role of chance: All real-time PCR, western blot and immunohistochemistry showed a decreased ovarian expression of BMP15, GDF9, and c-kit in a aging-dependent manner. Accompanied by this result, the follicle count, the number of ovulated oocytes, and developmental rate were significantly decreased in aged mice (30 and 40 weeks old) compared to young mice (10 weeks old).
Limitations, reasons for caution: This study do not show that these results could equally applicable to the human study and these facotrs can be a good marker for human ovarian aging.
Wider implications of the findings: Recent data indicate that ovarian expression of BMP15, GDF9, c-kit can be a standard marker for the evaluation of ovarian aging. This result may be very useful standard marker when examining whether a candidate material shows an anti-aging effect on female reproductive aging.
Trial registration number: No

P-432

Abstract withdrawn by the author

P-433 The long non-coding RNA nuclear-enriched abundant transcript 1 is downregulated in granulosa cells from women with advanced age

Y.D. Liu[1], S.L. Chen[1], S.X. Feng[1], D.S. Ye[1], P.P. Guo[1], X.L. Li[1], X.Y. Zhou[1]
[1]Nanfang Hospital of Southern Medical University, Center for Reproductive Medicine, Department of Gynecology and Obstetrics, Guangzhou, Guangdong, China

Study question: To analyze the expression level of the long non-coding RNA (lncRNA) nuclear-enriched abundant transcript 1 (NEAT1) in human granulosa cells and analyze its role in the ageing ovary.
Summary answer: The expression of NEAT1 is significantly decreased in women with advanced maternal age, which is localized in the nuclei of human granulosa cells.
What is known already: Neat1 is a non-protein-coding RNA that constitutes nuclear bodies known as paraspeckles, nuclear domains implicated in mRNA nuclear retention. Cell-based studies indicate that Neat1 is a crucial regulator of gene expression. Neat1 knockout mice stochastically fail to become

pregnant despite normal ovulation, and corpus luteum dysfunction may be the primary causes of the decreased fertility. Studies on gene expression and regulation in human granulosa cells are of interest due to their potential for estimating the oocyte viability and *in vitro* fertilization (IVF) success. However, studies on lncRNA level in the human ovary have been scarce, especially in ageing granulosa cells.

Study design, size, duration: In this study, we described lncRNA profile in mural granulose cells isolated from sixty patients undergoing routine IVF treatment.

Participants/materials, setting, methods: Sixty patients (31 women <35 years with normal ovarian reserve and 29 women ≥38 years) referred to our center for IVF were included in this study after obtaining written informed consent. Gene expressions were examined by real-time quantitative reverse transcription-PCR in granulose cell collected from follicular fluid. Cell fractionation was performed to isolate nuclear and cytoplasmic RNAs using a Paris kit.

Main results and the role of chance: There was no difference between patients in the two groups in terms of body mass index (BMI), serum concentration of luteinizing hormone (LH), folliclestimulating hormone (FSH), prolactin (PRL), estradiol (E2), progesterone (P) and total testosterone (TT). Compared to women <35 years with normal ovarian reserve, the number of eggs retrieved (10.74 ± 0.54 vs. 7.69 ± 0.70, $P = 0.001$) and the expression level of NEAT1 (1.40 ± 0.14 vs. 0.82 ± 0.08, $P = 0.001$) was significantly lower in women with advanced maternal age. A negative correlation was observed between the NEAT1 expression and the age ($r = -0.336$, $P = 0.009$).

Furthermore, NEAT1 was found to localized in the nuclei of human granulosa cell tumor cells (KGN) as expected.

Limitations, reasons for caution: The data on lncRNA NEAT1 are preliminary and are further investigated. Additional molecular studies regarding the function and mechanism of abnormal expression of NEAT1 in granulosa cells will be performed.

Wider implications of the findings: Our results indicate that reduced expression of the nuclear long noncoding RNA NEAT1 is potentially associated with ageing ovary. To reveal the function of lncRNA NEAT1 in ovary will provide novel insights into reproductive ageing.

Trial registration number: NA.

P-434 Efficacy and safety of follitropin delta in an individualised dosing regimen: a randomised, assessor-blind, controlled phase 3 trial in IVF/ICSI patients (ESTHER-1)

A. Nyboe Andersen[1], J.C. Arce[2], &. ESTHER-1[3]
[1]*Copenhagen University Hospital Rigshospitalet, Fertility Clinic, Copenhagen, Denmark*
[2]*Ferring Pharmaceuticals, Reproductive Health – Global Clincal R&D, Copenhagen, Denmark*
[3]*on Behalf of the ESTHER-1 Trial Group, Evidence-Based Stimulation Trial with Human rFSH in Europe and Rest of World, Copenhagen, Denmark*

Study question: To evaluate ovarian response, ongoing pregnancy and implantation rates, and safety outcomes of follitropin delta (FE 999049; recombinant FSH preparation produced from the human cell line PER.C6®) administered according to an individualised dosing regimen based on anti-Müllerian hormone (AMH) and body weight in comparison to follitropin alfa in first cycle IVF/ICSI patients.

Summary answer: Follitropin delta in an individualised fixed-dose regimen yields non-inferiority versus follitropin alfa in ongoing pregnancy/implantation, more patients with appropriate ovarian response and reduced OHSS risk.

What is known already: Identical IU doses (in-vivo rat Steelman-Pohley bioassay) of follitropin delta and follitropin alfa do not result in comparable pharmacokinetic and pharmacodynamic profiles in humans. Therefore, follitropin delta doses are expressed in protein content (µg) and not by bioactivity (IU). The follitropin delta dosing regimen stratifies patients according to response potential and applies an individualised dose based on an ovarian biomarker (AMH) and a patient characteristic (body weight). This approach constitutes an opportunity for safer stimulation without compromising success rates.

Study design, size, duration: Randomised, assessor-blind, controlled trial in 1,326 women, 18–40 years, undergoing their first IVF/ICSI cycle. Patients underwent single blastocyst transfer except those 38–40 years without good-quality blastocysts who had double blastocyst transfer. Ongoing pregnancy and ongoing implantation were assessed 10–11 weeks after transfer (co-primary endpoints; prespecified non-inferiority margin: lower limit (LL) of 95% confidence interval (CI) >−8.0%).

Participants/materials, setting, methods: The daily follitropin delta dose was individualised and fixed throughout stimulation – AMH <15 pmol/L: daily dose of 12 µg, AMH ≥15 pmol/L: daily dose decreasing from 0.19 to 0.10 µg/kg body weight by increasing AMH (maximum daily dose 12 µg). Elecsys® AMH, Roche Diagnostics was used. The daily follitropin alfa dose was 150 IU (11 µg) for the first five days and could thereafter be adjusted by the investigator according to the patient's response.

Main results and the role of chance: The number of oocytes retrieved was similar for follitropin delta and follitropin alfa in the overall population (10.0 and 10.4, respectively). However, more ($p < 0.05$) patients using the individualised fixed-dose regimen of follitropin delta obtained 8–14 oocytes, despite dose adjustments in 36.8% of follitropin alfa patients in contrast to 0% of follitropin delta patients. Among patients with AMH <15 pmol/L, treatment with follitropin delta was associated with more ($p < 0.05$) oocytes compared to follitropin alfa (8.0 vs. 7.0, $p < 0.05$) as well as a lower ($p < 0.05$) incidence of patients with <4 oocytes. Among patients with AMH ≥15 pmol/L, treatment with follitropin delta was associated with fewer ($p < 0.05$) oocytes compared to follitropin alfa (11.6 vs. 13.3, $p < 0.05$) as well as a lower ($p < 0.05$) incidence of patients with ≥15 or ≥20 oocytes. OHSS and/or OHSS preventive interventions occurred less ($p < 0.05$) frequently in patients receiving an individualised dose of follitropin delta than in patients in the follitropin alfa group. The number of blastocysts obtained was comparable between follitropin delta and follitropin alfa (3.3 and 3.5, respectively). Non-inferiority was established for ongoing pregnancy (30.7% vs. 31.6%; LL 95% CI −5.9%) and ongoing implantation (35.2% vs. 35.8%; LL 95% CI −6.1%) for follitropin delta compared to follitropin alfa.

Limitations, reasons for caution: The individualised dosing regimen based on the patient's serum AMH and body weight is developed specifically for follitropin delta due to its differential pharmacokinetic and pharmacodynamic profiles. The regimen documented in this confirmatory trial is derived from prospective investigation in a phase 2 dose-response trial followed by modelling and simulation.

Wider implications of the findings: This trial demonstrates the clinical relevance of tailoring fertility treatment in a personalised/stratified medicine approach. By application of an ovarian biomarker (AMH) and a patient characteristic (body weight), individualised dosing of follitropin delta in a simple fixed-dose regimen provides more appropriate ovarian response and improved OHSS risk management.

Trial registration number: NCT01956110

P-435 Long-term melatonin treatment for the prevention of ovarian aging

H. Tamura[1], T. Taketani[1], H. Asada[1], N. Sugino[1]
[1]*Yamaguchi University School of Medicine, Obstetrics and Gynecology, Ube, Japan*

Study question: Does the long-term melatonin treatment prevent ovarian aging in mice?

Summary answer: Long-term melatonin treatment increased the number of ovulated oocytes and fertilization rates. The present results indicate that melatonin prevents ovarian aging in mice.

What is known already: Ovarian aging occurs as a result of a decrease in the number and quality of oocytes in ovarian cortex follicles. Oxidative stress caused by reactive oxygen species (ROS) is thought to be major cause of ovarian aging. However, there are no established treatments to prevent ovarian aging. On the other hand, melatonin, which is a hormone secreted by a pineal gland, is known as a powerful free radical scavenger and a broad-spectrum antioxidant.

Study design, size, duration: Female ICR mice (10 weeks old) were divided into two groups: half were fed with water as a control (control group: C) and the other half were supplemented with 100 µg/ml melatonin water (melatonin group: M) until 43 weeks. Mice were superovulated by PMSG and hCG injection. Oocytes and ovaries were collected 15 h after hCG injection.

Participants/materials, setting, methods: 1) Oocytes were recovered from the oviduct. 2) *in vitro* fertilization was performed using spermatozoa from male ICR mice. 3) The ovaries were fixed in 4% paraformaldehyde, and serially sectioned in 5 mM slices and stained with hematoxylin–eosin. 4) Transcriptome changes in the ovaries were analyzed by microarray. This study was approved by the ethics committee for animal experimentation.
Main results and the role of chance: 1) The number of ovulated oocytes was decreased (33 week: 10.4 ± 6.4, 43 week: 6.4 ± 1.1) during aging process in C. However, the number of ovulated oocytes was greater (33 week: 19.0 ± 10.0, 43 week: 11.6 ± 3.2) in M compared with C. 2) The fertilization rate was higher in M (33 week: 67.4%, 43 week: 50.9%) compared with C (33 week: 52.9%, 43 week: 21.4%). 3) The number of primordial follicle was higher in M compared with C. 4) The transcripts decreased with aging and increased by melatonin treatment were detected, and ribosome-related genes and free radical scavenging network were identified.
Limitations, reasons for caution: The study used the mouse as a model and the applicability of the observed phenomena in humans warrants further investigation.
Wider implications of the findings: Many women are suffering age-related infertility because the age of marriage has increased. Long-term melatonin treatment may become a new management to prevent the decrease in number and quality of oocytes with age.
Trial registration number: non

P-436 Unique geometry of sister kinetochores in human oocytes during meiosis I may explain maternal age-associated increases in chromosomal abnormalities

J. Patel[1], S.L. Tan[2], G. Hartshorne[1], A. McAinsh[1]
[1]*University of Warwick, Warwick Medical School, Coventry, UK*
[2]*McGill University, Department of Obstetrics and Gynecology, Montreal, QC, Canada*

Study question: How are sister kinetochores in human oocytes arranged to enable the co-segregation of sister chromatids at the first meiotic division?
Summary answer: Sister kinetochores in human oocytes appear separated during meiosis I and are each able to act as separate attachment sites for microtubule fibres.
What is known already: Human oocytes are highly prone to chromosome segregation errors at the first meiotic division. During this division, sister chromatids segregate together, which requires kinetochores on sister chromatids to form attachments to spindle kinetochore-fibres (k-fibres) emanating from the same pole of the spindle. Of the meiotic sister kinetochores that have been studied so far, in maize, yeast and mouse, all appear to be fused and act as a single functional unit. However, in humans oocytes, the arrangement of sister kinetochores and the mode of k-fibre attachment have not been characterised.
Study design, size, duration: Fixation and immunofluorescence of whole human MI oocytes donated by women undergoing *in vitro* fertilisation or intracytoplasmic sperm injection (IVF/ICSI).
Participants/materials, setting, methods: Oocytes no longer required for treatment were donated by women undergoing IVF/ICSI at the Centre for Reproductive Medicine at University Hospital Coventry & Warwickshire. Meiotic metaphase I (MI) stage human oocytes were fixed in paraformaldehyde and immunofluorescence was performed using primary antibodies targeted to kinetochores (CREST, Bub1 and CENP-E) and microtubules (α-tubulin). Cold-shock treatment was used to visualise k-fibre attachments. High-resolution 3D image stacks of the oocyte chromosomes were acquired by spinning-disk confocal microscopy.
Main results and the role of chance: Analysis of over 1900 kinetochores stained with CREST revealed that the majority (78%) of sister kinetochores pairs in human MI oocytes appear as two distinct spots, indicating that sisters are not physically fused. Markers for the outer (Bub1) and fibrous corona (CENP-E) regions of the kinetochore also appeared separated, indicating that the entire kinetochore is distinct between sisters. The presence of dual k-fibre attachments, in which each kinetochore within a pair had formed an attachment to a spindle k-fibre, indicated that sister kinetochores can act as separate attachment sites. Notably, with increasing female age, the separation between kinetochores increased, from a mean of 0.65 µm in women under 33 to 0.79 µm in those over 38 ($p < 0.0001$, unpaired t-test). This is indicative of a decline in centromeric cohesion with female age.
Limitations, reasons for caution: Human MI oocytes available to research are those that did not mature *in vivo* and come from a population of women experiencing fertility problems.
Wider implications of the findings: The increasing separation of sister kinetochores and their ability to act as independent attachment sites may explain the high proportion of unstable attachments that form in MI and thus indicate why human oocytes are prone to aneuploidy, particularly with increasing maternal age.
Trial registration number: N/A

P-437 Effect of body mass index on the outcomes of controlled ovarian hyperstimulation in Chinese women with polycystic ovary syndrome: a multicenter, prospective, observational study

Y. Sheng[1], Z.J. Chen[1], G.X. Lu[2], J.Y. Liu[3], X.Y. Liang[4], Y.P. Ma[5], X.H. Zhang[6], S.Y. Zhang[7], Y.P. Sun[8], Y. Sun[9], W.H. Fang[10]

Study question: What is BMI distribution of Chinese women with PCOS and whether BMI influence the outcomes of IVF/ICSI techniques in this population?
Summary answer: More than one-third of Chinese women with PCOS are overweight or obese. Elevated BMI associated with higher rFSH dosage requirement and lower pregnancy rate.
What is known already: IVF/ICSI with controlled ovarian hyperstimulation is important option for women with infertility due to PCOS. Studies conducted outside China have reported that 35–65% of patients with PCOS are obese, and that BMI can influence the success rate of IVF/ICSI techniques. However, BMI distribution varies in different ethnic populations. No large scale study has been reported on BMI and its influence on IVF outcomes in Chinese PCOS women.
Study design, size, duration: This was a multicenter, prospective, observational study conducted at 9 hospitals in China between August 2011 and April 2013. Of 801 subjects initially enrolled, total 774 PCOS patients underwent IVF/ICSI were included into the intention to treat (ITT) analysis and observed through one IVF/ICSI cycle.
Participants/materials, setting, methods: The study enrolled women (aged 20–35 years) with PCOS undergoing IVF/ICSI, using rFSH and a long down-regulation protocol. The primary outcome was BMI distribution (underweight, <18.5 kg/m^2; normal, 19–23.9 kg/m^2; overweight, 24–27.9 kg/m^2; obese, ≥28 kg/m^2). Secondary outcome measures, including baseline demographic characteristics, laboratory biochemical tests, rFSH dosage, ovulation and pregnancy outcomes and adverse events were compared among different BMI groups.
Main results and the role of chance: Among 774 subjects (age, 27.9 ± 3.1 years; BMI, 23.0 ± 3.5 kg/m^2), 51 (6.6%) were underweight, 449 (58.0%) normal weight, 211 (27.3%) overweight, and 63 (8.1%) obese. When compared between groups with different BMIs, no statistical difference was detected in basal testosterone levels. Dose of rFSH in the obese group was greatly higher than that used in the underweight group ($P < 0.001$). Number of follicles in diameter 14–18 mm was higher ($P = 0.002$) in normal weight subjects compared to other subjects. Overweight subjects were with the lower implantation rate ($P < 0.001$), biochemical pregnancy rate per stimulation cycle ($P = 0.025$), as well as clinical pregnancy rate per transferred cycle ($P = 0.033$), compared to normal weight subjects. The miscarriage rate in the first trimester in total subjects was 2.2%. Total incidence of AEs was 47.8% with 20.4% as treatment-related. Severe AEs only occurred in 5 subjects (0.6%). Major recorded AEs included OHSS (11.8%), twin pregnancy (9.7%) and ectopic

pregnancy (1.5%). A total of 180 subjects (22.8%) had cycle cancelled due to risk of OHSS.

Limitations, reasons for caution: The sample size was still relatively small for estimation of BMI status in full PCOS population. Confounding factors other than BMI may have influenced the outcomes. Also no intervention was performed to assess the effect of BMI change on outcomes.

Wider implications of the findings: The overweight and obese population in Chinese PCOS patients seems to be in the lower range compared to the reported data in other populations, yet still significantly influence IVF/ICSI outcomes. Further studies are in need to explore whether interventions to normalize BMI reduce rFSH requirement and improve outcomes.

Trial registration number: None.

P-438 Localization of toll like receptors (TLRs) in human fallopian tube epithelial cells

F. Amjadi[1], E. Salehi[2], M. Mehdizadeh[3], M. Ashrafi[4], A. Aflatoonian[5], A. Fazeli[6], R. Aflatoonian[7]

[4]Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Department of Endocrinology and Female Infertility, Tehran, Iran
[5]Shahid Sadoughi University of Medical Sciences, Research and Clinical Center for Infertility, Yazd, Iran
[6]The University of Sheffield, Academic Unit of Reproductive and Developmental Medicine, Sheffield, UK
[7]Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Department of Endocrinology and Female Infertility, Tehran, Iran

Study question: Are there any proteomic differences between expression and localization of the TLRs in fallopian tube epithelial cells?

Summary answer: There is a difference signature between expression and localization of the TLRs in fallopian tube epithelial cells.

What is known already: Infections of the female reproductive tract may contribute to infertility to a various extent depending on the site of inflammation, especially in fallopian tube. Histologically, fallopian tube epithelium is formed by a ciliated and secretory cells. The immune system related to epithelial cells of the FRT represents the first line of defence against sexually transmitted pathogens. Recognition of these pathogens is attributed to the family of Toll like receptors (TLR) as a major part of the innate immune system. This study clarifies the expression, function and localization of the TLRs in fallopian tube epithelial cells.

Study design, size, duration: The current study was approved by the Local Ethics Committee and informed written consent was obtained prior to the collection of tissue samples. Human fallopian tube tissues were collected from 5 cases undergoing tubal ligation. TLRs expression in fallopian tube ciliated and non- ciliated epithelial cells was investigated

Participants/materials, setting, methods: We firstly investigated TLRs localization in fallopian tube epithelial cells by immunostaining, surprisingly we found the intensity of staining was not equal in epithelial cells, then after primary cell culture of fallopian tube epithelial cells, ring cloning was used to isolate colonies of ciliated from non- ciliated epithelial cells and then the expression of TLR1–10 was examined by Quantitative real time PCR, and protein localization confirmed by immunostaining

Main results and the role of chance: We found TLR1–10 to be expressed in Fallopian tube epithelial cells, our studies revealed enriched localization of TLRs in Fallopian tube ciliated epithelial cells. We showed that TLRs expression in fallopian cells, with a higher level in the cilia cells versus non-ciliated cells ($P < 0.05$). Treatment fallopian tube epithelial cells with peptidoglycan, poly(I:C), flagellin, Loxoribine and CPG oligonucleotide resulted in secretion of IL-6 and IL-8.

Limitations, reasons for caution: Further experiments are needed to extend our understanding of function of the ciliated cells *in vivo*.

Wider implications of the findings: TLRs is localized in human Fallopian tube epithelial cells. Based on cyclical changes in ciliation and cell height of fallopian tube epithelial cells, under the influence of ovarian hormones, it seems immune system related to epithelial ciliated cells provide a safe environment for fertilization in the fallopian tubes

Trial registration number: This study is an experimental case controlled study.

P-439 Three dimensional ultrasound and hysteroscopy in diagnosing benign intrauterine lesions in infertile women

C. Lavopa[1], I. Cobuzzi[1], M. Tartagni[2], G.M. Vizziello[1], D. Baldini[1]
[1]Momò Fertilife, Clinic of Reproductive Medicine, Bisceglie, Italy
[2]AUOC Policlinico, Obstetrics and Gynecology, Bari, Italy

Study question: The purpose of this retrospective study was to assess whether 3D ultrasound (3D US) could replace diagnostic hysteroscopy in infertile women prior assisted reproductive treatments (ART)

Summary answer: Our study suggest that 3D US is a safe alternative to hysteroscopy.

What is known already: Three dimensional ultrasound has recently been introduced into clinical practice. Whit this technology any desired place through an organ can be obtained. It has enabled the accurate, noninvasive, outpatient measurement of the follicular, ovarian and endometrial volumes feasible and the diagnosis of congenital uterine anomalies. In addition, 3D dimensional reconstruction of the uterine cavity is possible and can be analyzed without particular expertise in ultrasound diagnosis. At the same, it has very low inter-observer and intra observer variability for calculating endometrial volume and also was found to be highly reproducible for estimating ovarian and endometrial characteristics.

Study design, size, duration: A retrospective study during 2012–2013 was conducted comparing 3D transvaginal (TV) ultrasound evaluation and hysteroscopy at the "Momo' Fertilife" Private Centre for Reproductive Medicine, Bisceglie, Italy.

Participants/materials, setting, methods: The present study involved 519 women aged 21–48 years undergoing *in vitro* fertilization (IVF) techniques. The mean duration of infertility was 1–15 years. Transvaginal sonography was performed first in the follicular phase of the menstrual cycle. Assessment of morphological features, including uterine dimension, myometrial lesions, endometrial lesions and thickness, adnexal abnormalities was carried out. After the sonographic examination, hysteroscopy was performed within a day or two in the same menstrual cycle.

Main results and the role of chance: In 414 patients a normal uterine cavity was diagnosed by 3D US and hysteroscopy. A diagnosis of endocavitary uterine pathology was done in 105 cases and those patients were available for the analysis of diagnostic performance of the tests. Concordance between 3D ultrasound and endoscopy around was verified in all cases of endometrial polyps (50 cases- 47.6%), submucosal myomas (35 cases – 33.3%) uterine septa (15 cases – 14.28%). Differing results were found in 5 cases (4.76%) of endometritis diagnosed only by hysteroscopy. The diagnostic performance of 3D US examination versus hysteroscopy was expressed as accuracy, sensitivity and specificity. The sensitivity of 3D US for the diagnosis of intrauterine lesions was 87% vs. 100% of hysteroscopy. The specificity was 100% for both the tests. Positive and negative predictive values of three dimensional ultrasound and hysteroscopy were 100%, 99%, 100%, 1005 respectively.

Limitations, reasons for caution: In our study no correlation was found between endometrial measurements and pattern obtained by 3D US and histological diagnosis derived by endometrial biopsy during hysteroscopy. In fact, chronic endometritis is a subtle condition that is difficult to detect.

Wider implications of the findings: We suggest that 3D US should be the first clinical noninvasive diagnostic test in the investigation of the uterine cavity in infertile women. The total examination time for the patient is significantly reduced and all further investigations can be performed without the presence of the patient.

Trial registration number: No trial registration number

P-440 Preclinical data support the safety of egg precursor cell (EggPC) repositioning using a method designed to address poor response to controlled ovarian stimulation

Y.A. White[1], J.D. Luterman[1], B. Zhang[1], H.E. Cummings[1], C.M. Burgess[2], R.A. Fischer[3], G.M. Cohn[3], A.O. Tzianabos[1]
[1]*OvaScience Inc., Research and Development, Waltham, MA, USA*
[2]*OvaScience Inc., Embryology, Waltham, MA, USA*
[3]*OvaScience Inc., Medical Affairs, Waltham, MA, USA*

Study question: To test the safety of egg precursor cell (EggPC) repositioning in ovaries using the OvaPrime method in non-human primates, thus strengthening pre-clinical evidence supporting OvaPrime.
Summary answer: OvaPrime treatment is safe in non-human primates, thus supporting its investigation as a therapeutic approach for women with little or no egg reserve.
What is known already: Options are limited for women with poor ovarian response to controlled ovarian stimulation. OvaPrime is an innovative technique developed to address this unmet need by enhancing a woman's egg reserve through repositioning her own EggPCs in one/both ovaries to generate a good number of mature, high-quality eggs. This may improve live birth rate using autologous oocytes for women with poor ovarian response, diminished ovarian reserve, or primary ovarian insufficiency, among others. Preclinical studies demonstrated live births from EggPCs in mice and rats, and production of mature eggs from EggPCs in Rhesus macaques and immature human eggs in a xeno-transplanted model.
Study design, size, duration: A Good Laboratory Practices-level safety study in non-human primates. EggPCs were isolated from 1 ovary per animal and cryopreserved. Ovarian cortex tissue was mechanically and enzymatically digested, EggPCs isolated via antibody-mediated fluorescence-activated cell sorting and slow-frozen. Two weeks after ovarian removal, either 10% or 100% of the autologous EggPCs isolated from an individual were surgically reintroduced to the cortex of the contralateral ovary of the same animal via mid-line laparotomy, using a 25G needle.
Participants/materials, setting, methods: Overall, 18 female *Cynomolgus* monkeys (macaca Fascicularis) aged 3–4 years were evaluated. For up to 6 months after autologous EggPCs were reintroduced into the ovary, clinical and histological evaluations were conducted, including evaluation of the ovaries and reproductive organs, menstrual cycle assessment, body weight, hematology, serum chemistry, serum hormone analysis, and urinalysis. Sampling frequency varied by parameter (e.g., serum hormones sampled daily during certain phases of menstrual cycle, weight measured weekly, blood taken monthly).
Main results and the role of chance: In the 6 months after the OvaPrime treatment, no morbidity, mortality or treatment-related abnormalities were observed. Histology and clinical assessments were normal at 6 months post-transplantation. Specifically, no significant pre-to-post within-animal changes were observed for body weight, hematology, serum chemistry, or urinalysis parameters. All animals exhibited normal menstrual cycles following the EggPC reintroduction and there were no observed alterations in hormone levels related to menstrual cycles. The results demonstrate the safety of repositioning of up to 100% of EggPCs taken from a single ovary into the contralateral ovary using the OvaPrime method in non-human primates, adding to the evidence that it is safe and feasible and thus supporting future clinical evaluation of this treatment.
Limitations, reasons for caution: This was a safety study only; EggPC biologic activity after repositioning was limited to hormonal and menstrual cycle vs. estrus cycle continuation, and matings and pregnancy rates were not studied, so the effectiveness of the OvaPrime treatment (live birth rates) in non-human primates cannot be confirmed from this study.
Wider implications of the findings: Preclinical studies across multiple species have demonstrated the potential of EggPCs to increase the antral follicle pool. OvaPrime will be evaluated in the clinic as a potential therapeutic approach to address the significant unmet need in women with poor response to controlled ovarian stimulation by increasing the antral follicle pool.
Trial registration number: Not applicable.

P-441 MMPs and TIMPs gene expression regulates the human ovarian follicle, a microenvironment for oocyte differentiation

P. Piomboni[1], M. Gori[1], L. Crifasi[1], R. Focarelli[2], A. Capaldo[1], L. Boschi[1], G. Morgante[1], V. De Leo[1], A. Luddi[1]
[1]*University of Siena, Department of Molecular and Developmental Medicine, Siena, Italy*
[2]*University of Siena, Department of Life Science, Siena, Italy*

Study question: Validation of metalloproteases (MMPs) and their inhibitors (TIMPs) as diagnostic biomarkers helping in prediction of oocyte quality and embryo viability in IVF cycles.
Summary answer: Our results suggest the deep involvement of MMPs and of their specific tissue inhibitors (TIMPs) in the proper maturation of the human oocyte.
What is known already: Follicular fluid, as well as granulosa and cumulus cells may affect follicle growth, oocyte maturation and competence acquiring. Unfortunately, valid biomarkers for oocyte quality estimation and, maybe, for *in vitro* fertilization success improvement have not been still identified. Metalloproteinases and their specific tissue inhibitors are implicated both in the homeostasis of the ovarian follicle and mainly in oocyte maturation, ovulation and corpus luteum organization. The estimation of oocyte quality for ART, still now unsatisfactorily limited to morphological parameters, may be implemented by gene expression analysis of these biomarker helping in the selection of the best oocyte to be injected.
Study design, size, duration: For this study, we have collected follicular fluids, granulosa and cumulus cells from fifty women who underwent techniques of assisted reproduction starting from January to October 2015. Gene expression analysis of MMP2, 9 and 11 and of TIMP1 and TIMP2 was carried out both in granulosa and in cumulus cells. Data obtained by gene expression analysis were also confirmed at protein level by western blot analysis and immunofluorescence techniques.
Participants/materials, setting, methods: To identify key molecules of the cross-talk between somatic cells and oocyte, we performed an *in silico* analysis of the human follicular fluid proteome. MMPs and TIMPs, resulting *central hubs* in the MetaCore generated network, were further evaluated by gene expression studies on granulosa and cumulus cells in a cohort of 50 women. Our results, confirmed by western blot and immunofluorescence, allowed us to validate the selected genes as potential biomarkers for oocyte quality prediction.
Main results and the role of chance: Our results revealed the deep involvement of MMPs, in particular gelatinases (MMP2 and MMP9), in the development and maturation of the oocyte, with a differential expression in granulosa compared to cumulus cells, thus highlighting the important role exerted by cumulus cells in line with the high specialization of this cell type. In fact, MMP2 and MMP9 expression was significantly increased in granulosa cells compared to cumulus cells, while mRNA levels of MMP11 were increased in cumulus cells. MMP11 seems to play an important role in oocytes physiology, confirming the hypothesis that this protein is involved not in follicular rupture, but in other tissue remodeling process, such as follicle atresia. In spite of this and according to their spectrum of action, MMPs modulation has to be carefully controlled in order to prevent deleterious effects on ovarian functions. Hence, in the same cell types the modulation of specific tissue inhibitors of metalloproteinases TIMP1 and TIMP2 results highly relevant. Indeed, while TIMP1 mRNA levels are comparable in these cells, TIMP2 expression level resulted significantly increased in cumulus compared to granulosa cells. Hence, the balancing in MMPs/TIMPs expression is crucial for oocyte development. MMPs and TIMPs may be precious pharmacological target to improve fertility.
Limitations, reasons for caution: Different parameters may influence ovarian response to hyperstimulation protocols as well as the outcome of IVF cycles, therefore larger study needs to be carried out in order to definitively validate these findings.
Wider implications of the findings: This combined *in-silico* approach and gene expression profile allowed us to identify MMPs and TIMPS as key factors whose expression could predict the oocyte release, its quality and fertilizability. Therefore our study, if replicated in a larger population, might contribute in improving oocyte selection and ART protocols in infertile women.
Trial registration number: Not applicable

P-442 Immature oocyte collection during ovarian tissue harvesting and cryopreservation. What is the yield and outcome?

A. Kedem[1], G. Yerushalmi[1], M. Dar[1], H. Raanani[1], R. Orvieto[1], A. Hourvitz[1], D. Meirow[1]

[1]Sheba Medical Center, IVF Unit, Department of Obstetrics and Gynecology, Ramat Gan, Israel

Study question: What is the yield of collecting immature oocytes *in vivo* and ex vivo as potential fertility preservation techniques ?
Summary answer: Although a high number of mature oocytes and embryo can be stored. The limited number of pregnancies present poor reproductive outcome.
What is known already: There are relatively few clinical options for fertility preservation and the data on their clinical outcome is limited. Retrieval and storage of immature oocytes followed by *in vitro* maturation (IVM) have been proposed as a possible supplementary approach to fertility preservation prior to cancer treatment.
Study design, size, duration: A retrospective cohort study of patients treated from 2007–2014 in single tertiary center in Israel. A total of 119 cancer patient were included in the study.
Participants/materials, setting, methods: Fifty seven patients underwent ovarian tissue cryopreservation (OTC) plus ex-vivo oocytes collection from the ovarian tissue (OTO-IVM). Twelve patients underwent in-vivo oocyte aspiration from both ovaries and IVM (OPU-IVM) and 50 patients underwent OTO-IVM and OPU-IVM. Main outcome measures were oocyte yield and outcome post thawing.
Main results and the role of chance: Obtaining oocytes using the combined technique of OTO IVM+OPU IVM yielded significantly more oocytes (11.87 ± 1.22 vs. 6.95 ± 0.83; $p < 0.001$), M2 oocytes (6.58 ± 0.7 vs. 2.47 ± 0.1; $p < 0.01$), maturation rate (57% vs. 35%; $p < 0.01$) and cryopreserved oocytes (6.00 ± 1.37 vs. 2.42 ± 0.49; $p < 0.01$), as compared to OTO IVM alone. Thirty two embryos from five patients were thawed (16 embryos from the OPU IVM and 16 embryos from OTO IVM+OPU IVM group). Thirteen embryos survived (81% survival rate) and were transferred in each group. One out of the 26 transfers yielded a pregnancy that resulted in a normal delivery of a healthy baby.
Limitations, reasons for caution: Low number of thawed embryos
Wider implications of the findings: Retrieval of immature oocytes is time consuming and relatively inefficient for the majority of the population. IVM maybe beneficial to young patients with high AFC as in PCOS and for those patients who are at high risk for reintroducing hemthological or other malignancies and cannot perform emergency IVF.
Trial registration number: 7222-09-SMC

P-443 Egg donors' characteristics and acceptance procedure according to the Israeli egg donation law

R. Ron-El[1], Y. Barkat[2], I. Ben-Ami[2], Y. Gidoni[2], Z. Brover[2], D. Hadari[2], E. Kasterstein[2], D. Strassburger[2], O. Bern[2], D. Komarovsky[2], B. Maslansky[2], O. Lemberberg-Karpel[2], A. Raziel[2]
[1]Assaf Harofeh Medical Centre, Zerifin, Israel
[2]Assaf Harofeh Medical Centre, IVF, Zerifin, Israel

Study question: To study the characteristics and mode of selection of the Israeli egg donors in accordance with the recent local egg donation (ED) law.
Summary answer: A third of the donors are academic, 44% are mothers of children. Their dropout rate due to the long and complicated acceptance procedure is 53.2%.
What is known already: ED involves ethical and moral issues. Few countries have settled an ED law, where donors' anonymity and rights are controlled. The law also defines the amount of compensation payment, where half of it is subsidized by the Ministry of Health in order to encourage ED. Computerized database of the Ministry controls the number of donations per donor and the matching between donor and recipient, ruling out the possibility of a relationship between both parties, and the eligibility of the donor to donate.
Study design, size, duration: For the past two years, ED has been performed in our Center. In the first interview general information is given and possible risks are explained. On her second visit signed informed consent is collected and an interview with a psychologist takes place. Following the approval of our Committee her candidacy is entered into the database of the Ministry of Health. So far 94 donors appeared for the first meeting with the physician and nurse coordinator.
Participants/materials, setting, methods: Donors were investigated for their past and family history, education and profession. The data from the psychologists and Confirmation Committee were examined and summarized. Objective data such as age, occupation, height, weight and proven fertility in the past were given to the recipient before her acceptance of the donor. The data were analyzed and evaluated.
Main results and the role of chance: Of the 94 applicants, 71% were unmarried, 13% divorced with children, 10% singles with children, and 8% married with children. Thirty one (33%) donors were students in the university. Sixty one (65%) were born in Israel and 34% were immigrants from Eastern Europe. Only 54 donors (57%) arrived for the second visit, 10% were not approved by the psychologist due to either an immature personality or psychiatric past history. The Committee did not approve 4 donors who were refused by the psychologist and an additional candidate who had a family history of Marfan syndrome. A total of 54 donors received final approval for the procedure, of them 5 (9.2%) decided not to donate. At the end of the procedure 38 donors (40.4%) performed ED. This complicated and long procedure resulted in the loss of many potential candidates. However, this thorough workup of the donors gives a good feeling to both, the medical staff and the recipients.
Limitations, reasons for caution: The size of the study group is limited, and so conclusions may not be well established. With a larger experience the law should be revised in order to simplify the procedure.
Wider implications of the findings: The procedure for acceptance of the donor is complicated and long. However, selection of donors is performed very carefully and the donor has several options to drop out of the project.
Trial registration number: NA

P-444 Uterine function and its relation with pregnancy complications and outcomes among childhood cancer survivors treated with radiotherapy involving the uterus

L.E.X.M. van de Loo[1], E. Van Dulmen-den Broeder[1], A. Overbeek[2], M. Van Dijk[1], C.B. Lambalk[2], C.M. Ronckers[3], L.C.M. Kremer[3], M.M. Van den Heuvel-Eibrink[4], W.J.E. Tissing[5], J.J. Loonen[6], A.B. Versluys[7], D. Bresters[8], G.J.L. Kaspers[1], F.E. Van Leeuwen[9], M.H. Van den Berg[1]

Study question: Does uterine irradiation administered during childhood reduce uterine volume, and does it lead to an increased risk of pregnancy complications and adverse pregnancy outcomes?
Summary answer: Exposure to uterine irradiation during childhood significantly reduces adult uterine volume, and leads to an increased risk of pregnancy complications and adverse pregnancy outcomes.
What is known already: Different types of cancer treatment may impair female fertility. Radiotherapy (RT) administered during childhood appears to have a negative impact on uterine function, leading to reduced adult uterine volumes and diminished blood flow in the uterine arteries. However, studies investigating this topic had small RT-exposed study populations, and further comparison with other cancer treatments is necessary.
Study design, size, duration: The study is part of the DCOG LATER-VEVO study, a nationwide retrospective cohort study on female fertility in Dutch childhood cancer survivors (CCSs). Data collection took place between January 2008 and May 2014.
Participants/materials, setting, methods: Fifty-five CCSs who had been treated with radiotherapy involving the uterus (RT-exposed CCSs) were age- and parity-matched to two types of comparison groups: 110 CCSs not treated with any type of radiotherapy (non-RT-exposed CCSs) and 110 females from the general population (healthy controls). Uterine volume was

measured by three-dimensional transvaginal ultrasound. Information on pregnancy complications and pregnancy outcomes was obtained through a questionnaire.

Main results and the role of chance: Among the nulligravidous participants, median [interquartile range (IQR)] uterine volume was 41.1 (18.1–53.2) ml for RT-exposed CCSs, compared to 48.1 (35.7–61.8) and 61.3 (49.1–75.5) ml for non-RT-exposed CCSs and healthy controls, respectively. Results of the multivariate regression analyses show that, after correction for age and estradiol levels (as a measure of menopausal status), RT-exposed CCSs are at increased risk of having a reduced uterine volume (<34.9 ml) compared to both non-RT-exposed CCSs and healthy controls (OR=2.70 (95% CI 1.06–6.90) and OR=11.80 (3.29–42.30) respectively). Additionally, non-RT-exposed CCSs also appeared to be at increased risk of having smaller uterine volumes compared to healthy controls. This outcome was no longer significant after correction for alkylating agents dose-score. Furthermore, among gravidous participants, RT-exposed CCSs had an increased probability of ever having experienced a pregnancy complication and of ever having delivered pretermly (<37 weeks) compared to healthy controls (OR=12.70 (2.55–63.40) and OR=9.74 (1.49–63.60) respectively). Additionally, RT-exposed CCSs had an increased probability of delivering an infant with low birth weight (2500 gr) compared to both non-RT-exposed CCSs and healthy controls (OR=6.86 (1.08–43.75) and OR=15.66 (1.43–171.35) respectively).

Limitations, reasons for caution: For gravidous participants, we had no information on uterine volume prior to pregnancy. This severely hampered our ability to investigate the effect of reduced uterine volume on risk of pregnancy complications and adverse pregnancy outcomes.

Wider implications of the findings: CCSs exposed to uterine irradiation should be counselled early about increased risks of impaired uterine function, pregnancy complications and adverse pregnancy outcomes. Furthermore, close obstetric monitoring of CCSs exposed to uterine irradiation is advised in case of pregnancy. Further research is necessary to investigate the chemotherapy-related effect on uterine volume.

Trial registration number: NTR2922

P-445 Freeze all policy in cases of high risk of ovarian hyperstimulation syndrome does not impair cumulative pregnancy rates in a center with slow freezing program

P. Moreno Fernandez[1], N. Ruiz[1], E. Escalante[1], M. Abad[1], M. Carrera[1], L. De la Fuente[1]
[1]Hospital 12 de Octubre, Infertility Department, Madrid, Spain

Study question: Should our frozen pregnancy rate be a limitation for a freeze all policy in cases of high risk of ovarian hyperstimulation syndrome (OHS)?

Summary answer: With 11.6% difference in pregnancy rate between fresh and frozen embryos transfers, no harm in cumulative pregnancy rate was observed with this policy.

What is known already: To avoid OHS, a differed embryo transfer has been proposed as a very effective security tool. Nevertheless, it seems difficult to settle without a high effective cryopreservation program, because it may affect the pregnancy expectations of patients.

As embryo vitrification seems to be the more effective embryo freezing technique, centers with slow freezing cleavage embryo program and lower cryotransfer pregnancy rates may be reluctant to switch to a freezing all attitude. A correct patients selection of high risk of OHS and good prognosis women should offer equivalent outcome in terms of cumulative pregnancy rate in a hyperstimulation free milieu.

Study design, size, duration: In a retrospective case control study, 50 high-risk OHS women defined as patients with more than 15 oocytes obtained, final Estradiol (E2) >3000 pg/nl or previous history of OHS, were included. We selected 25 cases and 25 controls, completing all embryo transfers from the study stimulation cycle without pregnancy or who got pregnant after one of the transfers. Patients where selected between January 2013 and June 2014. Primary end point was cumulative pregnancy rate.

Participants/materials, setting, methods: First completed 25 cases of OHS risk patients who underwent freezing all policy in 12 de Octubre Hospital were included. One control per case was selected between 2014 cycles considering that no difference in cryopreservation program or in embryo culture or transfer technique had been introduced in our unit meanwhile. They all had similar characteristics regarding ovarian reserve parameters, previous cycle results or OHS risk factors.

Main results and the role of chance: Cumulative pregnancy rates were the same in both groups: 64% (16 pregnant patients per group, $p > 0.05$) even if 7 out of the 16 pregnancies (43.75%) occurred in the fresh transfer in the control group. No severe OHS was observed but 3 women in the control group had to be controlled for mild OHS. No difference could either be found in miscarriage rate (6.2% in both groups).

Cycles characteristics were similar in both groups: final E2 of 3662.6 ± 16.10 in the cases vs. 3072.8 ± 1074.69 in the control group ($p > 0.05$); follicles 19.5 ±5.42 and 19.8 ± 4.37 ($p < 0.05$), oocytes retrieved 14.2 ± 4 and 16.8 ±3.53 ($p < 0.05$); embryos available 7.4 ± 3.25 and 7.7 ± 2.51 ($p < 0.05$) with 2.9 ± 2.43 and 2.8 ± 2.41 good quality embryos respectively ($p < 0.05$).

Those were young patients (33.8 ± 3.89 years in case group and 32.4 ± 5.19 in control group; $p < 0.05$); good antral folicular count (19.7 ±9.71 and 16.8 ± 5.26; $p < 0.05$) and normal FSH basal level. Clinical pregnancy rate per thawed transfer embryo is not comparable to general IVF patient population (37.2% in cases; 19.24% in controls and 17.8% in general population).

Limitations, reasons for caution: The retrospective design is an important study limitation, although differences were favorable to control group.

Characteristics of the selected population: young women with 40% of polycystic ovarian syndrome (in both cases and control group) should be considered before extrapolating data, as well as the type of cryopreservation policy and protocol.

Wider implications of the findings: This example may help other center with slow freezing technique or sub-optimal pregnancy rate in frozen/thawed cycles to undergo a freezing all policy in high-risk OHS patients. These selected patients have an especially favorable prognosis with a high cumulative pregnancy rate with no impairment in pregnancy chances and safer conditions.

Trial registration number: None

P-446 Immature myeloid cells in reproductive system versus tumor angiogenesis

R. Hertz[1], S. Hantisteanu[1], E. Milner[1], S. Kol[1], O. Fainaru[1]
[1]Rambam Medical Center, IVF Unit, Obstetrics and Gynecology, Haifa, Israel

Study question: We sought to determine whether ovarian stimulation and placental development leads to an influx of proangiogenic immature myeloid cells as observed in tumors.

Summary answer: IMC subpopulations diverge in tumor versus reproductive tissues, favoring monocytic IMCs in the former and granulocytic IMCs in the latter.

What is known already: In close resemblance to other inflammatory states, gonadotropin stimulation is accompanied by influx of inflammatory cells such as neutrophils and monocyte-derived effector cells, into the ovarian stroma. Ovarian follicular development and corpura lutea formation are examples of the few physiologic events in which the formation of new blood vessels form existing ones, i.e., angiogenesis takes place. We have previously shown that bone marrow derived immature myeloid cells (IMCs) promote angiogenesis in both health (placentas) and disease (malignant tumors) and thus express similar proangiogenic genes. Nevertheless, the unique properties of IMCs populating these physiologic- versus malignant tissues have not been explored.

Study design, size, duration: Animal experiment, using 4–5 week old C57Bl6J-Cx3CR1$^{GFP/+}$ transgenic mice, in which granulocytic (Ly6G^{+}) and monocytic (Ly6C^{+}) IMCs can be defined by flow cytometry. We analyzed placentas from timed pregnancies and tumor tissues from B16-melanomas that were implanted subcutaneously. For ovarian hyperstimulation we treated mice with 20U pregnant mare serum gonadotropins (PMSG) for 2 days. On day 3 human chorionic gonadotropin (HCG) (5U) was injected to induce ovulation. Control unstimulated mice were treated with sham injections.

Participants/materials, setting, methods: Harvested tissues were weighed and enzymatically digested. Single cell suspensions were immunostained using fluorescently labeled anti-CD11b, Gr-1, CD11c, major histocompatibility II (MHCII), CD45, Ly6G, and Ly6C and analyzed by flow cytometry. For global gene expression, IMCs were isolated by flow cytometry, RNA prepared and

analyzed by Affymetrix gene microarrays. Validation of single gene expression was performed by qPCR.

Main results and the role of chance: Analysis of the subpopulations of IMCs revealed a significant enrichment (over 2-fold, $P < 0.01$) of the $Ly6G^{med}/Ly6C^{high}$ monocytic IMC fraction in tumor derived $CD45^{+}$ hematopoietic cells compared to placenta, paralleled by a concomitant, more than 2-fold decrease ($P < 0.01$) of the $Ly6G^{high}/Ly6C^{med}$ granulocytic IMC subpopulation. In gonadotropin stimulated ovaries we observed a ~2.5 fold increase in Ly6Ghigh/$Ly6C^{med}$ granulocytic IMCs compared to unstimulated controls. Tumor derived- and gonadotropin stimulated ovaries derived $Ly6G^{med}/Ly6C^{high}$ IMCs expressed low levels of Cx3CR1 compared to the same cell population in placentas and unstimulated ovaries. Decreased expression of Cx3CR1 within IMCs has been shown to delineate a cellular population that actively contributes to tumor progression.

We next assessed the global transcriptional signature of tumor derived IMCs (T-IMCs) compared to placental IMCs (P-IMCs). Analysis of the top overexpressed genes in T-IMCs revealed several key players in tumor angiogenesis including Sema3a, and matrix metalloproteinases such as Mmp2, Mmp3, Mmp13, and Mmp14, as well genes that are involved in cancer progression and cell proliferation. Of note, various genes that were up-regulated in P-IMCs were shown to play a role in reproductive tissue angiogenesis, including Serpine1, Arg1, and Flt1.

Limitations, reasons for caution: This is an animal experiment and its findings need to be further validated also in humans.

Wider implications of the findings: IMC subpopulations diverge in tumor versus reproductive tissues, favoring monocytic IMCs in the former and granulocytic IMCs in the latter. This divergence is associated with unique expression of proangiogenic genes. Selective targeting of these genes may thus be further investigated as selective angiogenic therapies for cancer, placental disease, and ovarian-hyperstimulation.

[5]*University Hospital, Unit of General Practise, Oulu, Finland*
[6]*University Oulu, Department of Epidemiology and Biostatistics, Oulu, Finland*
[7]*University Helsinki, University Helsinki, Helsinki, Finland*
[8]*University Hospital, Obstetrics and Gynecology, Helsinki, Finland*

Study question: Is the former or current use of combined hormonal (CHC) and progestin-only (POC) contraceptives associated with abnormal glucose metabolism in premenopausal women?

Summary answer: Former CHC or former/current POC use was not associated with prediabetes/type 2 diabetes (T2DM), but the association was significant in current CHC users.

What is known already: Combined contraceptive use has been associated with impaired glucose tolerance (IGT) and increased insulin resistance, which are risk factors for prediabetes and T2DM. To date there are only few population-based studies with large enough population and with adequate adjustments. The results concerning hormonal contraceptive use and prediabetes/T2DM are inconsistent and no clear association between them has been demonstrated in general populations, but some prospective population-based studies have revealed an increased risk in current CHC users.

Study design, size, duration: In a prospective follow-up of a large national birth cohort ($n = 5889$) the women were clinically examined at the age of 46 and asked for their former and current use of hormonal contraceptives. The glucose metabolism indices were compared between current CHC ($n = 194$) or POC ($n = 1090$) and current non-hormonal contraceptive users ($n = 1204$), and on the other hand between former CHC ($n = 1884$) or POC ($n = 72$) users and women with no history of hormonal contraceptive use ($n = 358$).

Participants/materials, setting, methods: At age 46, a questionnaire was sent to 5123 women. Of them, 3708 (72.4%) answered, 3280 (64.0%) participated in clinical examinations and 2780 in a 2-h oral glucose tolerance test (OGTT). Prediabetes (impaired fasting glucose, IFG and/or IGT) and newly diagnosed T2DM (nT2DM) were diagnosed by OGTT. Diagnosis for previously diagnosed T2DM (pT2DM) was assessed from postal questionnaires and confirmed from hospital discharge and national drug registers.

Main results and the role of chance: Current CHC, POC and non-hormonal contraceptive users as well as former CHC and POC users and women who had never used hormonal contraception did not differ regarding BMI and waist circumference.

Current CHC use was significantly associated with prediabetes (odds ratio, OR: 2.1, 95% confidence interval, 95% CI: 1.3–3.4), nT2DM (OR: 3.4, 95% CI: 1.4–10.1), prediabetes/nT2DM (OR: 2.2, 95% CI: 1.5–3.5) and prediabetes/nT2DM/pT2DM (OR: 1.9, 95% CI: 1.3–2.9), but not with pT2DM compared with use of non-hormonal contraception.

Current POC use was not significantly associated with pre-diabetes, nT2DM or pT2DM compared with use of non-hormonal contraception.

Compared with current POC use, current CHC use was significantly associated with prediabetes (OR: 2.0 95% CI: 1.2–3.1) and prediabetes/nT2DM (OR: 2.0, 95% CI: 1.3–3.1), but not with pT2DM. Former CHC use was not significantly associated with prediabetes or nT2DM/pT2DM compared with former POC use or never use of hormonal contraception.

Former use of POC was not associated with prediabetes or pT2DM/nT2DM compared with never use of hormonal contraception.

The results did not change after adjustment for socio-economical status, alcohol consumption, smoking, number of deliveries and use of cholesterol lowering medication.

Limitations, reasons for caution: Use of hormonal and non-hormonal contraception was based on self- reporting which may have led to information bias. We excluded women reporting CHC use at any time of their life from the group of former POC users, which could have distorted the results.

Wider implications of the findings: Current CHC use in premenopause associates with a significant risk for prediabetes and T2DM, supporting active screening for these disorders in premenopausal CHC users. These findings also raise the question of whether it is advisable to recommend CHC use in older premenopausal women and in women with adverse metabolic profile.

Trial registration number: NA

P-448 CBL gene is a central gene overexpressed in cumulus cells of obese Polycystic Ovary Syndrome (PCOS) women without clinical insulin resistance compared to non-obese PCOS

M. Chehin[1,2], T. Bonetti[2,3], P. Serafini[4,5], E. Motta[2,4]

[1]*Huntington Medicina Reprodutiva, Clinical, São Paulo, Brazil*
[2]*Universidade Federal de São Paulo, Escola Paulista de Medicina UNIFESP-EPM, Departamento de Ginecologia, Disciplina de Ginecologia Endocrinológica, São Paulo, Brazil*
[3]*Huntington Medicina Reprodutiva, Scientific, São Paulo, Brazil*
[4]*Huntington Medicina Reprodutiva, Clinical Head, São Paulo, Brazil*
[5]*Faculdade de Medicina da Universidade de São Paulo FM-USP, Departamento de Obstetrícia e Ginecologia, Disciplina de Ginecologia, São Paulo, Brazil*

Study question: Which genes of the insulin pathway are relevant in cumulus cells of obese PCOS women when undergoing to an IVF cycle?

Summary answer: The gene CBL is overexpressed and acts as central gene of insulin signaling pathway in the cumulus cells of obese PCOS women.

What is known already: Insulin plays a central role on PCOS women and can be responsible for worst IVF outcomes on those patients. The precise mechanism of insulin action on cumulus cells and the consequences to oocyte maturation is not completely elucidated in obese or even in non-obese PCOS patients. PCOS women have oocytes of poorer quality even without clinical evidence of insulin resistance. The gene expression profiles from insulin pathway in cumulus cells could provide new insights, mainly in obese patients, where hyperinsulinemia should be deleterious and may explain the

worst IVF outcomes. New therapy strategies would be possibly offered to those patients.

Study design, size, duration: Cross-sectional study to evaluate gene expression at the insulin pathway in *cumulus* cells of patients submitted to IVF treatment from January 2013 to October 2014. Fifteen PCOS patients according to Rotterdam criteria were subdivided in non-obese (n = 9, BMI <25, Control-group) and obese (n = 6, BMI >30, Obese-group). Both groups demonstrated a normal insulin resistance index according to the homeostasis model assessment insulin resistance (HOMA-IR).

Participants/materials, setting, methods: PCOS infertile patients were submitted to IVF with standard ovarian stimulation protocol, oocytes were recovered to IVF and cumulus cells were removed for gene expression analysis. RNA purification was carried out and quantitative PCR array analysis of gene expression profile (RT^2 Profiler™ PCR Array Human Insulin Signaling Pathway- PAHS-030ZC-Qiagen, USA) was done according with manufacturer instructions. We considered genes up- or down-regulated in obese-group compared to control-group, those presenting fold-change ≥3 or ≤3 and $p < 0.05$.

Main results and the role of chance: Among the 84 genes of insulin pathway analyzed, nine genes were statistically significant overexpressed in obese patients compared to non-obese. There were no down-regulated genes in obese-group compared to controls. The up-regulated genes were BCL2L1 (fold=4.7; p = 0.021), BRAF (fold=3.8; p = 0.031), DOK1 (fold=4.6; p = 0.040), FBP1 (fold=5.3; p = 0.011), FRS2 (fold=4.1; p = 0.044), PCK2 (fold=4.4; p = 0.041), RPS6KA1 (fold 4.2; p = 0.044), SORBS1 (fold=3.6; p = 0.014) and CBL (fold=6.2; p = 0.019). The mentioned genes are mainly involved on glucose uptake and cell proliferation, regulation of insulin sensitivity and promoting gluconeogenesis, diminishing available pyruvate. All actins could damage the energetic balance in early stages of embryo development. The bioinformatics tool (SABiosciences – GNCPro™ –Qiagen, USA) was used to evaluate the network and interaction among up-regulated genes. That analysis showed that 75% of the overexpressed genes have a strong relationship to CBL gene. CBL is a gene involved in cell signaling and protein ubiquitination, which inhibits intracellular signal transduction by targeting some tyrosine kinases. There is growing evidence that CBL acts inhibiting systemic insulin resistance promoted by macrophage pro-inflammatory cytokines, which are secreted in adiposity tissue of obese women.

Limitations, reasons for caution: A small sample size was included to screen the 84 genes. However, the sample power was calculated and higher than 80%. Although insulin resistance was not clearly demonstrated, insulin may play different effects in obese patients. Also ovarian stimulation might produce damages in the cumulus cells and oocyte competence.

Wider implications of the findings: CBL is a central gene to the perfect cumulus cells signaling function. In obese PCOS patients, where insulin resistance leads to hiperinsulinemia and may selective overexpress the CBL activity, which could promote detrimental effects on the follicle development.

Trial registration number: Not applicable

P-449 GnRH agonist triggering reduces pain symptoms during IVF/ICSI cycles

V. Gayet[1], M. Bourdon[1], P. Santulli[1], L. Marcellin[1], C. Maignien[1], V. Blanchet[1], J. Gonnot[1], D. de Ziegler[1], C. Chapron[1]
[1]*Centre Hospitalier Universitaire CHU Cochin Port-Royal, Assistance Publique-Hôpitaux de Paris AP-HP, Université Paris Descartes, Faculté de Médecine, Department of Gynecology, Obstetrics II and Reproductive Medecine, Paris, France*

Study question: To assess the dynamic of pain symptoms during IVF/ICSI cycles when final oocyte maturation is triggered by GnRH-agonist (GnRH-a) or hCG.

Summary answer: Using GnRHa for triggering ovulation limits the progression of pain symptoms following IVF/ICSI as compared to hCG triggering.

What is known already: Timely administration of GnRH-a has been shown to induce a surge of endogenous LH and FSH and trigger ovulation. The advent of antagonist COS protocols allows to use GnRH-a trigger, although endometrial alterations make deferring ET preferable. The shorter duration of LH effects on the growing follicles as compared to the long-lasting stimulation exerted by hCG reduces or suppresses the risk of OHSS. It therefore plausible that GnRH-a trigger might reduce the pain aggravation normally encountered in IVF/ICSI after ovulation induction and oocyte retrieval.

Study design, size, duration: This is a retrospective observational cohort study nested in a prospective published cohort (Santulli et al., 2015) conducted between 01/01/2014 and 31/12/2014 in a tertiary care university hospital. A total of 122 cycles from patients who underwent IVF or ICSI programs were analysed. Patients received an oral contraceptive synchronization treatment followed by ovarian stimulation with FSH and oocyte triggering with an injection of GnRHa or rhCG. Only non-pregnant women were retained for this study.

Participants/materials, setting, methods: Women were allocated to two groups: GnRHa triggering with a scheduled deferred embryo-transfer (n = 70) or hCG triggering with a fresh embryo transfer (n = 57). Pelvic pain scores were evaluated using a visual analogue scale. Total VAS score was defined as the sum of VAS scores of the different painful symptoms. Two evaluations were performed: during oral contraceptive synchronization treatment before ovarian stimulation and three weeks post-retrieval. Univariate and multivariate logistic regression models were conducted.

Main results and the role of chance: VAS average values for each symptom and for Total VAS score were comparable except for dysmenorrhea at final evaluation which was lower in "GnRHa triggering" group (4.81 ± 3.23 and 3.52 ± 3.23, p = 0.046). For both groups, pain increased during ART procedure. Trends for Total VAS change, calculated by subtracting the final VAS score evaluation from that at synchronization evaluation, revealed a significant lower pain increase in "GnRH-agonist triggering" group compared to "hCG triggering" group (3.77 ± 7.73 and 6.50 ± 6.57, $p < 0.05$, respectively). After multivariate logistic regression, GnRH-agonist triggering was associated with lower pain increase during the ART as compared to "hCG triggering group" (OR=0.31, IC95% 0.13–0.71, p = 0.006).

Limitations, reasons for caution: For comparing the dynamic of pain without biases from a developing pregnancy only non-pregnant women in "hCG triggering" group were analysed. Yet, we cannot rule out that selecting the non-pregnant sub-group of women did not introduce a bias of its own.

Wider implications of the findings: Finding that GnRH-a triggering is associated with less pain makes this the primary ART strategy for any woman fearing pain or at increased risk of pain, as for example in case of endometriosis. GnRH-a triggering is therefore a sound low pain option when ART related pain is best avoided.

Trial registration number: 0

P-450 Single human spermatozoon freezing technique for cryptozoospermia or non-obstructive azoospermia patients

M. Nagayoshi[1], A. Tanaka[1], T. Miki[1], T. Yamaguchi[1], T. Ichiyama[1]
[1]*Saint Mother Hospital, Department of Obstetrics and Gynecology, Kitakyusyu, Japan*

Study question: Is it possible to freeze a single spermatozoon and keep a high recovery rate to improve the clinical outcome of cryptozoospermia or non-obstructive azoospermia patients?

Summary answer: Our data indicates that it is highly possible to freeze a single spermatozoon with a high survival rate of about 80%.

What is known already: Clinical outcome of non-obstructive azoospermia or cryptozoospermia has increased after ICSI when using fresh spermatozoa. When oocyte collection cannot be performed on the same day of the Micro-TESE or in the case of cryptozoospermia, cryopreservation of collected spermatozoa becomes crucial. However, conventional freezing procedures are not appropriate for very low numbers of spermatozoa with poor motility.

Study design, size, duration: We performed a retrospective analysis of the clinical outcome of 79 ICSI cycles using our novel cryopreservation procedures for ejaculated spermatozoa from 27 cases of cryptozoospermia in 52 cycles and testicular spermatozoa from 20 cases of non-obstructive azoospermia in 27 cycles from January, 2012 to December, 2014.

Participants/materials, setting, methods: This study dealt with 27 men with cryptozoospermia and 20 men with non-obstructive azoospermia. Moving spermatozoa were carefully aspirated into a pipette one by one and put into a micro-drop of medium. About 2 µl of freezing medium was put on the tip of the CRYOTOP. 1–10 sperms were aspirated into an injection pipette and inserted into the medium and left in liquid nitrogen vapor for 2 min before being stirred in liquid nitrogen.

Main results and the role of chance: Five healthy babies (5 ongoing) from 47 patients were born following this freezing method. Clinical outcome is listed in the following table.

Clinical outcomes	Cryptozoospermia	Non-obstructive azoospermia
No. of patients	27	20
No. of treatment cycles	52	27
No. of sperm frozen [per Cryotop®]	543	248
Sperm recovery rate after thawing (%)	81.03 (440/543)	78.23 (194/248)
Motile sperm rate after thawing (%)	57.27 (252/440)	40.72 (79/194)
No. of ICSI oocytes	215	98
Fertilization rate (%)	33.02 (71/215)	37.76 (37/98)
No. of embryos cultured for 5 days	42	19
Blastocyst rate (%)	45.24 (19/42)	36.84 (7/19)
No. of cycles transferred embryos	28	13
Clinical pregnancy rate (%)	28.57 (8/28)	38.46 (5/13)
Miscarriage rate (%)	25.00 (2/8)	20.00 (1/5)
No. of ongoing pregnancies	2	3
No. of births	4	1

Limitations, reasons for caution: This freezing procedure needs a special apparatus (Inverted microscope equipped with a micromanipulator) and requires a high level of technique for gathering and expelling 1–10 spermatozoa correctly and swiftly. So this procedure can only be performed by specialists, precious sperm can easily die with poor technique.

Wider implications of the findings: Once this procedure is mastered, the clinical outcome of severe male infertility is definitely improved. Especially in the treatment of azoospermia, precious spermatozoa surgically collected from epididymis or testicles can be cryopreserved to avoid repeating a biopsy. This procedure can lessen the patients' physical, mental and financial burdens.

Trial registration number: None.

P-451 Activin A mediates cumulus expansion by inducing hyaluronan accumulation and versican expression through Smad signaling pathways in human granulosa cells

S. Tian[1], H. Zhang[2], H.F. Huang[3], P.C.K. Leung[2]
[1]*The Second Affiliated Hospital of Zhejiang University School of Medicine, Reproductive Medicine, Hangzhou, China*
[2]*Child & Family Research Institute, University of British Columbia, Department of Obstetrics and Gynaecology, Vancouver, Canada*
[3]*The Key Laboratory of Reproductive Genetics, Ministry of Education Zhejiang University, none, Hangzhou, China*

Study question: What are the effects of activin A on the two key factors for cumulus expansion (hyaluronan and versican) in human granulosa cells and the molecular mechanisms?

Summary answer: Activin A induces hyaluronan synthase 2 (HAS2) and versican expression as well as hyaluronan accumulation through Smad2/3-Smad4 signaling pathways in human granulosa cells.

What is known already: Ovarian cumulus expansion is critical for ovulation. Hyaluronan is the fundamental component of expanded cumulus in preovulatory follicle, and HAS2 is its major synthase. Moreover, appropriate interaction between versican and hyaluronan is necessary for stabilization of expanded cumulus. Knockout studies show that activin and other TGFβ superfamily members (GDF9, BMP15) are vital for ovulation and female fertility in mice. However, the effects of activin A on cumulus expansion are species dependent. To date, a few studies show that activin A increases Has2 expression in mouse cumulus cells, meanwhile the effects of TGFβ on versican were determined only in cancer cells.

Study design, size, duration: We used SVOG cells and primary human granulosa cells for *in vitro* experiments. SVOG cells were immortalized human granulosa cells originally obtained from women undergoing *in vitro* fertilization (IVF). Primary human granulosa cells were obtained from patients undergoing IVF. Both cells were cultured with activin A up to 24 h to investigate its effects on HAS2 and versican expression and hyaluronan production, SVOG cells were cultured up to 12 h to investigate the signaling pathways.

Participants/materials, setting, methods: Levels of mRNA and protein were detected by RT-qPCR and western blotting, respectively. The accumulation levels of hyaluronan were examined by enzyme-linked immunosorbent assay (ELISA). Specific siRNA approaches were applied to knock down endogenous Smad2, Smad3 and Smad4 in SVOG cells.

Main results and the role of chance: In immortalized human granulosa cells, activin A upregulated both HAS2 and versican levels in time dependent manners ($p < 0.05$, respectively). Meanwhile, treatment of activin A induced hyaluronan production ($p < 0.05$). The inductive effects of activin A on versican, HAS2 and hyaluronan production in SVOG cells were abolished by TGF-type I receptor (TβRI) inhibitor. Moreover, activin A activated both Smad2 and Smad3 phosphorylation. Knocking down of Smad2 or Smad3 alone partially attenuated the activin A-induced HAS2 and versican levels in mRNA and protein levels, suggesting that Smad2 and Smad3 were both required for the upregulation of HAS2 and versican by activin A in SVOG cells. In addition, inhibition of Smad4, the essential common Smad for activin/TGF-β signaling pathway, completely abolished the activin A-induced HAS2 and versican expression in SVOG cells.

To better simulate the physiological situation, we also used primary cultured cells. In primary human granulosa cells, activin A increased HAS2 and versican expression ($p < 0.05$ and $p < 0.01$, respectively). Also, activin A induced hyaluronan accumulation in the culture medium ($p < 0.05$), this effect was subsequently blocked by TβRI inhibitor. Taken together, our data showed that activin A upregulated versican and HAS2 expression and induced hyaluronan production through Smad2/3-Smad4 signaling pathways in human granulosa cells.

Limitations, reasons for caution: We conducted only *in vitro* experiments, without further confirmation of the effect of activin A on hyaluronan and versican levels *in vivo*. Because this part of study was completed in UBC, SVOG cells were kindly provided by Prof. Leung. I intend to add animal study in the future in China.

Wider implications of the findings: For the first time, our data indicate that in human granulosa cells, activin A induces versican expression as well as hyaluronan accumulation via Smad signaling pathways.

This gives a better understanding on the subject of the effect of TGFβ superfamily members on cumulus expansion and ovulation, especially in human being.

Trial registration number: This is a basic science trial.

P-452 Similar egg recipient pregnancy rates are obtained following donation from egg-share providers or altruistic egg providers

D.W. Polson[1], J. Engler[2]
[1]*Manchester Fertility, Cheadle, UK*
[2]*Manchester Fertility, Clinical, Cheadle, UK*

Study question: Do oocytes donated from a sub-fertile woman as an egg-share provider (ESP) produce lower pregnancy rates than those donated from a healthy altruistic egg provider (AEP)?

Summary answer: Our results confirm similar recipient pregnancy rates following D3/D5 embryo transfer regardless of the source of the donor eggs.

What is known already: Few large studies have addressed this issue, principally due to the low numbers of AEP in the UK. A report from Oyesanya et al. (2009) suggested similar pregnancy rates could be obtained but the number in each group were low. Most UK studies have compared outcomes between the ESP and her recipient. These have suggested similar pregnancy rates and also that a lower age of the ESP and success in the ESP are predictive of success (Ahuja et al., 1998).

Study design, size, duration: A retrospective study over 3 years between January 2012 and December 2014, involving all matched egg share providers with their recipients, and all matched altruistic egg share providers and their recipients. We excluded all egg shared providers donating to their female partners in same sex relationships.

Participants/materials, setting, methods: In 3 years there were 211 matched pairs of egg providers with recipients. The matching was performed by a nurse taking into account the physical characteristics of the recipient/provider. These details and a personal written profile from the provider were sent to the recipient who could then accept or decline. 93 pairs were in the egg share group and 118 pairs involving altruistic egg donation.

Main results and the role of chance: During the 3 years there was an increase in altruistic egg providers from 15 in 2012 to 57 in 2014. The number of egg share providers remained the same at ~30/year.

The ages of the recipients were similar in the 2 groups, but the AEP were significantly younger than the ESP ($p < 0.001$). The altruistic egg recipients (AER) received significantly more eggs than the egg share recipients (ESR) 11 compared with 7 ($p < 0.001$): created significantly more embryos 7 compared with 5 ($p < 0.001$); and were significantly more likely to have embryos for cryopreservation 71% vs. 46% ($p < 0.001$)

However the pregnancy rates/ET were similar for all 3 groups. For D3 transfer 25%; 26%; 31% and for D5 transfer 61%; 53% and 56% for the ESR, AER, and ESP, respectively.

The age of the provider, her serum AMH and whether or not she became pregnant, did not influence the likelihood of pregnancy in the recipient.

Limitations, reasons for caution: The study involves a reasonable number in each group but larger numbers would always be beneficial

The results of the frozen embryo transfer cycles are not available. This may indicate a higher cumulative pregnancy rate in the AER group due to the greater number of women with embryos cryopreserved.

Wider implications of the findings: This study confirms that ESP should still be used in an oocyte donation programme as they do not reduce their own chance of a pregnancy through their donation, and they provide the same chance of a pregnancy to the recipient, as those receiving eggs from an AEP.

Trial registration number: NA.

P-453 Analysis of cumulative Live Birth Rate (cLBR) after up to five IVF/ICSI treatments in relationship to the number of the complete cycle

A. Borini[1], C. Zacà[2], E. Sereni[2], M.A. Bonu[2]
[1]*Tecnobios Procreazione, Reproductive Medicine IVF Clinical Unit, Bologna, Italy*
[2]*Tecnobios Procreazione, Reproductive Medicine IVF Laboratory Unit, Bologna, Italy*

Study question: What is the relationship between the number of complete IVF/ICSI treatment and the cLBR considering previous completed treatments?

Summary answer: The chance of cLBR is higher at the first attempt, and there is no statistically significant decrease from the second attempt up to the fifth.

What is known already: Despite the growing success rates of IVF treatments during the last decade many couples have to undergo several cycles before obtaining live birth. Surely, it is important to link the success and so the LBR to the age of the woman, but this information is not useful for patients who underwent previous treatments or those who intend to undergo multiple cycles.

Some authors assumed as the first cycle, the first one performed in their centres, others showed the results/single episode of transfer without investigating the real chance of the completed cycle (fresh + frozen) after a certain number of treatments.

Study design, size, duration: This retrospective multicentric cohort study analyzed 4200 complete IVF cycles conducted between May 2009 and June 2013. One complete cycle was defined as the transfer of all fresh and frozen embryos resulting from one ovarian stimulation. Complete cycle data were stratified according to the number of the completed cycle (from the first to the fifth treatment) and the woman's age. The mean woman age was 35.8 ± 4.1.

Participants/materials, setting, methods: Participants were between 18 and 43 years old undergoing oocytes retrieval at one of the IVF centres. We included cycles with at least one retrieved oocyte. We discussed the relationship between the number of treatment and clinical outcome in terms of cLBR and then, thanks to the high number of cycles analyzed, we stratified and evaluated this relationship in the different age groups (Group 1: ≤34 years, Group 2: 35–38 years, Group 3: 39–43 years).

Main results and the role of chance: Out of 4200 complete IVF cycle, 1210 resulted in a live birth (28.8%). The overall analysis showed the following cLBR/cycle: 31.8% at the first treatment, 26.7% at the second one, 23.1% at the third one, 25.0% at the fourth one, 18.2 at the fifth treatment.

Statistical analysis shows the first treatment with the highest success rate ($p < 0.05$). From the second treatment up to the fifth no significant differences were found ($P = 0.143$).

cLBR was 36.4, 30.3, and 17.3% in Group1, Group2 and Group3, respectively. The analysis of groups according to the patient age and number of complete treatment showed that in Group 1 the cLBR/cycle is significantly higher at the first treatment ($p < 0.05$), whereas by the second to the fifth one there is no statistically significant difference between the rates ($P = 0.065$) (Group 1: 38.7%, 35.3%, 27.8%, 31.3%, 12% respectively). There is no statistically significant difference by the first treatment until the last one in Groups 2 and 3 (Group 2: 32.8%, 27.3%, 27.2% 28.2%, 29.4%; Group3:18.5%, 17.4%, 14.1%, 19.4%, 8.9% respectively).

Limitations, reasons for caution: As this is a retrospective study, the information obtained is based on previously recorded data. Consequently, certain informations that could influence the outcome, such as total gonadotropin consumption, BMI, markers of ovarian reserve and others, are not in the dataset.

Wider implications of the findings: Our data shows as cLBR is highest at the first attempt while by the second to the fifth no significant decrease is recorded. It could be helpful for linking the number of treatment to likelihood of cLBR suggesting a substantial positive potential of further treatment cycles, when not physiologically contraindicated.

Trial registration number: Not a clinical trial.

P-454 A higher risk of the metabolic syndrome in subfertile women

D. Pattinaja[1], J. Bons[2], M. Spaanderman[1], R. van Golde[1]
[1]*Maastricht University Medical Centre, Department of Obstetrics & Gynaecology, Maastricht, The Netherlands*
[2]*Maastricht University Medical Centre, Department of Clinical Chemistry and Hematology, Maastricht, The Netherlands*

Study question: Is the incidence of the metabolic syndrome higher in subfertile women and is it related to the cause of their subfertility?

Summary answer: The prevalence of the metabolic syndrome is higher in subfertile women, but is not related to the cause of subfertility.

What is known already: The metabolic syndrome is a well-known risk factor for cardiovascular disease. Subfertile women may have a higher risk of cardiovascular related problems. For instance, the risk of developing preeclampsia increases in women with a reduced ovarian reserve who receive an IVF treatment. Furthermore obesity, a parameter of the metabolic syndrome, is associated with reduced fecundity in subfertile ovulatory women. Several studies show subfertility is associated with an elevated risk of maternal obstetric complications. Whether this is the result of the used artificial reproductive technique (ART) procedures or related to the health of the subfertile woman is still an ongoing debate.

Study design, size, duration: We performed an interim-analysis of an ongoing prospective cohort study.

Participants/materials, setting, methods: Subfertile women who visited the Maastricht University Medical Center ($n = 41$) were included. The control group consisted of participants with a history of an uneventful spontaneous pregnancy ($n = 13$). We collected clinical measurements, blood and urine samples to determine the variables necessary to define the metabolic syndrome. This definition was met when a participant fulfilled the criteria of the World Health Organisation (WHO), the Third Adult Treatment Panel (ATP) III or the International Diabetes Federation (IDF).

Main results and the role of chance: The incidence of the metabolic syndrome in the overall study group of subfertile women was 13.2% (5/38), 5.4% (2/37) and 13.8% (4/29), according to the WHO-, ATP III- and IDF-criteria respectively compared to 0% (0/13, 0/13, 0/13) in the control group; OR 1.40 [95% CI 1.16–1.67], OR 1.37 [95% CI 1.15–1.63] and OR 1.52 [95% CI 1.21–1.91]. Nineteen women were diagnosed with an unexplained subfertility. In this subgroup of unexplained subfertility an incidence of 0% for all definitions was found. A significant higher diastolic blood pressure and waist-to-hip ratio was found compared to the control group, respectively from 67.5 (55–90) to 62.0 (53–79) mmHg and 0.81 (0.70–1.01) to 0.75 (0.69–0.87). In the study subgroup with unexplained subfertility a statistical significant higher waist-to-hip ratio, blood pressure and mean arterial pressure (MAP) were found compared to the control group (p-value <0.05).

Limitations, reasons for caution: We performed an interim-analysis in an ongoing study and therefore the presented sample sizes are still small. Our clinic is not performing fertility work-up and treatment in women with a body mass index >35 kg/m^2.

Wider implications of the findings: The results show that it can be beneficial to screen all subfertile women for the metabolic syndrome. Lifestyle interventions or medical treatment of the metabolic syndrome may result in a higher chance of an uneventful pregnancy.

Trial registration number: Clinicaltrials.gov, NCT02136472.

P-455 miRNAs expression profile in human oocytes from women undergoing different IVF stimulation protocols

M.D'Aurora[1], C. Di Pietro[2], C. Tatone[3], M.E. Vento[4], R. Ciriminna[5], S. Franchi[1], L. Stuppia[1], V. Gatta[1], G.P. Artini[6]
[1]*University of Chieti, Department of Psychological, Health and Territorial Sciences, Chieti, Italy*
[2]*University of Catania, BioMolecular, Genome and Complex Systems BioMedicine Unit BMGS, Section of Biology and Genetics G Sichel, Department of BioMedicine and BioTechnology, Catania, Italy*
[3]*University of l'Aquila, Department of Life, Health, and Environmental Sciences, L'Aquila, Italy*
[4]*Cannizzaro Hospital, IVF Unit, Catania, Italy*
[5]*AMBRA, Associazione Medici e Biologi per la Riproduzione Assistita, Palermo, Italy*
[6]*University of Pisa, Department of Clinical and Experimental Medicine, Pisa, Italy*

Study question: Which is the role of IVF stimulation protocols in modulating oocyte miRNome?
Summary answer: Data have shown a differential miRNA activation depending on the IVF stimulation protocol used.
What is known already: Recently, has emerged that miRNAs play a pivotal role in regulating oocyte maturation efficiency during ovarian follicle development. miRNAs modulate several transcripts having important roles in regulating known molecular pathways that determine the fate of ovarian follicle development. It has been reported that miRNAs expression depends on different stimulation protocols. In this view, miRNAs have gained a great scientific interest for the implication in clinical research: they could represent non-invasive biomarkers, prognostic factors and also therapeutic targets.
Study design, size, duration: Ten healthy women with regular cycles and tubal disease or unexplained infertility were included in this study. MII oocytes were retrieved from five patients treated with r-hFSH + r-hLH, and five treated with r-hFSH. Oocyte miRNome variations were evaluated by array cards containing 768 mature miRNA probes.
Participants/materials, setting, methods: Total RNA was extracted from oocytes using mirVana™ miRNA Isolation Kit.

Each experiment was carried out on miRNA pools obtained by mixing the miRNAs from oocyte of five patients treated with rLH + rFSH and five patients treated with r-hFSH alone.

Real time PCR was employed to analyze the miRNA expression level using TaqMan Array Human MicroRNA A + B cards.
Main results and the role of chance: The study of miRNA expression profile of oocytes from women treated with different stimulation protocols provided evidence that r-hLH + r-hFSH or r-hFSH alone produce different effects in terms of regulation of gene expression.

r-hLH + r-hFSH modulates miRNAs (miR-130a, miR-21, miR-15, miR-10a, and Let-7 family members) involved in oocyte reprogramming, proliferation of granulosa cells and the bidirectional cross-talk with cumulus cells.

r-hFSH regulates miRNAs (miR-135a, miR-98, miR320, miR-106a, and Let-7b) involved in the regulation of oocyte maturation, embryonic development and granulose cells steroidogenesis. Ingenuity pathway analysis showed that both treatments are able to modulate miRNAs involved in P53 pathway.
Limitations, reasons for caution: This research included few samples and could be considered as a pilot study.
Wider implications of the findings: Our results suggest that the two drugs affects the expression of different miRNAs playing a crucial role in periovulatory events and could influence the developmental competence of the oocyte and granulose development.
Trial registration number: NA

P-456 *In vitro* fertilization treatment outcomes following standard 2D ultrasound vs. 3D automated follicle tracking (sonoAVC), a prospective randomized study

A. Ben-Haroush[1], R. Nagar[2], G. Oron[1], R. Bardin[2], B. Fisch[1]
[1]*Beilinson, Infertility and IVF Unit- Helen Schneider Hospital for Women- Rabin Medical Center, Beilinson Hospital, Petach Tikva, Israel*
[2]*Beilinson, Ultrasound Unit- Helen Schneider Hospital for Women- Rabin Medical Center, Beilinson Hospital, Petach Tikva, Israel*

Study question: To compare three-dimensional ultrasound imaging of follicular volume to the standard two-dimensional ultrasound follicular surveillance during *in vitro* fertilization (IVF) treatment in a randomized control study.
Summary answer: Implementation of 3D sonographic measurements during follicular surveillance in *in vitro* fertilization treatment was not found to increase oocyte maturation, fertilization rate or pregnancy rate.
What is known already: Use of Sono AVC leads to a significantly lower intra- and inter-observer variability with a significant advantage in time gain for both the doctor and patient. It offers the possibility of continuous training and standardization of follicular monitoring. Sono AVC was found to be highly reliable for ovarian reserve testing by measurement of antral follicle count. Manual and automated follicular measurements during IVF treatment are reported to be comparable, however not in a randomized control trial.
Study design, size, duration: A prospective randomized control study. 54 women undergoing IVF treatment were randomly assigned to undergo follicular measurements with either 2D or 3D ultrasound imaging. Demographic, treatment and laboratory characteristics were collected.
Participants/materials, setting, methods: All patients underwent a fixed antagonist protocol and sonographic assessments were performed throughout ovarian stimulation up until day of oocyte retrieval. Treatment parameters including number of ovarian follicles, diameter/volume averages and endometrial thickness were assessed.
Main results and the role of chance: Mean age, cause of infertility, cycle parameters including duration of treatment, total dose of gonadotropins, large diameter follicles (>13 mm), peak estradiol levels were similar in both groups. The number of sonographic measurements were also similar in the 2D and 3D groups (3.2 ± 1 and 3.6 ± 1.2, $p = 0.1$, respectively). The number of retrieved oocytes (9.9 ± 5.2 and 10.4 ± 5.5, $p = 0.7$), number of mature oocytes (7.7 ± 4.3 and 8.3 ± 4.5, $p = 0.62$), ICSI fertilization rate (0.7 ± 0.3 and 0.79 ± 0.22) and pregnancy rates (17/27–63% and 12/27–44%, respectively, $p = 0.172$) were comparable between the two groups. In a multivariate logistic regression analysis, sonographic tracking method (2D or 3D) was not a significant predictor for follicular maturation rate or achieving a pregnancy.
Limitations, reasons for caution: While the number of participants is small, this is a prospective randomized control study evaluating the efficacy of 3D sonographic follicular surveillance in *in vitro* fertilization.
Wider implications of the findings: 3D sonographic follicular volume measurement was not found to be superior to standard 2D follicular measurement during in-vitro fertility treatment for increasing follicular maturation rates or pregnancy rates.
Trial registration number: ClinicalTrials.gov Identifier: NCT01723267.

P-457 Cohesins SA1/SA2 expression profiling and DNA telomere sizing of cumulus cells as potential indicator of oocyte quality and embryo competence.

A. Luddi[1], D. Valerio[2], V. De Leo[1], S. Longobardi[3], P. Piomboni[1]
[1]*University of Siena, Department of Molecular and Developmental Medicine, Siena, Italy*
[2]*Institute for Genetic Research, Department for Genetic Research, Naple, Italy*
[3]*MerckSerono S.p.A, Medical Department, Darmstadt, Hesse, Germany*

Study question: Are the relative telomere length and cohesins SA1/SA2 mRNA quantitative evaluation of cumulus cells predictive biomarkers of oocyte quality and embryo development potential?
Summary answer: The relative telomere length and expression profiling of cohesins SA1/SA2 of cumulus cells are eligible biomarkers of oocyte competence in ART scenario.
What is known already: Cohesin-SA1 and SA2 form a protein complex that mediates sister chromatid cohesion at telomere termini (SA1) and alongside chromatid arm (SA2), allows chromatin accessibility to regulate gene transcription and triggers DNA repair in G2. Inadequate expression of cohesion SA1 by ageing or cytoplasmic immaturity may led to telomere shortening (defective replication) and affect oocyte quality and embryo competence.
Study design, size, duration: Collectively 280 cumulus/oocyte complex samples were recovered from a total of 51 patients (<38 years old) undergoing different stimulations protocols (FSH, FSH + LH, recombinant or extractive). According to the number of retrieved follicles/patient from 3 to 8 cumulus cells were pooled for the analysis.

Participants/materials, setting, methods: DNA and total mRNA were extracted from cumulus cells and assayed for telomere sizing and SA1/SA2 expression profiling by qPCR and qRT-PCR. The quantification of telomere DNA was accomplished to a single copy housekeeping gene to generate a telomere/single copy gene ratio. Expression levels of SA1/SA2 cohesins and telomere length measurements of samples were ranked in relation to the clinical setting parameters (BMI, age, hormonal protocol stimulation) and oocyte development indicators (embryo quality, reproductive outcome).
Main results and the role of chance: Cohesins SA1 and SA2 mRNAs were both expressed in all cumulus cells analyzed in this study, even if their expression level resulted significantly different. On the whole, SA2 expression was significantly increased in comparison to SA1; moreover, SA2 mRNA resulted more expressed in young (<35 years old) in comparison with old patients (>38 years old). When the expression level was evaluated according to embryo quality and positive reproductive outcome, we observed an increase of the SA2 levels in cumulus cells. We also analyzed the relation between both cohesins mRNA levels and telomere length in the same samples, highlighting a significant raise of SA1 expression level in cumulus cells were the telomere sequence were increased. The same analysis did not revealed any significant correlation with SA2 mRNA expression level.
Limitations, reasons for caution: Only a limited number of single cumulus/oocyte complex were analyzed. Results from pooled cumulus, as gathered in the majority of cases of the present study, may not be fully predictive of single oocytes ontogeny.
Wider implications of the findings: To our knowledge this is the first study addressing the issue of cohesins SA1 and SA2 expression in cumulus cells together with the telomere relative length sizing as biomarkers of oocyte competence. The reported observations may stimulate further research to uncover the role of cohesins in oocytes aneuploidies.
Trial registration number: Not applicable.

P-458 Transplantation of ovarian tissue in high risk patients treated for leukemia; safe approach resulting in ovulations, IVF cycles and pregnancy

D. Meirow[1], H. Raanani[1], S. Derech-Haim[1], S. Aviel-Ronen[2], M. Nagar Marciano[3], M. Brenghausen[1], E. Schiff[1], I. Barshak[2], N. Amariglio[3]
[1]Sheba – Tel Hashomer Medical Center, ObGyn, Ramat Gan, Israel
[2]Sheba – Tel Hashomer Medical Center, Pathology, Ramat Gan, Israel
[3]Sheba – Tel Hashomer Medical Center, Hemato-Oncology, Ramat Gan, Israel

Study question: Patients with leukemia are at high risk for transfer of malignant cells with the transplanted ovarian tissue.

Can we provide safe and effective OTCP-transplantation in patients with leukemia?
Summary answer: However, these young patients are treated with high dose chemotherapy and would highly benefit from the ovarian tissue cryopreservation (OTCP) technique.
What is known already: OTCP-Orthotopic transplantation is an effective technique to restore fertility. Young patients with leukemia are frequently treated with high dose chemotherapy would highly benefit from OTCP. However as studies indicate risk of leukemic cells contamination in the graft, use of this technology has been avoided. Chemotherapy pre-OTCP reduces the risk of leukemic cells presence in the graft. Histology, immunostaining, molecular markers and animal studies can be used to reduce risk of possible infiltration by leukemic cells.
Study design, size, duration: During twelve year period a cohort of 490 patients underwent OTCP in a tertiary oncology reproductive center. Forty six patients had the diagnosis of leukemia and thirteen of these patients were interested in transplantation of stored tissue in order to conceive.
Participants/materials, setting, methods: Eleven patients had acute myeloid leukemia (AML), 2 had chronic myeloid leukemia (CML). Seven AML patients had known molecular markers, bcr-abl translocation was evaluated in CML. Molecular studies used RT-PCR, next generation sequencing (NGS) and novel Trusight Myeloid Sequencing Panel (Illumina). SCID mice transplantation was performed only in AML.
Main results and the role of chance: Histology indicated ovarian follicles despite pre-harvesting chemotherapy exposure but no leukemic cells were found. In 7 AML patients with known genetic markers, 1 patient showed positive marker (translocation 15/17) while all others were negative. In 2 AML patients NGS and myeloid panel revealed new markers in original leukemic cells, but ovarian tissue was negative. RT-PCR for bcr-abl was positive in 1 CML patient. Transplantation into SCID mice was negative in all AML patients evaluated.

Ovarian tissue was transplanted in 2 patients (CML and AML). AML patient conceived following IVF and is in her 2nd trimester of normal pregnancy. There is no evidence of cancer recurrence with more than 5 years follow-up of the CML patient and 1 year for the AML patient.
Limitations, reasons for caution: To use new advanced molecular technologies efficiently we must have access to original leukemic cells in order to search for patient specific new markers. NGS technologies and myeloid panel cannot reveal pathognomonic markers in all cases. The cost of searching for cancer cells in the ovary is still high.
Wider implications of the findings: Transplantation technique is an effective technique and can be used cautiously in patients treated for leukemia. The outcomes of OTCP post chemotherapy are not inferior to those obtained in chemotherapy naive patients. Searching for cancer cells in ovarian tissue should be performed in centers specialized in new technologies.
Trial registration number: 7222-09-SMC.

P-459 Reproductive outcome after oocyte banking

E. Balkenende[1], T. Dahhan[2], F. van der Veen[2], S. Repping[2], M. Goddijn[2]
[1]Academic Medical Center, Amsterdam, The Netherlands
[2]Academic Medical Center, Center for Reproductive Medicine, Amsterdam, The Netherlands

Study question: What are the reproductive outcomes of women after oocyte banking?
Summary answer: The majority of women banking oocytes conceives naturally.
What is known already: Women at risk for premature ovarian insufficiency may increase their chances of future childbearing by banking their oocytes. Published data regarding reproductive follow-up of these women is scarce.
Study design, size, duration: We carried out a cohort study in 2015 in all 292 women who banked oocytes between 2006 and 2013 in our center.
Participants/materials, setting, methods: We retrieved medical data, e.g., indications and outcomes of ovarian stimulation from medical files. We asked all women who banked oocytes during the study period to participate and fill out an additional questionnaire on demographics, diagnosis, gonadotoxic treatment or ovarian surgery received, menstrual cycle and contraception, relationship status, pregnancy attempts and intended use of banked oocytes.
Main results and the role of chance: A total of 202/292 (69%) women responded and 184/292 (63%) women consented to participate and returned the questionnaire. Of these women, 106/292 (36%) were trying or had tried to become pregnant after oocyte banking. In our study 59/106 (56%) women became pregnant. These 59 women reported 75 pregnancies, 45/75 (60%) of the pregnancies were spontaneously conceived and 30/75 (40%) pregnancies were conceived with ART. The 75 pregnancies resulted in 42 (56%) live births, 16 (21%) ongoing pregnancies, 16 (21%) miscarriages and one (1%) induced abortion. From the 30 pregnancies conceived with ART in 8/30 (27%) pregnancies the women used their banked oocytes.
Limitations, reasons for caution: Since this was a single centre study our results might not be generalizable to other settings and populations. An even longer follow-up of the fate of banked oocytes is needed to further explore the efficacy of the treatment.
Wider implications of the findings: Our results suggest that most women wish to become pregnant in the next few years after cryopreservation of oocytes. Considering that most women in our study conceived naturally, the chances of natural conception should be discussed during the counseling of oocyte banking.
Trial registration number: W15_041.

P-460 Chronic inflammation *in utero* may reduce ovarian reserve

E. Shalom-Paz[1], S. Grodzinski-Weil[2], A. Ellenbogen[1], Y. Ginsberg[3], K. Nizar[3], R. Beloosesky[3]
[1]Hillel Yaffe Medical center, IVF, Hadera, Israel
[2]Hillel Yaffe Medical center, OBGYN, Hadera, Israel
[3]Rambam Medical Center, OBGYN, Haifa, Israel

Study question: Does maternal inflammation during pregnancy leads to reduction of the ovarian reserve of the offspring?

Summary answer: Chronic maternal inflammation induced IUGR offspring and a reduction of the offspring' ovarian reserve.
What is known already: There is an association between intrauterine malnutrition and hormonal imbalance and negative consequences on the development of the reproductive system in females. Excess maternal inflammation and oxidative stress while *in utero* have been known to affect gross fetal development. However, an association between the inflammatory process *in utero* and the effects on ovarian development and future fertility has not yet been demonstrated. This study focused on LPS-induced inflammation in early pregnancy and its effect on ovarian development and reserves of the offspring, using a rat model.
Study design, size, duration: An animal model with Sprague-Dawley pregnant rats ($n = 11$) received (50 µg/kg bodyweight) intraperitoneal lipopolysaccharide (LPS group) or saline solution (Control group) on day 14, 16, and18 of gestation. Pups were delivered spontaneously. At 3 months, female offspring were weighed and sacrificed.
Participants/materials, setting, methods: Ovaries were harvested for: 1. Follicle count using Hematoxylin and Eosin staining, 2. Apoptosis: ovaries were stained for Caspase and 3. Serum CRP and AMH levels were determined.
Main results and the role of chance: Birth weight of pups was significantly lower in the LPS group compared to the control group (6.0 mg ± 0.6 vs. 6.6 mg ± 0.4; $P = 0.0003$). The LPS group had lower proportion of preantral follicles, as well as increased intensity of Caspase 3 staining (510 u vs. 155.5 u; $P = 0.007$). There was no significant difference in the CRP levels between the two groups (1.06 vs. 0.96; $P = 0.42$). AMH levels were significantly lower in the LPS group (4.155 ng/ml ± 0.4669 vs. 6.082 ng/ml ± 1.884; $P = 0.016$).
Limitations, reasons for caution: We were not able to count the total number of follicles in the ovaries, we calculated only the proportion of the different follicles in each ovarian section.
Wider implications of the findings: LPS induced inflammation *in utero* maybe linked to a premature depletion in follicular count through a process of premature induction of apoptosis. It highlight the importance of prevention or early treatment of maternal infection/inflammation, because it can lead to a more promising outcome for the future fertility of the offspring.
Trial registration number: Not relevant.

P-461 A predictive nomogram based on multiple biomarkers leads to appropriate rFSH starting dose in IVF/ICSI cycles: a randomized controlled trial

A.A. Marino[1], A. Allegra[1], A. Volpes[1], F. Coffaro[1], P. Scaglione[1], F. Sammartano[1], S. Gullo[2], A. La Marca[3]
[1]*ANDROS Day Surgery Clinic, Reproductive Medicine Unit, Palermo, Italy*
[2]*ANDROS Day Surgery Clinic, Medical Statistics Unit, Palermo, Italy*
[3]*University of Modena and Reggio Emilia and Clinica Eugin, Mother-Infant Department, Modena, Italy*

Study question: What is the role of a nomogram based on multiple biomarkers (age, basal FSH and AMH) to determine the most appropriate rFSH starting dose in IVF/ICSI cycles?
Summary answer: The nomogram allows the choice of an appropriate rFSH starting dose for optimizing the ovarian response.
What is known already: The number of oocytes retrieved is a key prognostic marker in women undergoing IVF/ICSI. Choosing different doses of gonadotropins for different patients is therefore a crucial clinical decision in the treatment of infertile couples. Although tailored therapy based on markers of ovarian reserve is an agreed-upon approach by most, studies suggesting how to determine individualized therapy compared to "one size fits all" are scarce. Recently a nomogram based on female age, FSH and AMH has been proposed to suggest the starting dose (La Marca et al., 2012). In the present study, the nomogram has been externally validated in a RCT.
Study design, size, duration: This RCT involved 194 couples attending their first IVF/ICSI cycle between 2013 and 2015. The patients underwent a long protocol and were randomized to receive rFSH starting dose selected on the basis of their age (150 IU if ≤35 years, 225 IU if >35 years) (control group) or on the basis of the nomogram (study group).

The primary outcome measure was the optimal number of retrieved oocytes defined as 8–14.

Participants/materials, setting, methods: The study was conducted at ANDROS Day Surgery Clinic, Palermo, Italy. Inclusion criteria were: female age 18–40 years, BMI 18–25 kg/m^2, AMH 1.0–4.0 ng/ml, FSH ≤15 mIU/ml. Exclusion criteria were PCOS, irregular cycles, endometriosis, previous ovarian surgery, ovarian cysts, any known endocrinological disease.

It was calculated that a total sample size of 354 achieves 90% power to detect a difference in optimal response of 15% (α-level = 0.05). An interim analysis was pre-planned at 50% of recruitment.
Main results and the role of chance: Data of 194 patients were available for the interim analysis: 99 (control group) and 95 (study group). 191 couples started the cycle (3 couples dropped out in study group).

There were not significant differences between the two groups in age, BMI, infertility years, AFC, AMH, FSH. In the control group, 57 and 43% of patients received the dose of 150 and 225 IU, respectively. In the study group, 48% of patients received 225 IU of rFSH, while 52% received a dose ranging between 125 and 212.5 IU.

The optimal response was observed in 58/92 patients (63.0%) in the nomogram group and in 42/99 (42.4%) in the control group ($p = 0.004$), a difference sufficient for terminating the trial.

Patients with <8 oocytes retrieved were 24/92 (26.1%) in the nomogram group and 40/99 (40.4%) in the control group ($p = 0.04$). Patients with >14 oocytes retrieved were similar between the two groups.

Embryological data and clinical pregnancy rates (CPRs) were similar between the groups.

The CPRs in the whole population were significantly higher in those patients with an optimal response than in those with a non-optimal response both per started cycle (46/100, 46% vs. 15/91, 16.5%, $p = 0.001$) and per embryo transfer (46/95, 48.4% vs 15/56, 26.8% $p < 0.01$).
Limitations, reasons for caution: Since the nomogram is based on hormonal markers that may have some inter-lab degree of variability, a well-designed multicentric trial is needed before the clinical diffusion of the algorithm.
Wider implications of the findings: The nomogram could become the basis for the selection of the most appropriate rFSH dose to obtain an adequate number of oocytes.

P-462 Should intrauterine insemination be performed before or after ovulation? – A retrospective analysis of 6701 cycles

L. Svenstrup[1], K. Erb[2], J. Fedder[2], C. Yding Andersen[3], P.E. Rasmussen[2], P. Humaidan[4]
[1]*The fertility Clinic, University South of Denmark, Gynecology and obstetric department D, University Hospital, 5000 Odense, Denmark*
[2]*The Fertility Clinic, Gynecology and obstetric department D, Odense University Hospital, 5000 Odense, Denmark*
[3]*The Laboratory of Reproductive Biology, Copenhagen University Hospital, Rigshospitalet, 2100 Copenhagen, Denmark*
[4]*The Fertility Clinic, Skive Hospita, 7800 Skive, Denmark*

Study question: Is there a difference in clinical pregnancy and live birth rates between inseminations performed before and after ovulation
Summary answer: No differences were found in pregnancy and live birth rates when comparing inseminations performed before and after ovulation.
What is known already: Heterologous Insemination (IUI-H) is an established effective non-invasive treatment for infertile patients. IUI-H is often offered as a first-line treatment of infertility. In 2014, a total of 9498 IUI-H cycles were conducted in Denmark. The correct timing of the insemination around the time of ovulation is important since the human gametes have a limited survival time
Study design, size, duration: A retrospective study using data from 6701 IUI-H treatment cycles from April 1990 to August 2011, performed at the Fertility Clinic, Odense University Hospital, Denmark.
Participants/materials, setting, methods: IUI cycles were either natural or stimulated with Clomifen, FSH or HMG. Ovulation was induced with 6500 IE or 10,000 IE hCG. Vaginal ultrasound at the time of insemination, 38 h after hCG, revealed whether ovulation had occurred. Ovulation was defined as a collapsed or blood filled follicle. The primary outcome of the study was live birth rate, secondary outcome was pregnancy rate.

Main results and the role of chance: In 2128 cycles (31.8%) ovulation had occurred at the time of insemination, whereas in 3870 cycles (57.8%) ovulation had not occurred. In 703 cycles (10.5%) ovulation had occurred only in one ovary. The overall pregnancy rate was 15.5% and the overall live birth rate 12.1%. In cycles where ovulation was absent before IUI, the clinical pregnancy rate was 15.7% and the live birth rate was 12.6%. When ovulation was detected the pregnancy rate was 15.4% and the live birth rate 12.9%. With one-sided ovulation only, the pregnancy rate was 15.5% and live birth rate 10.3%. No significant differences were seen in live birth rates between groups.
Limitations, reasons for caution: The results are based on retrospective observational data, however, from a single fertility center and including a large sample size. Selection bias may be present, and generalizability can be limited. Although the data is older, the same insemination procedures were used all through the period.
Wider implications of the findings: This is the largest study until now, showing that in IUI-H, pregnancy and live birth rates are similar, whether or not ovulation has occurred at the time of insemination. Thus, timing of insemination before or after ovulation as well as ultrasound examination prior to insemination is redundant.
Trial registration number: Not relevant.

P-463 Pioglitazone is effective for multiple phenotypes of the Zucker fa/fa rats used as a model of polycystic ovary syndrome with insulin resistance

T. Endo[1], M. Morishita[1], Y. Kuno[1], T. Baba[1], T. Kiya[2], T. Saito[1]
[1]*Sapporo Medical University, Obs & Gynae Dept., Sapporo-Hokkaido, Japan*
[2]*Ena Ladies' Clinic, Department of Infertility, Sapporo-Hokkaido, Japan*

Study question: What effects, other than on insulin sensitivity, does treatment with pioglitazone, a thiazolidine derivative, have on a rat model of PCOS induced by insulin resistance?
Summary answer: Pioglitazone treatment reduced the percentage of atretic follicles and serum anti-mullerian Mullerian hormone levels, and stimulated the serum adiponectin level in Zucker fa/fa rats.
What is known already: Hyperandrogenism and insulin resistance may be related to the etiology of PCOS. Zucker fa/fa rats complicated with polycystic ovary, are obese, have insulin resistance without diabetes mellitus or hyperandrogenism and can be utilized as a PCOS rat model without effects of hyperandrogenism. PCOS patients are reported to have elevated serum AMH and low serum adiponectin levels. Excessive AMH is reported to interfere with follicle growth in these patients and adiponectin blocks apoptosis in some tissues. Pioglitazone is administered to PCOS patients with insulin resistance to induce ovulation but the mechanisms by which it does have not been elucidated.
Study design, size, duration: We purchased female Zucker fa/fa rats, 4 weeks age, and also as well as Zucker$^{+/+}$ rats for use as normal control rats with normal insulin sensitivity, and then administered pioglitazone or vehicle to groups of 5 rats of each type (4 groups in all). After 2 week of treatment, they were sacrificed for the study.
Participants/materials, setting, methods: From the dead rats, we got obtained serum samples and both ovaries. We checked determined the body weight, ovarian weight, and examined the serum AMH, adiponectin, testosterone, androstenedione levels. And we also examined ovarian histology to check follicle numbers by using HE staining, and check the number of atretic follicles using TUNEL methods.
Main results and the role of chance: Zucker fa/fa rats are significantly heavier than of Zucker$^{+/+}$ rats ($p < 0.05$), but pioglitazone treatment did not influence body weight in either group, nor did it influence ovarian weight. However, the total number of follicles was significantly increased in Zucker fa/fa rats compared with Zucker$^{+/+}$ rats ($p < 0.05$). Pioglitazone treatment did not alter the total number of follicles in Zucker fa/fa rats, but did significantly decrease the number of atretic follicles in Zucker fa/fa rats ($p < 0.05$). The serum AMH was significantly higher in Zucker fa/fa rats than in Zucker$^{+/+}$ rats ($p < 0.05$). Pioglitazone treatment significantly decreased the serum AMH level and significantly increased the serum adiponectin level in Zucker fa/fa rats ($p < 0.05$). Serum testosterone and androstenedione levels are quite low in Zucker fa/fa rats, and were not influenced by pioglitazone treatment.
Limitations, reasons for caution: In this study we examined the effects of pioglitazone treatment in a rat model of PCOS but not in humans.
Wider implications of the findings: In this study, pioglitazone reduced the serum AMH level and promoted follicle growth. In addition, it appeared to block follicle atresia via elevation of serum adiponectin. We have thus, for the first time. demonstrated that the effectiveness of pioglitazone treatment for PCOS occurs via the mechanisms described above.
Trial registration number: Our study is not a clinical trial.

P-464 Resting heart rate changes during the menstrual cycle

V. Högqvist Tabor[1]
[1]*BioWink, DxD, Berlin, Germany*

Study question: Can we accurately and precisely detect different phases of cycle through resting heart rates provided by electronic wearable technology?
Summary answer: Electronic wearable technology measuring number of daily steps/distances, sleep and parameters such as heart rate can be used to determine different phases of menstrual cycle.
What is known already: It is known that due to different reproductive hormone concentrations and dominances (determined as ratios between 2 hormones) during the menstrual cycle there is a vast physiological response, such as higher water retention (and consequently changes in weight, electrolytes, pH and perspiration), as well as changes in metabolism, ligament flexibility, vision and other.

The observation that resting heart rate (RHR) changes through different phases of menstrual cycle, reported by Moran and colleagues was a basis for this project.

According to their research RHR was significantly higher in both ovulatory and luteal phase when compared to menstrual and follicular phase.
Study design, size, duration: We have collected data on resting heart rate, ovulation, as well as menstrual cycle length and period duration. We have collected up to ten menstrual cycles of individual data on five cycling individuals, as well as three negative controls (either females on hormonal birth control or a male participant) aging 25–40 years.
Participants/materials, setting, methods: We used two mobile phone applications to collect data: Clue and FitBit

Resting heart rate (RHR) measurement was obtained using electronic wearable bracelet: *FitBitHR* (we allowed 7–10 days of "getting to used" time when first started to use).

Ovulation measurement-using Clearblue dual hormone indicator ovulation tests (detecting estradiol rise and luteinizing hormone surge).
For period and other entries-Clue application.

Exclusion: if any of the ailment categories was entered in Clue app on a given day.
Main results and the role of chance: We have observed similar resting heart rate (RHR) patterns as described by Moran and colleagues:

If we divide menstrual cycle in 4 phases: bleeding phase, follicular phase, ovulation and luteal phase.

Starting with the bleeding phase (the period) resting heart rate lowers towards the follicular phase, when it is the lowest throughout the entire menstrual cycle.

Resting heart rate starts to increase a few days before ovulation, and continues rising throughout the luteal phase.
At the start of the next cycle, resting heart rate starts dropping.

In the negative controls resting heart rate was not showing such patterns, but was more dependent on the overall health and activity of a given participant.
Limitations, reasons for caution: We observed that ailments such as cold, or fever have a strong impact on resting heart rate, but not ovulation and such results should be carefully examined or in the cases where the ailment lasted for more than 2 days discarded.
Wider implications of the findings: Findings presented here are the pilot and a start of a large-scale study that would take in consideration different age groups and lifestyles and try to determine if this phenomenon is found independently of the lifestyle differences.
Trial registration number: –

P-465 The oocyte utilization rate (OUR) a measure of pregnancy potential: multi-centre analysis of 7703 cycles

S. Hamamah[1], C. Avril[2], P. Barriere[3], J.L. Pouly[4], B. Salle[5]
[1]*Hôpital Arnaud de Villeneuve, Service de Biologie et de Médecine de la Reproduction B, Montpellier Cédex 5, France*

[2]Clinique Mathilde, AMP Mathilde, Rouen, France
[3]CHU de Nantes, Service de Médecine et Biologie du Développement et de la Reproduction, Nantes, France
[4]CHU de Clermont-Ferrand, Gynecologie Obstetrique et Reproduction Humaine, Clermont-Ferrand, France
[5]Hôpital Femme Mère Enfant Bron, Service de Médecine de la Reproduction, Lyon, France

Study question: How many mature (MII) oocytes obtained after ICSI are required to achieve an ongoing pregnancy in different age classes of women undergoing ICSI?
Summary answer: The oocyte utilization rate (number of clinical pregnancies per mature oocyte) remains stable in women upto age 37. Beyond 38 years, OUR significantly decreased.
What is known already: The clinical pregnancy and live birth per mature MII oocyte have been proposed to be valuable criteria to evaluate individual ART efficiency and to improve patient management. However, the number of human oocytes obtained from IVF/ICSI treatments that are competent to develop to a clinical pregnancy and live birth has been reported to be low, in the region of 2–5% depending on patient age. There is however no data at a national level on this measure and therefore to provide a starting point for subsequent initiatives to improve treatment outcomes the current multi-centre analysis was carried out.
Study design, size, duration: This was a multicentre retrospective audit on anonymised outcome data captured in an Exel file, then merged and analysed centrally. Overall data came from 6814 females who had 7703 oocyte retrievals. Data was captured from ICSI only treatment cycles in which ovarian stimulation was with follitropin alfa. Data capture was from 2011 to September 2015. Additional outcome information was obtained from subsequent vitrified embryo transfer cycles carried out in the same female cohort.
Participants/materials, setting, methods: Five French IVF centres having been involved in Fertility treatment for over 10 years participated. Female age was categorized into 5 groups (25–29 years; 30–34; 35–37; 38–39 and ≥40). Main assessment criterion was clinical pregnancy. Nonparametric LOESS method was used to estimate the relationship between pregnancy and the number of MII oocytes (on all attempts). Relationship between pregnancy at 1st attempt and female age and number of MII oocytes was estimated by logistic regression.
Main results and the role of chance: The mean female age was 33 ± 5 years and 48% of cycles were the first attempt and only a few (5.7%) were in the rank of 5 or more. There were in total 1892 clinical pregnancies and 341 from subsequent vitrified-thawed cycles. The pregnancy rate increased with the number of MII oocytes (up to 20), but in women older than 38 with high numbers of MII oocytes retrieved, it is not possible to give an accurate estimate in these age classes. Taking into account all fresh and frozen pregnancies, the number of MII oocytes required to achieve a pregnancy remained relatively stable below 37 years (25–29, 21.7; 30–34, 21; 35–37, 19.8) and then increased dramatically in subsequent age classes: 28.7 at 38–39 years and 30.8 at 40 years or more. These numbers revealed that the pregnancy cumulative OUR tended to increase from 4.6% (years 25–29) to 5% (35–37) and then decreased to 3.2% in women 40 or older. In a multiple logistic regression analysis on the first attempt, female age ($p < 0.0001$) and number of retrieved MII oocytes ($p < 0.0001$) were negatively and positively related to pregnancy, respectively.
Limitations, reasons for caution: Each cycle was considered as independent. Furthermore, over 30% of the cryopreserved embryos have not been used yet, representing residual clinical pregnancy and live birth potential not evaluated by the data.
Wider implications of the findings: Our results should lead to improve couple management. Moreover, these data may provide a tool to estimate the number of metaphase II oocytes needed to achieve a clinical pregnancy and live birth in case of female fertility preservation
Trial registration number: This was a retrospective clinical audit.

P-466 Anti-Müllerian hormone levels and female fecundity – results from a prospective cohort study comprising 654 women with a follow-up period of four years

H.W. Hvidman[1], J.G. Bentzen[1], A. Loft[1], A. Pinborg[2], A. Nyboe Andersen[1]
[1]Rigshospitalet, Copenhagen University Hospital, The Fertility Clinic, DK-2200 Copenhagen O, Denmark
[2]Hvidovre Hospital, Copenhagen University Hospital, The Department of Obstetrics and Gynaecology, DK-2650 Hvidovre, Denmark

Study question: Can anti-Müllerian hormone (AMH) levels predict fecundity in women?
Summary answer: Serum-AMH was not an age-independent predictor of female fecundity.
What is known already: Women seek assessment regarding their expected reproductive lifespan. AMH is a well-established predictor of ovarian response and, to some extent, to pregnancy rates after assisted reproductive technologies (ART). AMH is associated with age at menopause, but it remains uncertain whether AMH is an independent predictor of fecundity in women from the background population.
Study design, size, duration: A prospective cohort study comprising 863 women aged 20–41 years recruited from 2008 to 2010 of whom 709 (79%) participated in a questionnaire-based follow-up study four years after inclusion. The follow-up questionnaire was emailed to participants consecutively from September 2012 through February 2014, 4 years after the initial examination. The mean ± SD follow-up period was 4.0 ± 0.2 year. Women who were pregnant at the time of inclusion ($n = 55$) were excluded, leaving 654 women for analysis.
Participants/materials, setting, methods: At inclusion, the ovarian reserve was assessed by AMH and antral follicle count on Cycle Day 2–5, and baseline data were collected on reproductive and medical history, demography, and lifestyle. After four years, data were collected on subsequent conceptions, time to pregnancy (TTP), births, unsuccessful attempts to conceive, and fertility treatments. AMH was categorized in 1st (low), 2nd–9th (normal), and 10th (high) tentiles. Fecundability ratios (FR, 95% confidence intervals (CI)) were calculated by discrete-time survival-analysis.
Main results and the role of chance: At inclusion, the 654 women had a mean ± SD age of 32.7 ± 4.4 years; 363 (56%) had conceived and 306 (47%) had a history of ≥1 livebirths. The median (90% population limits) AMH-levels (pmol/l) were: 5.0 (1.1; 6.5); 19.9 (7.7; 43.2); and 65.2 (51.0; 99.7) in the low, normal and high AMH-group. During the 4-year follow-up period, 242/654 (37%) had not attempted to conceive, 359/654 (55%) had conceived at least once, 63/359 (18%) by means of fertility treatment, and 46/654 (7%) reported an unsuccessful attempt to conceive with a median (90% population limits) length of 16 (1; 72) months. Of the 412 women, who had conceived or attempted to do so, 80 (19%) reported a TTP or time of trying that exceeded 12 months. Low AMH was associated with reduced odds for conception (OR 0.5, 95% CI: 0.3; 0.8), but there was no association between AMH and conception after age-adjustment (aOR 0.7, 95% CI: 0.4; 1.3). Furthermore, TTP and the time of trying was prolonged in women with low AMH (FR 0.5, 95% CI: 0.3; 0.8), but not in women with high AMH (FR 1.3, 95% CI: 0.9; 1.9). However, fecundability was independent of both low (FR 0.7, 95% CI: 0.4; 1.1) and high (FR 1.1, 95% CI: 0.8; 1.6) AMH-levels in the age-adjusted model.
Limitations, reasons for caution: Data on TTP and unsuccessful attempts to conceive were collected retrospectively, which implies a risk of recall bias. The participants were health care personal which may limit the extrapolation to other populations. Additionally, the data do not allow analysis beyond the age of 45 years at follow-up.
Wider implications of the findings: Our data suggests that overall AMH adds little predictive value to female age when advising women on their future fecundity. It remains important to further develop reliable methods to identify women at risk of infertility, including those at risk of premature ovarian insufficiency, to prevent unwanted childlessness.
Trial registration number: Not applicable.

P-467 Oncologists' and haematologists' perceptions of fertility-related communication – a nationwide survey

C. Micaux Obol[1], L. Wettergren[1], G. Armuand[1], C. Lampic[1]
[1]Karolinska Institutet, Department of Neurobiology-Care Sciences and Society, Stockholm, Sweden

Study question: What are the main factors influencing the likelihood of physicians discussing fertility-related issues with female and male cancer patients of reproductive age?
Summary answer: The majority of oncologists and haematologists address fertility issues but important reasons for not doing so including patient factors and organizational barriers like high workload.

What is known already: Many cancer treatments have a negative impact on fertility. Despite international guidelines recommending health care professionals to bring up fertility-related issues with cancer patients of reproductive age many patients, especially women, report inadequate information provision. Previous research from the physician perspective has been mainly descriptive or examining the influence on single factors on communication behavior.
Study design, size, duration: The present study is a cross-sectional, nationwide survey study targeting all physicians registered as working in cancer care in Sweden (n = 821). In 2015 all eligible physicians were approached regarding anonymous participation in a survey about fertility-related communication with patients of reproductive age (women 18–45 years; men 18–55 years). The questionnaire was available both on paper and via a web link.
Participants/materials, setting, methods: Physicians registered as working in cancer care were eligible; exclusion criteria were no recent clinical activity and very few patients of reproductive age. Total response rate of 55%. A questionnaire was developed on the basis of two US surveys and adapted to the Swedish context. Questions assessed practice behaviour, perceived barriers and attitudes towards fertility communication, and confidence in knowledge regarding treatment-related fertility risks. Data were analysed with Chi-Square tests and logistic regression.
Main results and the role of chance: More than 90% of responding physicians agreed that discussing fertility is their responsibility and a majority stated often or always discussing fertility-related issues with patients of reproductive age. Multivariate regression models were performed to investigate factors associated with not routinely discussing treatment-related fertility risks with patients of reproductive age, which was reported by 27% of surveyed physicians for female patients and 30% of physicians for male patients. The factors significantly associated with not routinely discussing fertility risks were: the patient already having children, a high workload, seeing 5 patients of reproductive age weekly, and having access to a reproduction clinic at the hospital (both sexes). Additional factors associated with a lower frequency of fertility discussions were: the need to start cancer treatment immediately, and the physician having <5 years experience from cancer care (female patients only), as well as a low confidence in knowledge regarding treatment-related fertility risks (male patients only). In addition, a patient presenting with a poor prognosis was by 90% of physicians perceived as a circumstance that would make it unlikely for them to bring up fertility issues.
Limitations, reasons for caution: While the relatively low response rate (55%) is comparable to that of other studies targeting physicians, it limits the potential for generalizing results to the entire population. As the survey was anonymous in order to avoid social desirability responding, comparison of responders and non-responders was not possible.
Wider implications of the findings: The present results suggest that clinical circumstances constitute important reasons for not discussing fertility issues with cancer patients of reproductive age. However, some of the factors related to a low frequency of fertility discussions should be possible to alter through organizational changes or educational efforts.
Trial registration number: N/A.

P-468 Cumulative live birth rates (CLBR) after first ART cycle including subsequent frozen-thaw cycles in 1050 women attending a randomized trial comparing GnRH-antagonist versus GnRH-agonist protocol

M. Toftager[1], J. Bogstad[1], K. Løssl[1], L. Prætorius[1], A. Zedeler[1], T. Bryndorf[1], L. Nilas[2], A. Pinborg[1]
[1]*Hvidovre Hospital, Department of Obstetrics & Gynaecology- Fertility Clinic, Hvidovre, Denmark*
[2]*Hvidovre Hospital, Department of Obstetrics & Gynaecology, Hvidovre, Denmark*

Study question: Is CLBR similar in GnRH-antagonist and GnRH-agonist protocol in first ART cycle including subsequent frozen-thaw cycles from same oocyte retrieval?
Summary answer: Chances of at least one live birth following utilization of fresh and frozen embryos after first ART cycle are similar in GnRH-antagonist and GnRH-agonist protocol.
What is known already: Reproductive outcomes of ART treatment are traditionally reported as pregnancies per cycle. However, the primary concern is the overall chance of live birth. After first fresh ART cycle our results showed LBR of 22.8% and 23.8% (P = 0.70) for GnRH-antagonist and GnRH-agonist, respectively. But with CLBR including both fresh and frozen embryos from first oocyte retrieval, chances of at least one live birth increases. There is no previous Randomized controlled trial (RCT) comparing CLBR in GnRH-antagonist versus GnRH-agonist protocol. Previous studies on CLBR are either retrospective cohort studies including multiple fresh cycles or RCT comparing SET with DET showing CLBR around 50%.
Study design, size, duration: Phase IV, dual centre, open-label, RCT including 1050 women allocated to short GnRH-antagonist or long GnRH-agonist protocol in a 1:1 ratio over a five-year period with a minimum of 2-years followup. The aim was to compare CLBR between the two groups following utilization of all fresh and frozen embryos from the first ART cycle.
Participants/materials, setting, methods: Women referred for first ART cycle <40 years of age were included. All started standardized ART protocols with fixed rFSH dose according to age, planned day-2 SET and freezing of additional embryos. Frozen embryos were used in subsequent frozen-thawed cycles. CLBR is defined as at least one live birth per allocated woman after fresh and frozen cycles. Subjects were censored out after first live birth. Sub-group analyses were performed for stratified BMI and age categories.
Main results and the role of chance: When combining all fresh and frozen-thaw embryo transfers from first oocyte retrieval with a minimum of 2-years followup, the CLBR to first delivery was 33.3% (178/534) in the GnRH-antagonist group versus 30.6% (158/516) in the GnRH-agonist group (P = 0.34; OR:1.13; 95% CI:0.87 to 1.47).

Mean time to first live birth was 10.6 months in the GnRH-antagonist group compared to 11.3 months in the GnRH-agonist group (P < 0.01). Number of women with a secondary live birth was n = 7 and n = 12 for GnRH-antagonist and GnRH-agonist, respectively. At the end of trial n = 11 had unused frozen embryos and still no live birth in the GnRH-antagonist group compared to n = 9 in the GnRH-agonist group.

The stratified BMI groups were lean BMI <25 kg/m^2, overweight BMI 25–30 kg/m^2 and obese BMI>30 kg/m^2. Similar CLBR were found for lean women (36.9 vs. 33.8%) and women with overweight (30.1 vs. 37.7%), but for obese women CLBR was significantly higher in the GnRH-antagonist group 32.0% (24/75) vs. 12.0% (10/83) in the GnRH-agonist (P < 0.01).

No differences were found in the stratified age groups =<36 and >36 when comparing GnRH-antagonist with GnRH-agonist.
Limitations, reasons for caution: The duration of the trial is a limitation with introduction of new methods as "Freeze all," "GnRH-agonist triggering," and blastocyst culture of surplus embryos for freezing. However the RCT-design ensured that new methods were introduced to both groups simultaneously. Further, with minimum 2-years follow-up a minority still have cryopreserved embryos.
Wider implications of the findings: With the improvement of embryo culture, freezing and thaw methods as well as a strategy of elective single embryo transfer, CLBR until first live birth provides an all-inclusive success rate for ART. When comparing GnRH-antagonist and GnRH-agonist protocol we find similar CLBR.

P-469 Angiotensin-(1–7) in human follicular fluid correlates with oocyte maturation

I.K. Cruzeiro[1], M.L. Oliveira[2], H. Del Puerto[1], V.N. Lobach[1], M. Casalechi[2], M.G. Camargos[1], C. Dela Cruz[1], A.M. Reis[2], R.A. Santos[2], F.M. Reis[1]
[1]*Hospital das Clinicas da Universidade Federal de Minas, Dept. of Obstetrics and Gynecology, Belo Horizonte, Brazil*
[2]*Institute of Biological Sciences, Universidade Federal de Minas Gerais, Department of Physiology, Belo Horizonte, Brazil*

Study question: Do angiotensin (Ang)-(1–7) levels in human ovarian follicular fluid (FF) correlate with the number and proportion of mature oocytes obtained for *in vitro* fertilization (IVF)?
Summary answer: Ang-(1–7) levels in human FF correlate not with the total number but with the proportion of mature oocytes collected upon ovarian stimulation for IVF.
What is known already: Angiotensin (Ang)-(1–7) is an active peptide of the renin-angiotensin system that stimulates oocyte maturation in

isolated rabbit and rat ovaries. However, its role in human ovulation remains unexplored.

Study design, size, duration: This was a prospective cohort study including 64 participants from a single IVF center. Sample size was calculated to achieve a statistical power of 90% in detecting meaningful quantitative differences between group medians. The participants were enrolled in the study during six consecutive months. Plasma samples were obtained from all subjects at day 21 of the last menstrual cycle before starting pituitary blockade and controlled ovarian stimulation (COS), and immediately before oocyte pickup.

Participants/materials, setting, methods: Plasma and FF samples were quickly mixed with a protease inhibitor cocktail and stored at –80°C. Ang-(1–7) was quantified in plasma and FF samples by a highly sensitive and specific radioimmunoassay. FF Ang-(1–7) levels were stratified into tertiles and the patients of each tertile were compared for COS/IVF outcomes using Kruskal-Wallis analysis of variance. Multiple regression analysis was used to adjust correlations for potential confounders.

Main results and the role of chance: There was a fourfold increase in plasma Ang-(1–7) after ovulation induction (median 160.9 vs. 41.4 pg/ml, $p < 0.0001$). FF Ang-(1–7) levels were similar to (169.9 pg/ml) but did not correlate with plasma Ang-(1–7) levels ($r = –0.05$, $p = 0.665$). Patients at the highest FF Ang-(1–7) tertile had a higher proportion of mature oocytes compared to patients at the lower FF Ang-(1–7) tertile (median 100% vs. 70%, $p < 0.01$). There was a linear correlation between FF Ang-(1–7) and the proportion of mature oocytes ($r = 0.380$, $p < 0.01$), which remained significant after adjustment for age and duration of infertility ($r = 0.447$, $p < 0.001$).

Limitations, reasons for caution: This is an observational study, therefore no causal relationship can still be established between Ang-(1–7) and human oocyte maturation.

Wider implications of the findings: The present study shows for the first time that Ang-(1–7) levels in human FF correlate with the proportion of mature oocytes after ovarian stimulation for IVF. Since this peptide promotes oocyte maturation in other species, it deserves further investigation as a potential maturation factor to human oocytes.

Trial registration number: Does not apply.

P-470 An approach to calculate the number of MII oocytes required to guaranty IVF success in a fertility preservation programme

G. Perez-Bermejo[1], F.J. Prados Mondéjar[1], V. Santos[1], A. Díaz-Morales[2], A. Fuertes[2], I. Bruna[1]
[1]*Hospital HM Montepríncipe, HM Fertility Center, Boadilla del Monte, Spain*
[2]*Hospital HM Puerta del Sur, HM Fertility Center, Móstoles, Spain*

Study question: How many MII oocytes are needed to reach a reasonable likelihood of pregnancy in non-infertile women?

Summary answer: In good prognosis patients 7,7 MII oocytes were needed per implanted embryo and 9,1 per baby born.

What is known already: Oocyte vitrification for fertility cryopreservation is now frequent in IVF clinics. Patients need to be counseled about the probabilities of success as a function of the number of MII oocytes stored. The direct ratio of implanted gestational sacs per MII oocyte delivers a pessimistic message because infertile patient population is biased towards lower pregnancy results than in fertility preservation patients.

Study design, size, duration: The ratio of implanted gestational sacs with heart activity per MII oocyte was calculated in patients with at least one ongoing implantation in their IVF cycles. From 2006 to 2014 a total of 1608 own oocyte IVF cycles were included in the study. Only frozen embryo transfer performed before 2016 were analyzed.

Participants/materials, setting, methods: All cycles performed to women who underwent their first IVF treatment aged <40 years and achieved at least one ongoing pregnancy after fresh or frozen embryo transfer. The number of metaphase II oocytes in the 3.7% conventional IVF cycles of this study was calculated according to the MII/Total oocyte ratio in the ICSI cycles. This calculation together with the observed in ICSI cycles gave a total of 12.293 MII oocytes.

Main results and the role of chance: A total of 916 ongoing pregnancies were obtained after fresh embryo transfer and 387 after frozen embryo transfer. Overall the observed gestational sacs with heart activity were 1.588. The ratio of MII oocytes per gestational sac was 7.7. The number of babies born was 1.351 and the ratio of MII oocytes per baby born was 9.1. The remaining frozen embryos in this group of patients are 1.149 (68% of those already thawed), this can lower the ratio of MII oocytes needed for a successful outcome.

Limitations, reasons for caution: This is a retrospective study. The population of infertile patients undergoing IVF treatment is not comparable to fertile women who need to postpone their maternity, however, the patients included in this study, who obtained at least one pregnancy, are more likely to resemble the success likelihood of fertile women.

Wider implications of the findings: The data presented here can be a tool for counselling women who need to cryopreserve their fertility either for medical or social reasons. Another application of these results can be the quality control evaluation of oocyte wastage in relation to the stimulation regime of the clinic.

Trial registration number: NA.

P-471 Impact of thyroid autoimmunity on fertility outcome in IVF patients

M. De Brucker[1], D. Unuane[1], B. Velkeniers[1], S. Deridder[1], N. Polyzos[1], B. Bravenboer[1], H. Tournaye[1]
[1]*UZ Brussel, CRG, Jette Brussels, Belgium*

Study question: What is the effect of anti-thyroperoxidase antibodies on live birth rate after *in vitro* fertilisation?

Summary answer: No significant difference was seen in pregnancy-, delivery- or miscarriage rate between the TAI positive and TAI negative group.

What is known already: Currently available data support that it is reasonable to test TSH and anti thyroperoxydase antibodies in infertile women attempting pregnancy. However data regarding the outcome of fertility treatment in the presence of thyroid autoimmunity are conflicting and the optimal upper value of TSH in the presence or the absence of thyroid autoimmunity (TAI) remains debated.

Study design, size, duration: Cohort study. A two armed study design was performed: patients with TAI and patients without TAI. We included all patients who start their first IVF cycle in our center between January 2010 1st and 31 December 2014 with follow-up of outcome until 31 December 2015. Live birth delivery after 25 weeks of gestation is taken as the primary endpoint of our study.

Participants/materials, setting, methods: A total of 3254 patients underwent their first IVF/ICSI cycle between 01/01/2010 and 01/06/2014. Patients with clinical thyroid dysfunction were excluded, as were patients under treatment with levo-thyroxine or antithyroid drugs. Primary endpoint is the effect of TAI on live birth rate. Secondary endpoint is the effect of TSH on live birth rate, according to TAI status of patient.

Main results and the role of chance: After exclusion 3254 patients were finally included in the study. 340 had a TAI positive and 2914 a TAI negative status. There was no significant difference in mean age, BMI nor in AMH. Thyroid function revealed a significantly higher TSH level in the TAI positive group compared to the TAI negative group (2.01 vs. 1.72 mIU/L). Of the 340 patients in the TAI positive group 39% ($n = 134$) became pregnant. Of the 2914 patients in the TAI negative group 36% ($n = 1037$) became pregnant.

Chi squared testing did not show any significant difference ($p>0.01$) between the TAI positive and TAI negative group in respect to pregnancy-, delivery- or miscarriage rate. Moreover there was no significant difference in pregnancy-, delivery- or miscarriage rate when comparing subgroups according to TSH level (TSH ≥ 2.5 mIU/L vs TSH <2.5 mIU/L). Cox regression analysis in the TAI positive group, with live birth delivery as the outcome variable and age, fT4, TSH, BMI, smoking habits, ovarian reserve and type of stimulation as explanatory variables, indicated that thyroid function (TSH) did not influence delivery rate. Only age had a significant and independent effect on delivery rates.

Limitations, reasons for caution: Retrospective design of this study. Absence of region-specific reference ranges for thyroid hormones and the absence of follow-up of TSH values during ART and subsequent pregnancy.

Wider implications of the findings: Actually a lot of patients receive a treatment with thyroid hormones once the TSH is above 2.5 ml/L. We believe that overtreatment in this population can be avoided.

Trial registration number: n/a.

POSTER VIEWING SESSION

MALE AND FEMALE FERTILITY PRESERVATION

P-472 Prospective, multicentric study of AMH decay during chemotherapy for breast cancer treatment in 134 young women of reproductive age

F. Thomas[1], A. GALLAIS-UMBERT[2], P. Barriere[1], D. MASSON[2]
[1]CHU Nantes, Biologie de la Reproduction, Nantes Cedex 01, France
[2]CHU Nantes, laboratoire de biochimie, Nantes Cedex 01, France

Study question: The aim of the study was to describe serum AMH dynamics throughout chemotherapy (CT) in young women of reproductive age treated for breast cancer.
Summary answer: Serum AMH rapidly falls in young women treated for breast cancer with (neo)adjuvant chemotherapy.
What is known already: Serum AMH has been shown to be very low in women of reproductive age after CT treatment in various cancer types, including a few ones in breast cancer. While all studies are consistent in reporting such a fall in serum AMH levels after CT in breast cancer, most of them were conducted in women aged 40 or more on average, and very few of them performed a longitudinal follow-up of serum AMH during CT protocol.
Study design, size, duration: This observational, longitudinal, prospective, multicentric, cohort study was conducted between January 2010 and July 2011. Eligible patients were 18 to 39 years of age suffering from breast cancer treated with CT according to the FEC/T regimen (Fluorouracil, Epirubicin and Cyclophosphamide [cycles 1–3], Docetaxel [cycles 4–6]). Serum AMH concentration was measured at each chemotherapy administration using AMH/MIS (Beckman Coulter) according to the manufacturer's instructions. All assays were centralized in one lab.
Participants/materials, setting, methods: Women aged 18–39 years treated by FEC/T regimen in one of the 11 participating French Cancer Institutes (Unicancer network) were included. Women with serum AMH <0.42 µg/L (n = 6) or >7 µg/L (n = 25) on diagnosis were excluded from the subsequent analysis on AMH decay during CT. Prospective data (demographic, clinical, histological and menstrual data) were extracted.
Main results and the role of chance: A total of 92.7% of the patients were diagnosed with ductal carcinoma. On diagnosis, women were aged 35.3 ± 3.7 years on average. Mean serum AMH was 2.84 ± 1.64 ng/mL on diagnosis, and sequentially decreased to 1.63 ng/ml (49.2% relative decrease of initial level), 0.78 ng/ml (84.5% decrease) and 0.58 ng/mL (94%) after each FEC administration, followed by 0.50 and 0.46 ng/mL (96% decrease) after each Docetaxel administration. The proportion of patients with undetectable serum AMH rose from 7.4% after first FEC administration to 79.7% after the last Docetaxel administration. Overall, patients <35 years old presented with a slower initial AMH decrease rate than patients ≥35 years, respectively −39% vs. 55% after first FEC treatment and −78 vs −88% after second FEC treatment. On average, serum AMH became undetectable after 3 CT treatments in women <35 years and after 2 CT treatments in women ≥35 years. AMH decay rate was comparable in women with serum AMH<2 ng/ml on diagnosis and those with 2 < AMH <7 ng/ml. Amenorrhea was observed in 63.6% patients after completion of CT and Docetaxel. These patients were significantly older and had a faster AMH decay rate than those with persistent menstruation at the end of the treatment.
Limitations, reasons for caution: Although calibrated with human recombinant AMH, the ELISA method used suffers from a few technical limitations, such as relatively high functional sensitivity. Only women treated with FECT regimen were included in this analysis. Further analysis will be conducted in all patients, including those receiving other chemotherapy protocols.
Wider implications of the findings: This study brings new insights into the dynamics of chemotherapy-induced alteration of ovarian reserve and paves the way for the study of long-term evolution of AMH after treatment completion. This will help providing guidelines for the evaluation of ovarian reserve before CT onset and improve counselling on fertility preservation strategies.
Trial registration number: This trial has been registered in Clinicaltrials.gov database under the reference NCT01114464.

P-473 Ovarian response to controlled ovarian stimulation for fertility preservation before oncology treatment: A retrospective cohort of 128 patients

N. Tsampras[1], S. Roberts[2], R. Dongol[1], D. Gould[1], C.T. Fitzgerald[1]
[1]St Mary's Hospital, Reproductive Medicine Unit, Manchester, UK
[2]The University of Manchester, Institute of Population Health, Manchester, UK

Study question: Should women undergoing ovarian stimulation for fertility preservation expect a lower number of oocytes, compared to patients of a similar age with male-factor infertility?
Summary answer: Ovarian stimulation for fertility preservation, before cancer treatment, results in a similar number of oocytes retrieved compared with male-factor infertility patients of the same age.
What is known already: Several studies have failed to demonstrate a significantly different response to ovarian stimulation between infertility patients and those undergoing fertility preservation before cancer treatment. However, others have found a poorer response. The meta-analysis by Friedler et al in 2011 concluded that there was a poorer response to controlled ovarian stimulation (COS) by oncology patients undergoing fertility preservation treatment compared to patients undergoing COS for infertility treatment. More recently, a large, retrospective analysis by Almog et al showed that, compared to those with infertility, oncology patients responded equally well.
Study design, size, duration: Retrospective analysis cohort study comparing the number of oocytes retrieved by oncology patients (n = 128) undergoing COS for fertility preservation treatment between April 2009 and September 2015, to women undergoing COS for IVF/ICSI treatment for male factor infertility in the same centre and time period (n = 1978).
Participants/materials, setting, methods: All oncology patients treated between April 2009 and September 2015 were included. The control group consisted of patients undergoing COS, during the same time period, for male factor infertility. Yields were plotted against age for both groups along with LMS-derived control centiles. Age-specific Z-scores were derived and compared between groups. Linear regression on squre-root transformed oocyte yield with a cubic spline age covariate was used to estimate the difference in yield between groups.
Main results and the role of chance: The median (IQR) ages in the study and the control group were similar [32(27–34) vs. 32(29–35)]. 62 (48%) patients were diagnosed with breast cancer, 6 (5%) with an ovarian malignancy (including borderline) and 60 (47%) with other malignancies. The cancer patients (after adjusting for age) had a very similar distribution of oocyte yield to the control group (with a mean z-score = −0.03 (95% CI −0.25 to 0.19). There was no significant difference in the number of oocytes retrieved between the groups with 95% confidence intervals excluding differences greater than ~1 egg (mean age-adjusted difference 0.07, 95% CI (−1.0 to −1.2) oocytes). In contrast to previous studies, no significant influence of a cancer diagnosis to the ovarian response after COS was demonstrated. All 6 patients diagnosed with ovarian disease had a poor response, but due to the small number of patients, this did not reach statistical significance. No patients in the study group developed ovarian hyperstimulation syndrome (OHSS).
Limitations, reasons for caution: Limitations, reasons for caution: The study group was treated with a higher dose of gonadotrophins to maximise oocyte yield. The numbers for any particular malignancy or co-morbidity are too small to enable the detection of any sub-groups with poor response.
Wider implications of the findings: This is the largest reported cohort of patients treated in the same centre for fertility preservation before oncology treatment. The ovarian response in such patients is similar to that of controls undergoing treatment for male factor infertility. This information should be reassuring both for the patients and their treating physicians.
Trial registration number: N/A.

P-474 Highly sensitive assessment of neuroblastoma minimal residual disease in testicular tissue using RT-qPCR – A strategy for improving the safety of fertility restoration

V. GREZE[1], J. KANOLD[1], F. CHAMBON[1], P. HALLE[2], M. CANIS[3], A.S. GREMEAU[3], B. PEREIRA[4], L. JANNY[5], C. BOUCHE[5], A. TCHIRKOV[6], F. BRUGNON[5]

[3]CHU Clermont Ferrand, Gynécologie Obstétrique, Clermont-Ferrand, France
[4]CHU Clermont Ferrand, Direction Recherche Clinique, Clermont-Ferrand, France
[5]CHU Clermont Ferrand, Biologie de la Reproduction-AMP-CECOS, Clermont-Ferrand, France
[6]CHU Clermont Ferrand, Cytogénétique médicale, Clermont-Ferrand, France

Study question: Improvement of a method to detect minimal residual disease (MRD) of neuroblastoma (NB) in human testicular tissue.
Summary answer: The detection of *PHOX2B* mRNA by quantitative reverse transcriptase polymerase chain reaction (RTqPCR) enables sensitive and specific detection of neuroblastoma cells which may contaminate testis.
What is known already: Cryopreservation of testicular tissue is the only option to preserve fertility in prepubertal boys with NB. NB is the most common extracranial solid tumor in children and affects typically infants and has a high dissemination potential. Testicular tissue may contain malignant cells which could lead to recurrence of the primary disease if the tissue is used after to restore fertility. High levels of *TH* (Tyrosine Hydroxylase), *PHOX2B* (Paired-Like Homeobox 2b) and *DCX* (Doublecortin) transcripts in bone marrow and blood at diagnosis and at the end of induction treatment were recently shown to be poor prognostic factors in NB patients.
Study design, size, duration: Detection of residual disease was performed on fresh and frozen testicular tissues from 20 men with azoospermia between November 2014 and September 2015 by RT-PCR after contamination by increasing amount of two cell lines of NB.
Participants/materials, setting, methods: Written informed consent was obtained for inclusion of any testicular sample from these patients in the Germetheque Biobank (ethical committee DC-2008-558). Frozen testicular tissues by slow freezing (n = 10) with cryoprotectant (DMSO) or by snap freezing in liquid nitrogen (n = 10) were contaminated by increasing amount (0, 10, 100, 1000 cells) of two human neuroblastoma cell lines (IMR-32 and SK-N-SH) before detection of *TH*, PHOX2B and *DCX* transcripts by RTqPCR. All measurements were performed in duplicate.
Main results and the role of chance: *TH* and *DCX* transcripts were detected in uncontaminated testicular tissues. *PHOX2B* was not detected in any uncontaminated testicular fragment (n = 20). We observed a positive correlation between the expression level of *PHOX2B* transcripts and the amount of contaminating cells. The weight of the testicular tissue and the freezing mode (with or without cryoprotectant) had no impact on the expression levels. *PHOX2B* is a reliable marker of NB cells contaminating testicular tissue and can be used for molecular diagnosis of residual disease in testis of prepubertal boys with NB. In contrast, *TH* and *DCX* are expressed in uncontaminated testicular tissue and are therefore unlikely to be useful for performing diagnostics in this setting.
Limitations, reasons for caution: NB transcripts detection confirms the presence of malignant cells, but can not predict their metastatic potential. Nevertheless, it would be unethical to use testicular tissue in which tumor cells are present. Our results need to be confirmed by the analysis of testis providing from boys with NB.
Wider implications of the findings: Our study is the first work to evaluate MRD detection using NB mRNAs in human testicular tissue. These results offer hope in the near future to use testicular tissue without oncological risk in men who survive NB, whose fertility has been jeopardized, and who have benefited from testicular tissue cryopreservation.
Trial registration number: NCT 02400970 (Clinical Trial).

P-475 Male fertility preservation outside reprotoxicant treatments: indications, use rate and ART outcome in 1,966 patients

J. Perrin[1], A. Papaxanthos-Roche[2], M. Daudin[3], *N*. Rives[4], J. Bessonnat[5], S. Hennebicq[6], M. Paci[7], G. Karsenty[8], B. Courbiere[9], C. Metzler-Guillemain[7], J. Saïas-Magnan[10]

[9]CHU La Conception AP-HM, Centre clinico-biologique d'assistance médicale à la procréation, Marseille, France
[10]CHU La Conception AP-HM, CECOS-Centre clinico-biologique d'assistance médicale à la procréation, Marseille, France

Study question: What are the indications and straw utilization rates of male fertility preservation outside reprotoxicant treatments?
Summary answer: The main indications were: risk of semen parameters decline, ejaculation disorders and pre-vasectomy; The overall straw utilization rate was 12.9% of patients.
What is known already: The vast majority of autologous sperm banking activity is performed in patients receiving gonadotoxic treatments (mainly cancer therapy); in large cohorts, the reported straw utilization rate is lower than 10% of patients. To our knowledge, very few data are available about male fertility preservation (FP) outside reprotoxicant treatments (ORT), generally obtained from monocentric and small sample studies.
Study design, size, duration: Multicentric retrospective cohort study in 5 centers of the French national sperm banking network (CECOS). Among the global sperm banking activity (10,508 patients), we included 1,966 patients who banked sperm for FP-ORT between 2000 and 2010. We excluded patients who banked sperm: (i) before gonadotoxic treatment (for cancer or other); (ii) before ART in a context of azoospermia, viral risk, oocyte donation, semen collection failure or personal convenience; (iii) with incomplete data.
Participants/materials, setting, methods: We analyzed: (i) the evolution of FP-ORT indications between 2000 and 2010; (ii) the proportion of FP-ORT indications among the global sperm banking activity. We recorded the straws characteristics, the rate of patients who subsequently used their straw for ART (until 2013), the delay between sperm banking and straw utilization, the number of straws used for ART, ART type and outcome.
Main results and the role of chance: Male FP-ORT increased from 10 to 22% of overall FP indications between 2000 and 2010. The indications of FP-ORT were classified as 6 groups: a) risk of semen parameters decline (RSPD, 59% patients), including sperm concentration fluctuations, severe oligoasthenoteratospermia (OATS) associated to abnormal hormonal and/or genetic examination (Y chromosome microdeletions, Klinefelter syndrome); (b) ejaculation disorders (17%), including spinal cord injury and diabetes; (c) pre vasectomy (14%); (d) surgical risk (6%) (before a surgery at risk for retrograde ejaculation or testicular function); (e) monorchidism (2.4%) (congenital & acquired etiologies); (f) post treatment (1.8%) (antibiotherapy, varicocele surgery).

Between 2000 and 2013, 12.9% (255/1966) of overall patients used their banked sperm for ART treatment (mean ± SD period of banking before use = 1.6 ± 0.6 year): 27% (89/327) of patients with ejaculation disorders, 14% (158/1161) of patients with RSPD, 0.4% (1/275) of patients with vasectomy. ART treatments included 488 cycles: 430 ICSI (88% of cycles), 15 IVF (3%) and 43 IIU (9%). A mean ± SD number of 3.6 (±4.1) straws/patient was used for ART treatments, which only represents 21% (935/4350) of available straws. ART led to an overall pregnancy rate of 28.4%/cycle, and to the birth of 112 children.
Limitations, reasons for caution: As straw utilizations were recorded until 2013, straw utilization rate could be underestimated for the patients who banked sperm in the last years of the study period.
Wider implications of the findings: Increase of FP-ORT indications in daily practice of sperm banking. Utilization rates higher than in cancer patients. Some indications seem particularly justified (ED, RSPD). Low rate of available straws used for ART treatments: what is the ideal amount of straws to bank?
Trial registration number: None

P-476 Telomerase length in granulosa cells and lymphocytes of women recently diagnosed with cancer

M. Martinez[1], M. Gallardo[2], S. Rabadan[1], L. Herrero[3], A. Pacheco[3], J.A. Garcia-velasco[1]
[1]IVI Madrid, MD, Madrid, Spain
[2]Centro Nacional De Investigaciones Oncologicas Cnio, PhD, Madrid, Spain
[3]IVI Madrid, PhD, Madrid, Spain

Study question: Is cancer – as a systemic disease – already damaging human ovarian granulosa cells due to telomerase shortening?
Summary answer: The lower ovarian response observed cannot be explained by a telomeric shortening that would suggest a systemic damage of the oncologic disease.
What is known already: The impact of oncologic therapies on fertility outcome is well known, as they may induce irreversible changes in the gonads in at least one third of the patients, affecting future fertility potential. For these reasons, fertility preservation has become a priority for young women with cancer. Interestingly, this group of young women suffering from cancer shows a lower response to ovarian stimulation, even prior to their chemo- or radiotherapy.
Study design, size, duration: Prospective, experimental study.
Participants/materials, setting, methods: we evaluated 24 patients recently diagnosed with cancer that requested fertility preservation and 25 oocyte donors as controls. Ovarian stimulation we performed with recFSH and GnRH antagonist along with letrozole in hormone dependent cancer. Telomeric length was measured in both granulosa cells and peripheral blood (lymphocytes) by quantitative (Q)-FISH, by marking telomeres of interphase nuclei and hybridizing with telomeric repetitions (Cy3).
Main results and the role of chance: We did not observe differences in the telomeric length between cancer patients and controls. When evaluating granulosa cells, mean% of telomere shortening in cancer patients was 13.9 kb (4.7–42.7) whereas in healthy controls was 17.1 kb (4.6–32.8), $p = 0.7$; when peripheral blood was analysed, mean shortening of telomeres was 18.1 kb (4.2–40.6) in cancer patients vs 17.4 kb (6.1–32.3) in healthy patients.
Limitations, reasons for caution: The lack of association between telomere length and ovarian response does not rule out that some of these young women recently diagnosed with cancer do not respond to gonadotropins as expected, may be due to other pathways.
Wider implications of the findings: Although we know today that cancer is a systemic disease with a local origin, we could not confirm that the lower ovarian response to gonadotropin stimulation observed in some women diagnosed with cancer was due to a shorter telomere length, as a reflection of advanced aging due to cancer.
Trial registration number: PI11/02747.

P-477 Transport and handling of oocytes after vitrification in a closed vitrification system (Rapid-i): Proposal for and implementation of a standard validation procedure

A. Ullm[1], B. Roßmann[1], A. Markus[2], A. Rayß[1], M. Freund[3], R. Naumann[4], M. Montag[5]
[1]*Seracell AG, Marketing, Berlin, Germany*
[2]*Seracell AG, Herstellungsleiter, Rostock, Germany*
[3]*Seracell AG, Geschäftsführer, Rostock, Germany*
[4]*MPI of Molecular Cell Biology and Genetics, Head of the Transgenic Core Facility, Dresden, Germany*
[5]*Ilabcomm GmbH, Geschäftsführer, Sankt Augustin, Germany*

Study question: Can one establish and validate a protocol for handling and transportation of mouse oocytes after vitrification in a closed vitrification system using quality control measures?
Summary answer: Vitrification of oocytes in a closed system and in particular subsequent transportation is safe and reliable but should be shown by a strict validation protocol.
What is known already: Vitrification of metaphase-II-oocytes has opened a new era in the field of fertility preservation. An important aspect of cryobanking of vitrified oocytes is the safety of transportation and handling of vitrified samples. Any increase in the temperature during transportation, storage or handling above a certain threshold will inevitably damage or even destroy oocytes/embryos. This risk an eventually occur when using dry shippers for transportation. Currently there is no international standard regarding the validation of transportation and handling conditions.
Study design, size, duration: After vitrification in a closed vitrification system (Rapid-I, Vitrolife), mouse oocytes were shipped over night to another cryobank, stored in another tank and transported back. Temperature was continuously logged at all stages of handling and transportation. Controls were kept in one cryobank and not shipped. For shipped oocytes and controls the survival after warming as well as fertilization and cleavage rates after ICSI were assessed.
Participants/materials, setting, methods: 16 vitrification experiments were performed, and for each experiment 12 mouse oocytes were vitrified on four Rapid-i straws (Vitrolife, Sweden). Oocytes from 8 vitrification experiments were independently transported back and forth from one cryobank to another using a dry shipper (MVE or Lab-Tec) equipped with temperature logging (Log 100/110 or Testo 176-T4). Oocytes were warmed according to protocol, subjected to ICSI and cultured.
Main results and the role of chance: In eight transportation experiments no adverse events with transportation or handling during loading/unloading of the transportation devices were noted. In all transportation experiments the logged temperature profile was below −150 degrees, which was taken as the highest acceptable limit for the upper temperature. The temperature profile during storage in the receiving cryobank showed a steady storage temperature at −185 degrees or below. After warming of oocytes, survival rates were not different between the control and the study group (90/96, 93.8% and 93/97, 95.9%, respectively). In-vitro fertilization with frozen/thawed mouse sperm resulted in a fertilization rate of 78.1% in the control group and 84.5% in the study group and all oocytes cleaved. Results were not significant for survival and fertilization rates.
Limitations, reasons for caution: This study was performed with mouse oocytes and results need to be validated for human oocytes. Study results only apply to the devices used and other devices may require independent validation by using a similar or adapted protocol.
Wider implications of the findings: Vitrification of oocytes is increasingly performed in human IVF. Although vitrification is accepted as a standard of care for cryopreservation of oocytes, transportation and handling of vitrified oocytes requires special precaution as even minor mistakes can cause complete damage. The validation protocol presented may serve as a standard validation protocol.
Trial registration number: Not applicable.

P-478 Time between exposure to first line of chemotherapy and oocyte retrieval for fertility preservation: cytotoxicity and genotoxicity assay of cytarabin and daunorubicin on mouse ovaries

E. Balenbois[1], V. Tassistro[1], C. Marc[1], V. Achard[2], R. Castellano[3], Y. Collette[3], J. Perrin[4], B. Courbiere[4]

[3]*Centre de Recherche en Cancérologie de Marseille CRCM, Inserm UMR 1068- Institut Paoli-Calmettes, Aix Marseille Université UM 105, CNRS UMR 7258, 13, Marseille, France*
[4]*Pôle Femmes-Parents-Enfants- Centre Clinico-biologique d'AMP- AP-HM-Hôpital de La Conception, 13, Marseille, France*

Study question: Do cytarabin and daunorubicin induce genotoxicity in mouse oocytes of non-growing and antral follicles exposed, and if so, is oocyte able to repair DNA damage?
Summary answer: Cytarabin and daunorubicin did not induce follicle loss. DNA damage was significant in mature oocytes 6 days and 4 weeks post-exposure but dropped at 12 weeks.
What is known already: Hematological disturbances of acute leukemia and the emergency to start chemotherapy do not allow a cryopreservation of ovarian tissue or oocytes at the time of diagnosis. Cryopreservation of ovarian tissue is currently discussed because of the risk of contamination by leukemic cells and the risk of relapse if reintroduction of malignant cells able to proliferate after ovarian transplantation. In acute leukemia, cryopreservation of mature oocytes after ovarian stimulation could be proposed, but would be performed after a first line of chemotherapy. Genotoxic risks of cytarabin and daunorubicin on oocyte DNA are currently not well known.
Study design, size, duration: Two groups of female CD1 mices aged 4 weeks were exposed for four days to cytarabin ($n = 32$) twice a day (10 mg/kg IP) or every 2 days to daunorubicin ($n = 32$) (1 mg/kg IV). Each group was compared with none-exposed ($n = 32$). In each group, three sub-groups of mice were stimulated respectively 6 days, 4 weeks and 12 weeks post-exposure to retrieve mature oocytes, whole ovaries in order to study chemotherapy effects at different stages of follicle maturation.
Participants/materials, setting, methods: Cytotoxicity was assessed by the number of mature oocytes retrieved, the cytological analysis of oocytes and the

histology of ovaries with quantification of intra-ovarian follicles. DNA damage was assessed by: (*i*) alkaline comet assay to quantify the tail DNA in mature oocytes (*ii*) fluorescent immunohistochemical staining in ovarian tissue sections to quantify accumulating γH2AX foci (expressed as corrected total cryosection fluorescence). The differences between the exposed and non exposed groups were assessed using ANOVA.

Main results and the role of chance: Cytarabin and daunorubicin did not induce a significant intra-ovarian follicular loss and had no impact on ovulation: superovulation was obtained in all mice 6 days, 4 weeks and 12 weeks post exposition and did not differ from control groups. Concerning intra-ovarian follicles, γH2AX foci were significantly increased 6 days, 4 weeks and 12 weeks post exposition compared to none-exposed mice. Binocular analysis did not observe differences of metaphase II oocyte morphology between exposed groups and negative control group. The tail DNA rate was significantly increased in mature oocytes after mice exposure to cytarabin and daunorubicin, compared with the none-exposed 6 days mice (respectively for cytarabin and daunorubicin: 10.7 ± 1.1 and 17.7 ± 1.2 vs. 7 ± 1, $p < 0.0001$) and the non-exposed 4 weeks mice (respectively 15.6 ± 0.8 and 14.2 ± 1 vs. 8 ± 1, $p < 0.0001$. Twelve weeks after cytarabin and daunorubicin exposure, DNA damage was no significantly different in mature oocytes between exposed groups and control group.

Limitations, reasons for caution: Mouse oocyte DNA is not exactly similar to human oocyte DNA, and would be more sensitive to genotoxic effects of chemotherapy agents. The kinetic of oocyte DNA repair post –chemotherapy exposure has to be studied by further assays.

Wider implications of the findings: Despite a good ovulation, DNA damage was observed in mature oocytes 6 days and 4 weeks after exposure to cytarabin or daunorubicin. Twelve weeks post exposure (i.e., after 4 cycles of mouse folliculogenesis), decrease of DNA strand breaks to normal levels let us hypothesis DNA repair mechanisms in non-growing follicles.

Trial registration number: Experimental protocols and animal handling procedures were reviewed and approved by Local Ethics Committee on Animal Experimentation.

P-479 Immature oocyte retrieval followed by *in vitro* maturation (IVM) and vitrification in combination with laparascopic ovarian tissue cryopreservation (OTCP) for fertility preservation: UK pilot study

C. Ross[1], K. Turner[1], T. Child[1], J. Davies[2], C. Becker[1], M. Fatum[1]
[1]*Institute of Reproductive Sciences, Oxford Fertility, Oxford, UK*
[2]*Oxford Heart Valve Bank, University of Oxford, John Radcliffe Hospital, Oxford, UK*

Study question: To study the feasibility of oocyte retrieval, *in vitro* maturation (IVM) and subsequent vitrification of mature oocytes in oncology patients undergoing ovarian tissue cryopreservation (OTCP) for fertility preservation

Summary answer: The pilot study revealed that IVM of immature oocytes followed by vitrification could be successfully achieved in some oncology patients undergoing OTCP

What is known already: Previous studies in Europe, USA and Israel have already shown that the combination of ovarian tissue cryopreservation and immature oocyte retrieval followed by vitrification is a feasible option, irrespective of the phase of menstrual cycle or age of the patient. This is the first time this approach has been attempted in the UK in both paediatric and adult patients to try to maximise fertility preservation with a patient as young as 2 years of age.

Study design, size, duration: Prospective cohort pilot study from 2013 to 2015 of 23 oncology patients, both paediatric and adult, age range 2–31. Laparoscopic immature oocyte retrieval and removal of ovarian tissue for cryopreservation was scheduled at the time of insertion of the Hickman line, to avoid the patient undergoing multiple procedures.

Participants/materials, setting, methods: Patients undergoing laparoscopic ovarian tissue harvesting before cancer therapy were offered immature oocyte retrieval. Oocytes were retrieved by three methods: *in situ* percutaneous video-assisted oocyte retrieval for those patients undergoing ovarian cortical strip resection (rather than oophorectomy), *ex-situ* puncturing of the excised ovary and removal of the fluid remnants post dissection and tissue processing of the ovarian tissue. Oocytes were then matured *in vitro* using standard IVM methodologies and any resultant mature oocytes vitrified.

Main results and the role of chance: Of the 23 patients who participated in the pilot study, 15/23 (65%) were paediatric (age 2–17) and 8/23(35%) adults (age 22–31). Successful immature oocyte retrieval was achieved in 78% of the patients, 80% in the paediatric v 75% in the adult group, with the majority of the oocytes being isolated from the dissection remnants (61%). A total of 140 oocytes were collected, of which 57 (41%) were degenerate and therefore non-viable. Of the remaining 83 oocytes, 40 reached metaphase (MII), giving a maturation rate of 48% following 24–48 h in IVM culture. The remaining 43 (52%) arrested at germinal vesicle (GV) stage. All metaphase II oocytes were subsequently vitrified. Vitrification of mature oocytes was achieved in 60%(9/15) of the paediatric patients (range 1–5), the youngest of which was aged 2 (1 frozen), which to the best of our knowledge is the youngest patient to date, in comparison to 38% (3/8) in the adult group.

Limitations, reasons for caution: None of the oocytes vitrified in this study have been thawed and therefore their viability remains unknown. Also, due to restrictions in both the timings and collection methods of the oocytes the quality of the oocytes may be compromised as the main priority was OTCP.

Wider implications of the findings: This pilot study showed that immature oocytes can be successfully harvested/matured and vitrified from both antral follicles and excised tissue in both paediatric and adult patients undergoing OTCP. This is in accordance with other published studies. However, this study has also demonstrated freezing for the youngest patient to date.

Trial registration number: Not applicable.

P-480 Oncofertility: Optimum transport conditions for ovarian tissue cryopreservation prior freezing

R. Dittrich[1], L. Lotz[1], S. Findeklee[1], I. Hoffmann[1], M.W. Beckmann[1]
[1]*University Erlangen, Department of Ob/Gyn, Erlangen, Germany*

Study question: Which is the optimal transport temperature for ovarian tissue and how long could the tissue be transported prior cryopreservation without disturbing viability?

Summary answer: This study provides evidence that storage at 4°C is superior to warm transport (38°C). Storage duration should be limited to a minimum to prevent potential damage.

What is known already: Cryobanking with transportation of ovarian cortex before cryopreservation is clinically used to make the option accessible to patients in regions in which a fertility centre with the required facilities and skills is not available. It is a useful option for patients with serious illnesses in whom the start of treatment cannot be postponed and who therefore may not wish to move from one center to another, or may not be able to. However data about transport conditions of ovarian tissue in general are limited. Further investigations on this field are necessary immediately to clearly guarantee the ovarian tissue viability.

Study design, size, duration: The aim of this prospective controlled animal study was to evaluate the rate of follicle loss over various time periods within temperature treatment of 4°C and 39°C and to assess whether ovarian follicle viability is affected following cryopreservation and thaw subsequent to the transportation of ovarian tissue by using markers of tissue viability. To address this aims, pig ovaries were utilized because pigs have been demonstrated to be an appropriate model for human reproductive biology.

Participants/materials, setting, methods: Pig ovaries were transported either at 4°C ($n = 20$) or at 38°C ($n = 20$) prior to cryopreservation. At 0 h, 4 h, 12 h and 24h ovarian tissue (same size $6 \times 4 \times 1$ mm) were fixed for histological examination. At the same time point's ovarian tissue were cryopreserved with a slow-freezing procedure and analyzed after thawing. Furthermore viability testing in SCID mouse transplantation model ($n = 120$) and a LIVE-DEAD assay were performed.

Main results and the role of chance: Histological evaluation showed an intact morphology in the fresh and cryopreserved ovarian tissue pieces at 4°C and at 39°C over the transportation time. The follicle reserve (primordial and primary follicles) decreased significantly in a time-dependent manner. The follicles in the cryopreservated ovarian tissue decreased statistically significantly in both storage groups compared with fresh ovarian tissue. At 39°C a significantly higher follicle loss over the transport duration was observed in comparison with 4°C ($p < 0.018$). At 4°C temperature, the Live Dead assay showed that the number of viable follicles remained approximately constant over the transport time up to 24 h (mean: 78% live cells). At 39°C the number of viable follicles was significantly reduced after 24 h (mean: 27% live cells) compared to the time point 0 h (mean: 82% live cells). Morphological quality and the number of follicles decreased in ovarian tissue that had been xenotransplanted in SCID mice in a time-dependent manner and were even poorer

if the tissue was cryopreserved after storage in comparison to fresh stored ovarian tissue. At 4°C follicle atresia was not significant over the transportation time, however at 39°C a significant follicle loss after 12 h transportation could be detected ($p < 0.4$).

Limitations, reasons for caution: In this study pig ovarian tissue was used. Further studies with human ovarian tissue need to evaluate the effect of temperature, duration and media during transportation and establish the present method as a full - scale clinical application. Since ovarian cryopreservation and transportation is increasingly used, further studies are urgently needed.

Wider implications of the findings: Prolonged tissue transportation must not be considered a routine and transportation durations should be kept at a minimum to prevent potential damage. In individual cases, where otherwise ovarian tissue cryopreservation could not be offered, prolonged transportation at 4°C could be performed, as the follicle loss is modest as shown.

Trial registration number: None.

P-481 Fertility preservation public program. Is it worthwhile?

A.B. Rodriguez Bujez[1], G. Marcos García[2], B. González Soto[3], Y. Pascual Arévalo[1], A.M. Muñoz Ledesma[1], E. Mancha Heredero[1], M. García-Yuste González[1], A.M. Arnal Burró[1], S. Del Olmo Bautista[1], A. Álvarez González[1], M. Azpeitia Rodríguez[1], G.G. Ledesma Saavedra[1]

[1]Hopital Universitario Rio Hortega, Human Reproduction Unit. Gynaecology and Obstetrician Department., Valladolid, Spain

[2]Hopital Universitario Rio Hortega, Medical Oncology Department., Valladolid, Spain

[3]Hopital Universitario Rio Hortega, Embriology, Laboratoty of Human Reproduction Unit, Gynaecology and Obstetrician Department, Valladolid, Spain

Study question: To evaluate first three yers of development of a fertility preservation (FP) public program and to analise the impact of the formation activities towards professionals who attend oncologycal patients.

Summary answer: Patients with malignant disease who undergoing FP techniques have risen.

There are important gender disparities in FP.

Information from health care providers is essential.

What is known already: For many young cancer survivors, the ability to have biological children is a significant goal and concern. FP has being used routinely for relatively few years and there is still a gap in knowledge about the performance of the technique in the future when female patients come back to use their oocytes. Vast majority of men use sper banking.

Despite the ASCO guidelines, many cancer patients do not receive enough information about FP.

On the other hand, females paid more for FP than males.

Study design, size, duration: Observational and retrospective study from 2013 to 2015 in a Spanish region over 1 million of habitants.

Male and female patients who attended for FP are included. All cases have medical indications (oncological and no oncological) for FP.

Participants/materials, setting, methods: A total of 69 male and female patients were enrolled in this observational study since we started the FP program three years ago.

Patients were submitted from oncologist or other specialist to Human Reproduction Unit.

We analyse the follow questions: number of patients who receive information for FP, number of patients who undergo FP techniques, techniques employed and number of patients that return to use their gametes.

Main results and the role of chance: From 2013 to 2015, we attended 69 patients (20 women and 49 men) who asked about FP options. Most prevalent female indication were breast cancer (64.28%) and Hodgkin disease (14.28%). Male indications were testicular tumors (61.22%), hematological diseases (36%) and chromosomal disorders (2.04%).

62 of all of them (89.85%) opted to undergo treatment. There were significant differences between female (70%) and male (98%) percentages. Women's reasons for not undergoing FP were lack of time to complete controlled ovarian hyperstimulation and lack of oncologist's agreement. Techniques employed were oocyte vitrification as first option or embryo preservation (if there was low number of oocytes and partner's agreement). Ovarian cortex preservation and ovarian transplantation are not legally allowed in our hospital.

All of men used sperm banking.

So far, no one, male or female, has returned to use their gametes or embryos.

Limitations, reasons for caution: Not enough time has elapsed to evaluate the cost effectives results of FP techniques, but the simple fact of undergoing FP improves the patient's experience with oncological treatments. Future studies could examine the reasons physicians are less likely to adress FP with women (higher costs and the time needed).

Wider implications of the findings: We should inform oncologists about referring patients to specialists in FP in a timely manner.

FP for oncological reasons seems out of question, but it needs to be clearly specified which women may benefit from FP. Recommendations should be individualized.

More studies are needed to evaluate results (new borns) from FP techniques.

Trial registration number: Present study is not a clinical trial.

P-482 Topical high concentration of anti-Müllerian hormone prevents follicle activation and loss caused by chemotherapy *in vivo*

S.J. Tan[1,2], C.H. Chen[1], C.R. Tzeng[1]

[1]Taipei medical university hospital, Center for Reproductive Medicine, Taipei, Taiwan, R.O.C.

[2]Taipei Medical University, College of Medicine, Graduate Institute of Clinical Medicine, Taipei, Taiwan, R.O.C.

Study question: Does anti-Müllerian hormone (AMH) prevent cyclophosphamide (Cy)-induced follicle activation and loss?

Summary answer: AMH prevents follicle activation and loss caused by Cy in mice.

What is known already: Chemotherapeutic regimens can damage the reproductive system and lead to infertility and premature ovarian failure. AMH, which is produced by the granulosa cells of growing follicles, can inhibit primordial follicle activation and follicle growth stimulated by follicle-stimulating hormone.

Study design, size, duration: It was an *in vivo* study, in which twenty-four mice were randomly divided into three groups: control ($n = 6$), Cy ($n = 6$) and AMH + Cy ($n = 12$). Examinations of ovaries were performed 7 days later.

Participants/materials, setting, methods: In the Cy group, six seven-week old ICR female mice treated intraperitoneally with Cy (150 mg/kg). Mice in the AMH + Cy group received intrabursal injection of low-dose recombinant AMH (1 μg/mL, left ovary) and high-dose recombinant AMH (10 μg/mL, right ovary), followed by Cy treatment 1 h later. Follicle counting, immunohistochemical analyses and mRNA levels of follicle stage-specific markers were performed after removal of ovaries.

Main results and the role of chance: In the Cy-treated ovaries, the number of primordial follicles was decreased significantly. Mice pretreated with recombinant AMH had more primordial follicles than those in the Cy group ($P < 0.05$) with dose-dependent effects. The results were compatible with the mRNA levels of Lhx8 and Nobox, indicating that recombinant AMH prevented the recruitment of follicles triggered by Cy.

Limitations, reasons for caution: The inconsistency between models might reflect different ovarian responses to different manipulations. The best dosage and time to treatment and examinations were still undetermined.

Wider implications of the findings: We first demonstrated that pretreatment with topical high concentration of recombinant AMH inhibited follicle activation and preserved more follicles *in vivo*. This preliminary report showed its therapeutic potential in oncofertility. The protective efficacy still needs more investigation.

Trial registration number: Not available.

P-483 Novel extracellular-like matrices and leukemia inhibiting factor for the *in vitro* culture of human primordial follicles

R. Abir[1], A.J. Younis[2], G. Lerer-Serfaty[3], D. Stav[4], B. Sabbah[5], G. Kessler-Icekson[6], M.A. Zahalka[6], M. Shachar[7], A. Ben-Haroush[4], B. Fisch[4]

[1]Rabin Medical Center and Tel Aviv University, IVF and Infertility Unit- Beilinson Women Hospital, Petach Tikva and Tel Aviv, Israel

[2]Rabin Medical Center and Tel Aviv University, Beilinson Women Hospital- IVF and Infertility Unit, Petach Tikva and Tel Aviv, Israel

[3]Rabin Medical Center and Tel Aviv University, Beilinson Women Hospital IVF and Infertility Unit, Petach Tikva and Tel Aviv, Israel
[4]Rabin Medical Center and Tel Aviv University, Beilinson Women Hospital and IVF and Infertility Unit, Petach Tikva and Tel Aviv, Israel
[5]Rabin Medical Center, Helen Schneider Women's Hospital IVF and Infertility Unit, Petach Tikva, Israel
[6]The Felsenstein Medical Research Center, Tel Aviv University, Petach Tikva, Israel
[7]Sami Shamoon College of Engineering, Department of Biotechnology, Beer-Sheva, Israel

Study question: Will novel culture matrices and leukemia inhibiting factor (LIF) improve development of human primordial follicles?
Summary answer: Human recombinant pure plant-line bioengineered collagen (Collage™) and alginate scaffolds seem to marginally improve culture results. LIF does not promote growth of human primordial follicles.
What is known already: Human recombinant vitronectin (hrVit), a matrix protein, promoted proliferation of human embryonic stem cells. Small intestine submucosa (SIS) (Cook Biotechnology), is a natural polymer that promoted growth of various cell types. Human recombinant collagen from bioengineered tobacco plant lines (Collage) does not pose any animal-derived pathogen hazards, and promoted proliferation of various cell types. Alginate scaffolds are biocompatible, allow efficient transport between cells, and have been used successfully to grow various cell types including human ovarian primordial follicles.

LIF increased growth of primordial follicles from rodents and goats. LIF and its receptors were detected in preantral follicles from women.
Study design, size, duration: Frozen-thawed human ovarian samples from 28 women/girls were utilized for the study. In the first part, tissue was cultured on hrVit and on SIS with: basic culture medium (α minimal essential medium + human serum albumin + insulin, transferrin, selenium + FSH) alone, basic culture medium + LIF or + LIF + anti-LIF neutralising antibody. In the second part, tissue was cultured on Collage and on alginate scaffolds with basic culture medium alone. Samples were cultured for six days in both parts of the study.
Participants/materials, setting, methods: Ovarian tissue was obtained from 28 women/girls who underwent ovarian cryopreservation in a tertiary medical center. Initially, tissue was cultured on hrVit and on SIS with: basic culture medium, basic culture medium + LIF (10 and 100 ng/ml) or basic culture medium + LIF (10 ng/ml) + anti-LIF antibody (1 mg/ml). Thereafter, tissue was cultured on Collage and on alginate scaffolds with basic culture medium alone. Growth was evaluated by follicular counts and classification, Ki67 immunohistochemistry and 17β-estradiol (E_2) and anti-Mullerian hormone (AMH) measurements.
Main results and the role of chance: There were significantly more Ki67-stained follicles on Collage and alginate than on hrVit and SIS, without LIF supplementation ($P < 0.0001$). E_2 levels were significantly higher after culture on Collage and alginate than on hrVit and SIS, without LIF supplementation ($P < 0.0003$).

The rest of the comparisons were nonsignificant. In the first part, samples incubated with basic culture medium had a higher developing (primary and secondary) follicle rate than primordial follicles, regardless of matrix (NS). Samples cultured on SIS or hrVit with LIF (both concentrations) and LIF + anti-LIF had a higher atretic follicle rate than samples cultured with basic medium alone, regardless of matrix (NS). Moreover, samples cultured on SIS or hrVit with LIF (both concentrations) and LIF + anti-LIF had a lower follicle rate than samples cultured with basic medium (NS), regardless of matrix. In the second part, there were more atretic follicles ($P = 0.06$), but also developing follicles in samples cultured on alginate than on Collage (NS). The differences in AMH secretion from follicles by culture matrix or by LIF supplementation were nonsignificant.
Role of chance: There is a variability in follicular distribution in human ovaries, which might have contributed to the initial low follicular content in cultured slices resulting in nonsignificant results.
Limitations, reasons for caution: There is a limited availability of human tissue for research. Therefore, only seven samples were used in parallel in both study parts. The variability in the initial follicular content between the different samples (between individual patients and between different samples from each patient) might have resulted in mostly nonsignificant results.
Wider implications of the findings: Unlike findings in other mammals, growth of human primordial follicles is not enhanced by LIF. Collage and alginate seem associated with marginally improved results than SIS and hrVit. Further studies should be conducted to investigate other matrices and additional growth factors and substances for growth promotion of human primordial follicles.
Trial registration number: This not a clinical study. Therefore, there is no trial registration number.

P-484 The effects of the cancer drug Cyclophosphamide on mouse fertility

M. Koike[1], Y. Kumasako[1], E. Otsu[1], Y. Kai[2], H. Itoh[3], F. Kawabe[4], Y. Araki[5], Y. Araki[5], T. Utsunomiya[4]
[1]St.luke clinic, Laboratory, Oita, Japan
[2]Oita University Faculty of Medicine, Obstetrics and Gynecology, Oita, Japan
[3]Fukuoka University Faculty of Medicine, Obstetrics and Gynecology, Fukuoka, Japan
[4]St.luke clinic, Department of Ob/Gyn, Oita, Japan
[5]Advanced Reproductive Medical Technology, director, Maebashi, Japan

Study question: To examine the effects of a cancer drug on ovarian function and maternal behavior
Summary answer: Cancer drugs negatively affect ovarian function (up to 2 month post-administration) and maternal behavior.
What is known already: According to studies on female rats, the teratogenetic action of fetus or embryonic death has been reported when cyclophosphamide has been administered.
Study design, size, duration: Study1: This is a cross-sectional, longitudinal study in which female mice were treated one time with a cancer drug and then mated: 0 h group $n = 10$; 2 weeks (post drug treatment) $n = 10$; 1 month $n = 16$; and 2 month $n = 2$, (control $n = 11$).

Study2: A cross-fostering experiment in which 7 female mice were treated with a cancer drug and immediately mated. The treated mothers and the 7 control mothers were switched to care for each other's pups.
Participants/materials, setting, methods: Study1: All mice used in these studies were 8 week old ICR mice. 38 female mice at 8 weeks old were treated with a single injection of cyclophosphamide (400 mg/kg intraperitoneally). The control group consisted of 11 mice treated with a single injection of saline. Study2: 400 mg/kg administered once to 7 mice, control group ($n = 7$) did not receive drug. Control group mated. Treated group mated. Control and treated mothers switched at post natal day 2.
Main results and the role of chance: Study1: The survival rate of infants in the Cyclophosphamide group at day 20 was significantly lower than the control group. However, though the sample size is currently limited ($n = 2$), preliminary results are positive with the test group survival rate dramatically increasing when measured at 2 months post drug treatment. Study2: The survival rate of the pups significantly increased when the cyclophosphamide treated mother was replaced with the mother of the control group. Conversely, the survival rate significantly decreased when the cyclophosphamide administered mother raised the pups born from the control group.
Limitations, reasons for caution: The study was limited to one kind of cancer drug, administered once, and 1 mouse strain. Moreover, the study population is small, but the study is ongoing.
Wider implications of the findings: These preliminary date suggest that the cancer drug affects mothers' behavior while not having strong effects on oocyte quality.
Trial registration number: Not applicable.

P-485 Antral follicle responsiveness to exogenous FSH assessed by the Follicular Output RaTe (FORT) is altered in Hodgkin lymphoma patients in comparison with breast cancer

M. Comtet[1], C. Sonigo[1], J. Benard[1], H. Gronier[1], C. Sifer[2], M. Grynberg[1]
[1]Jean Verdier Hospital, Reproductive Medicine, PARIS, France
[2]Jean Verdier Hospital, Cytogenetics and Reproductive Biology, PARIS, France

Study question: To investigate whether responsiveness of antral follicle to exogenous FSH, assessed by the Follicular Output RaTe (FORT), differs between Hodgkin lymphoma and breast cancer patients?

Summary answer: Antral follicle responsiveness to exogenous FSH assessed by the Follicular Output RaTe (FORT) is altered in Hodgkin lymphoma patients in comparison with breast cancer.
What is known already: Oocyte and/or embryo cryopreservation after controlled ovarian hyperstimulation (COH) represents the most established method of fertility preservation (FP) before cancer treatment. Several line of evidence indicate that patients suffering from malignancies may be less prone to respond to ovarian stimulation, possibly as a result of a reduced antral follicle endowment. The percentage of antral follicles that successfully respond to FSH administration (FORT), which presumably reflects the health of granulosa cells and follicle quality, may differ according to the type of malignancy.
Study design, size, duration: From July 2013 to April 2015, we prospectively studied 80 cancer patients, 20–40 years of age, candidates for FP using oocyte and/or embryo vitrification following COH. Of these, 58 were suffering from breast cancer and 24 had Hodgkin lymphoma.
Participants/materials, setting, methods: All women had 2 ovaries, no history of chemotherapy, and underwent COH using GnRH antagonist protocols. Evaluation of the follicular ovarian status by measurement of serum anti-Müllerian (AMH) levels and antral follicle count (AFC) was systematically performed before exogenous FSH administration. FORT was determined by the ratio between the pre-ovulatory follicle count (PFC, 16–20 mm) on the day of oocyte triggering (dOT) × 100/AFC measured just before initiation of the stimulation (d0).
Main results and the role of chance: Overall, women in the Hodgkin lymphoma group were younger in comparison with breast cancer patients (26.7 ± 3.7 vs 33.6 ± 3.9 years, $p < 0.0001$, respectively). Although d0 AFC was significantly higher in women suffering from hemopathy (24 ± 13 vs. 19 ± 14 follicles, $p < 0.02$), serum AMH levels remain similar in both groups (3.7 ± 2.7 vs. 3.3 ± 3.4 ng/mL, *NS*). Interestingly, the FORT was significantly decreased in patients with Hodgkin lymphoma when compared with breast cancer group (25 ± 16 vs 37 ± 19%, $p < 0.02$, respectively), leading in the end to a comparable number of oocytes vitrified (9.9 ± 5.6 vs. 9.4 ± 7.2 oocytes, *NS*, respectively).
Limitations, reasons for caution: FORT presents inherent limitations. Indeed, FORT calculation assumes that small antral follicles, respond in a coordinated manner to FSH and that only follicles having reached diameters ranging between 16 and 20 mm on dOT effectively responded to FSH. In addition, the sample size may limit the generalization of these findings.
Wider implications of the findings: The present findings indicate that the percentage of antral follicles that successfully respond to FSH administration (FORT) is reduced in Hodgkin lymphoma when compared to breast cancer patients, supporting the hypothesis of a detrimental effect of the hemopathy on follicular quality.
Trial registration number: No.

P-486 Exploring the fertility potential of GV-retrieved oocytes for future fertility preservation

W.L.J. Phoon[1], J. Olofsson[2], L. Barbunopulos[3], J. Menezes[3], V. Tohonen[2], K. Rodriguez-Wallberg[2]
[1]*KK Women's & Children's Hospital, Reproductive Medicine, Singapore, Singapore Rep. of*
[2]*Karolinska University Hospital- Karolinska Institutet, Reproductive Medicine, Stockholm, Sweden*
[3]*Karolinska University Hospital, Reproductive Medicine, Stockholm, Sweden*

Study question: What is the fertility preservation (FP) potential of GV-retrieved oocytes after denudation, *in vitro* maturation (IVM), vitrification and ICSI?
Summary answer: Seventy percent of GV to MII stage IVM oocytes were fertilized and half of these developed into cleavage stage embryos.
What is known already: In clinical programs for fertility preservation, following conventional ovarian stimulation regimens and follicular aspiration, approximately 15–20% of oocytes retrieved are found at an immature stage upon denudation, prior to vitrification. IVM of such immature oocytes has been proposed as an additional method of fertility preservation to increase the yield of mature oocytes which can later be thawed and fertilized by ICSI.
Study design, size, duration: A step-wise prospective randomized study in an academic reproductive medicine center. Power calculation estimated a need of 50 GV oocytes per group to identify an optimal culture media setting in step I. In step II, IVM matured oocytes were randomly assigned to either immediate vitrification or fresh ICSI using cryopreserved and thawed sperm from a single donor, followed by fertilization check after 16–20 h and subsequent embryo culture. The study is still ongoing.
Participants/materials, setting, methods: The study was approved by the regional ethics committee. Immature oocytes were donated to research from infertile women upon undergoing IVF-ICSI treatments, following written consent. In step I, a total of 100 denuded GV oocytes were randomized to either one of two commercially available IVM culture media. The identified optimal culture setting was applied in step II, where all procedures were performed by one of 2 experienced embryologists in a routine clinical embryology laboratory setting.
Main results and the role of chance: One of the two media culture used was identified as superior, as it resulted in significantly higher numbers of GV oocytes reaching MII stage after 24 h of culture, 85.7% vs. 41.2% ($P < 0.001$). No further improvement was observed after longer culture periods. Up to date, a total of 80 oocytes have been treated by ICSI after IVM with a fertilization rate of 70.6%. However, about only half of those have further developed to a cleavage stage embryo.
Limitations, reasons for caution: There is a substantial lack of published data regarding the outcome of GV-obtained oocytes that undergo IVM and the potential use of these for cancer patients undergoing FP by ovarian stimulation/oocyte retrieval prior to initiation of gonadotoxic chemotherapy.
Wider implications of the findings: IVM may improve the yield of mature oocytes for women undergoing ovarian stimulation/oocyte retrieval FP. However, the efficacy and safety aspects of IVM in combination with vitrification and subsequent ICSI requires further investigation.
Trial registration number: N/A.

P-487 Moues fresh and vitrified ovarian tissue transplantation under influence of the static magnetic field

V. Kazemein Jasemi[1], F. Samadi[1], H. Eimani[2], S. Hasani[1], R. Fathi[2], A. Shahverdi[2]
[1]*Gorgan University of Agricultural Sciences and Natural Resources, Faculty of Animal Science, Gorgan, Golestan, Iran*
[2]*Royan Institute for Reproductive Biomedicine- ACECR, Department of Embryology at Reproductive Biomedicine Research Center, Tehran, Iran*

Study question: Does the static magnetic field (SMF) influence in transplantation of fresh and vitrified ovarian tissues into the testis?
Summary answer: SMF with moderate intensity has been shown to be effective on biological systems also it is shown to be an effective method for ovarian transplantation.
What is known already: Ovarian tissue banking is a promising option for preserving fecundity in young female cancer patients facing sterilization by chemotherapy and/or radiotherapy. However, the limited functional duration of some non-vascularized ovarian grafts may be due in part to ischemic injury sustained until revascularization is adequate. Many researchers attempted to find a way for minimizing the length of time which tissue must spend in an ischemic state after ovarian transplantation.
Study design, size, duration: The SMF strength in all experiments was 1 mT and it applied for 10 min. In this study used from 6 to 8 week-old female Naval Medical Research Institute (NMRI) mice. Morphological evaluations of ovaries and molecular analysis for active-caspase 3 apoptotic protein and CD31 angiogenic molecule were performed next 3 weeks of transplantation.

To understand follicular and oocyte development was investigated the endocrine function of grafts in male mice receiving ovarian.
Participants/materials, setting, methods: Ovaries of mice randomly were divided into 4 groups: (1) fresh ovaries were immediately transplanted into testicular tissue (FOT group), (2) fresh ovaries were exposed to the SMF for 10 min then were transplanted into the testicular tissue (FOT^+ group), (3) vitrified-warmed ovaries were transplanted into the testicular tissue (VOT group) and (4) vitrified-warmed ovaries were transplanted into the testicular tissue then transplantation site were exposed to a SMF for 10 min (VOT^+ group).
Main results and the role of chance: data indicate that the lowest percentages of morphological dead primordial follicles and the highest percentages of morphological intact primordial follicles were seen in FOT^+ group (4.11% ± 2.88 and 41.26% ± 0.54) respectively. The lowest percentage of intact primordial follicles was seen in the VOT group (24.82% ± 1.03). Alteration in the number of blood vessels had a clear difference between FOT^+ (18.60 ± 0/51) and VOT (7.80 ± 0/58) groups but their results in existence of blood vessels were not significant against the other groups. There was not a statistically difference between FOT, FOT^+, and VOT^+ groups in terms of apoptotic rate and number of newly formed blood vessels.

The hormonal assay showed that the level of plasma progesterone increased in FOT+ group in compared to other groups. Also In grafted male mice, estrogen (E2) and progesterone (P4) concentrations were significantly higher than of the control mice. The level of testosterone (T4), in control group was analytically higher than the other experimental groups.

Limitations, reasons for caution: Since human ovarian tissue is scarce, the present protocol was developed in the mouse model. Further studies are necessary to determine the exact mechanism of SMF effects on human ovarian transplantation.

Wider implications of the findings: An optimal transplantation protocol enhances the chances for successful fertility restoration. Exposure of mice ovarian tissues to static magnetic field before transplantation resulted in greater transplantation outcomes against non-exposed grafted tissues. Exposure of the vitrified-warmed ovaries to SMF led to maintain the structure of the graft similar to fresh ovaries.

Trial registration number: NA.

P-488 Administration of a GnRH agonist during chemotherapy for breast cancer reduces ovarian toxicity in women aged under 40 years

R. Anderson[1], D. Adamson[2], A. Yellowlees[3], J. Dunlop[4], G. Thomas[5], R. Leonard[6]
[1]*University of Edinburgh The Queen's Medical Research Institute, MRC Centre for Reproductive Health, Edinburgh, UK*
[2]*Ninewells Hospital, Clinical Oncology, Dundee, UK*
[3]*Quantics Biostatistics, n/a, Edinburgh, UK*
[4]*NHS National Services Scotland, Scottish Clinical Trials Research Unit, Edinburgh, UK*
[5]*Imperial College, Surgery and Cancer, London, UK*
[6]*Imperial College, Cancer and Surgery, London, UK*

Study question: Does administration of a GnRH agonist during chemotherapy for breast cancer reduce ovarian toxicity, as reflected in the prevalence of ovarian failure?

Summary answer: Administration of goserelin during chemotherapy reduced the likelihood of ovarian failure at 2 years after randomisation, and this was most apparent in women aged ≤40.

What is known already: Chemotherapy can cause ovarian toxicity, usually determined as ovarian failure with amenorrhoea, with lesser degrees of damage resulting in incomplete loss of ovarian reserve. Whether administration of a GnRH agonist during chemotherapy for breast and other cancers can reduce this has been controversial for many years. Although recent RCTs have indicated that there may be a benefit, the degree of ovarian protection afforded and the applicability across all age groups remain unclear.

Study design, size, duration: OPTION' is a prospective, multicentre open parallel group RCT of the administration of goserelin vs no treatment in premenopausal women with early or locally advanced breast cancer where adjuvant or neo-adjuvant chemotherapy was indicated but ovarian suppression was not. We report the results for ovarian failure at 2 years after randomisation, defined as amenorrhoea between 12 and 24 months, supported by hormone measurements. Planned recruitment was 250 patients over 5 years, with stratification by age.

Participants/materials, setting, methods: Premenopausal women were randomised by a central trial centre to goserelin 3.6 mg sc starting 1-2 weeks before chemotherapy and continuing every 4 weeks until the end of chemotherapy, vs. no treatment. Chemotherapy included 6–8 cycles of cyclophosphamide and/or anthracycline-containing regimens. Patients were followed-up 6-monthly for 2 years. Hormone levels were determined pretreatment and at intervals to 2 years, during which time a menstruation diary was also kept.

Main results and the role of chance: 227 patients were randomized, 3 in each arm were omitted from analysis because they had died and a further 19 patients (11 in the control arm and 8 in the goserelin arm), because menstrual status between 12 and 24 months could not be determined. Women in the goserelin arm were significantly more likely to have amenorrhoea: 12% vs. 38% ($p = 0.015$, $n = 202$); this difference was more robust when a criterion of high FSH was added. Two alternative imputations were made assuming all 19 women with missing data either did or did not have ovarian failure: in both cases there remained a significant benefit of goserelin. Stratification by age indicated a beneficial effect from goserelin in women aged 40 or less (10% vs. 25% with menses, $p = 0.032$, $n = 119$) which was not apparent in those over 40 (43% vs. 57%, $p = 0.38$, $n = 83$). Anti-Mullerian hormone (AMH) was available in a subset of women; this did not show significant differences between treatment groups but highlighted the marked impact of chemotherapy, with a mean reduction of 76% vs pretreatment overall, and of 70% in those with ongoing ovarian function.

Limitations, reasons for caution: These data do not explore fertility or other long-term health outcomes. The AMH data indicate that the extent of preservation of ovarian function is limited compared to the amount lost from chemotherapy. It is unknown whether these results can be translated to other diagnoses or chemotherapy regimens.

Wider implications of the findings: The preservation of ovarian activity in some women may have implications for quality of life and longer-term health, such as fertility, and bone and cardiovascular health.

Trial registration number: EudraCT 2004-000133-11.

P-489 Comparison of GnRH agonist (GnRHa) and hCG for priming before *in vitro* maturation (IVM) and oocyte vitrification in cancer patients undergoing urgent fertility preservation (FP)

C. Sonigo[1], H. El Hachem[2], J. Benard[1,3], A. Benoit[1], C. Sifer[4], M. Grynberg[1,3]
[1]*Hôpital Jean Verdier, Reproductive Medicine and Fertility Preservation, Bondy, France*
[2]*Ovo Clinic, Department of Obstetrics and Gynecology, Montréal, Canada*
[3]*University Paris XIII,., Bobigny, France*
[4]*Hôpital Jean Verdier, Histology Embryology Cytogenetic CECOS, Bondy, France*

Study question: To compare the number of metaphase 2 (M2) oocytes vitrified following IVM in candidates for urgent FP having received a GnRHa or an hCG priming.

Summary answer: GnRHa priming significantly increases the number of cumulus-oocyte-complexes (COC) recovered but not the number of M2 oocytes available for cryopreservation when compared to hCG priming.

What is known already: IVM of oocytes retrieved at germinal vesicle stage, followed by vitrification of M2 oocytes, has recently emerged as an option for young women seeking urgent FP. This technique was originally developed for patients with polycystic ovary syndrome, in whom the induction of a LH surge, provided with hCG administration, 36 h before COC retrieval, improved outcomes. Evidence indicates that ovulation may be efficiently triggered in controlled ovarian stimulation cycles by administering a combination of FSH + LH activity using GnRHa. Whether GnRHa administration impacts on immature oocyte retrieval and their capacity to mature *in vitro* is not established.

Study design, size, duration: From January 2009 to April 2015, 436 cancer patients, 18–40 years of age, candidates for urgent FP, were prospectively studied. All women underwent M2 oocyte cryopreservation after IVM cycles primed either with GnRHa (triptorelin 0.2 mg, SC, $n = 276$) or hCG (Gonadotrophine Chorionic Endo, 10,000 IU, IM, $n = 160$).

Participants/materials, setting, methods: All participants were diagnosed with cancer and underwent FP using IVM. Inclusion criteria were: age 18–40 years; presence of two ovaries; no history of chemotherapy. Before urgent immature oocyte retrieval, follicles measuring 2–9 mm in diameter were counted on both ovaries and serum anti-Müllerian hormone (AMH) was measured, irrespective of the phase of the cycle. Primary outcomes were the number of COC retrieved, the maturation rate and the number of M2 oocytes cryopreserved.

Main results and the role of chance: Overall, patients in the GnRHa and the hCG groups were comparable in terms of age (31.6 ± 4.4 vs. 31.9 ± 4.9 years, respectively, $p = 0.4$), BMI (23.1 ± 4.2 vs. 22.8 ± 3.9 Kg/m^2, respectively, $p = 0.5$) and ovarian reserve tests (antral follicle count: 22.6 ± 14 vs. 20.8 ± 11.9 follicles, $p = 0.2$; serum AMH levels: 4.4 ± 3.9 vs. 4.3 ± 3.5 ng/mL, $p = 0.8$, respectively). The number of COC retrieved was significantly higher in the GnRHa group when compared with hCG group (10.8 ± 9.9 vs. 8.4 ± 6.7 oocytes, $p < 0.008$). Despite a trend to a reduced maturation rate after GnRHa priming (59.1 ± 24.1 vs. $63.7 \pm 20.2\%$, $p = 0.07$), the total number of M2 oocytes frozen was similar in both groups (5.9 ± 5.1 vs. 5.1 ± 4.6, $p = 0.1$, respectively).

Limitations, reasons for caution: The main limitation of our investigation is the absence of randomization. In addition, although oocyte cryopreservation following IVM is a promising method for urgent cases of FP, the true competence of these oocytes remains still ill-established.

Wider implications of the findings: Our findings confirm the capacity of a combined FSH + LH priming, provided by GnRHa administration, to potentially improve IVM cycle outcomes in cancer patients. Randomized control trials

are needed to objectively assess the need for priming in normo-ovulatory cancer patients, and the best way to provide it if required.
Trial registration number: N/A.

P-490 Effects of slow-freezing and vitrification on quality of human spermatozoa

N. Sayme[1], L. Dite[2], D. Töpfer[3], T. Krebs[2]
[1]*Team Kinderwunsch Hannover, Clinic, Hannover, Germany*
[2]*Team Kinderwunsch Hannover, Laboratory, Hannover, Germany*
[3]*Tierärztliche Hochschule Hannover, Reproduktionsbiologie, Hannover, Germany*

Study question: Is there an advantage of vitrifies sperms compared with slow-freezing technique regarding motility, survival rate, velocity parameters and acrosome reaction (AR) of human spermatozoa?
Summary answer: All velocity parameters were significantly higher after vitrification compared with the conventional slow-frozen spermatozoa. Higher proportion of AR could be observed in both cryopreserved groups.
What is known already: Cryoreservation of human spermatozoa is widely used in assisted reproduction. It is still under debate for cryopreservation of human semen whether the vitrification technique is superior to the slow-freezing technique or not. Isachenko (2012) already showed that vitrification of human spermatozoa is possible without permeable cryoprotectants to avoid the negative influence by their toxicity. Nevertheless several studies show contradictory results comparing both techniques with respect to different parameters, e.g., motility, viability, DNA integrity and many more.
Study design, size, duration: Human semen samples (n = 50) were obtained from patient donors as a part of their clinical evaluation for reproductive health status collected in three month. All donors practiced 3–5 days of sexual abstinence and their average age was 37.5 ± 6.4 years. Semen analysis was carried out in accordance with the WHO guidelines. Semen samples with a concentration of ≥20 million/ml were used.
Participants/materials, setting, methods: Each density gradient prepared sample was divided into three equal parts: (1) conventional slow-freezing (2) vitrification and (3) control without cryopreservation. The motility parameters that computed and recorded by CASA include progressive and non-progressive motility, vitality, curvilinear velocity (VLC), average path velocity (VAP), and amplitude of lateral head displacement (ALH). Chlortetracycline staining (CTC) was used to evaluate the acrosomal status (AR). The parameters were analysed using a one way ANOVA.
Main results and the role of chance: A one way ANOVA revealed a significantly higher curvilinear velocity (VLC), average path velocity (VAP) and amplitude of lateral head displacement (ALH) of spermatozoa after vitrification compared to the recorded measurements of slow-frozen spermatozoa ($p \leq 0.001$). A Higher but not significantly progressive motility rate (M = 16.18, SD ± 8.12 vs. M = 14.56, SD ± 7.74) and vitality rate (M = 28.36, SD ± 9.03 vs. M = 25.94, SD ± 8.24) could be observed after vitrification compared with slow freezing sperms. No significant difference between the cryopreserved groups could be found in respect to acrosome reaction. However, both cryopreserved groups show significantly higher levels of acrosome reacting ($p \leq 0.001$) and reacted ($p \leq 0.05$) spermatozoa than spermatozoa that did not undergo any cryopreservation.
Limitations, reasons for caution: In the study were oligo-, astheno-, terato- and normozoospermic samples included and only samples with a concentration of ≥20 million/ml after preparation were used. It is possible that for special pathologic findings different cryopreservation methods are superior to others.
Wider implications of the findings: Results described in the present study suggest that motility and vitality of human sperms did not differ after slow freezing and vitrification. According to McLaughlin (1993), no differences in acrosomal status occurred in both groups. However, vitrified spermatozoa show higher velocity parameter levels which are good predictors of fertilizing ability.
Trial registration number: None.

P-491 Letrozole co-administration does not alter antral follicle responsiveness to exogenous FSH assessed by the Follicular Output RaTe (FORT) in breast cancer patients seeking fertility preservation.

M. Grynberg[1], J. Benard[2], A. Benoit[2], I. Cédrin Durnerin[2], C. Sifer[3], C. Sonigo[2]
[1]*Hôpital Jean Verdier, Bondy, France*
[2]*Hôpital Jean Verdier, Reproductive Medicine and Fertility Preservation, Bondy, France*
[3]*Hôpital Jean Verdier, Reproductive Biology and Cytogenetic, Bondy, France*

Study question: To investigate whether letrozole co-administration alters antral follicle responsiveness to exogenous FSH, assessed by the FORT in breast cancer patients undergoing ovarian stimulation for fertility preservation?
Summary answer: The percentage of antral follicles that successfully respond to FSH administration remains comparable in breast cancer patients undergoing conventional ovarian stimulation or protocol using letrozole.
What is known already: Oocyte and/or embryo vitrification after controlled ovarian hyperstimulation (COH) represents the most established and efficient method of fertility preservation before cancer treatment. However, traditional COH regimens are associated with supraphysiologic levels of estrogen and as a result are not recommended for breast cancer patients. To protect the patients from the potential deleterious effects of elevated estrogen levels during ovarian stimulation for fertility preservation, protocols using aromatase inhibitors were developed. However, whether the percentage of antral follicles that successfully respond to FSH administration (FORT) differs between conventional and letrozole supplemented protocols remains not established.
Study design, size, duration: From July 2013 to April 2015, we prospectively studied 91 breast cancer patients, 25–40 years of age, candidates for FP using oocyte and/or embryo vitrification following COH. Of these, 37 had letrozole supplementation during COH while 54 underwent traditional GnRH antagonist protocol.
Participants/materials, setting, methods: All women had 2 ovaries, no history of chemotherapy, and a breast tumor that was surgically removed. Evaluation of the follicular ovarian status by measurement of serum anti-Müllerian (AMH) levels and antral follicle count (AFC) was systematically performed before exogenous FSH administration. FORT was determined by the ratio between the pre-ovulatory follicle count (PFC, 16–20 mm) on the day of oocyte triggering (dOT) × 100/AFC measured just before initiation of the stimulation (d0).
Main results and the role of chance: Overall, women in the letrozole and control groups were comparable in terms of age (34.6 ± 0.8 vs. 33.4 ± 0.4 years, *NS*, respectively), BMI (21.3 ± 0.5 vs. 21.5 ± 0.4 Kg/m^2, *NS*, respectively) and makers of the follicular ovarian status (AFC: 18.7 ± 1.7 vs. 18.5 ± 1.8 follicles, *NS*; AMH: 3.1 ± 0.4 vs. 3.2 ± 0.6 ng/mL, *NS*). After comparable initial doses and total amount of exogenous FSH (2965 ± 134 vs. 2849 ± 167 IU, *NS*, respectively), the number of PFC did not differ between both groups (10.7 ± 0.7 vs. 10.2 ± 0.5 follicles, *NS,* respectively*)*. As a result, FORT index were comparable in patients having received or not letrozole supplementation during COH (33.9 ± 3.4 vs. 37.6 ± 2.7%, *NS,* respectively*)*, as well as the number of oocytes vitrified (9.9 ± 5.6 vs 9.4 ± 7.2 oocytes, *NS*, respectively).
Limitations, reasons for caution: FORT presents inherent limitations. Indeed, FORT calculation assumes that small antral follicles, respond in a coordinated manner to FSH and that only follicles having reached diameters ranging between 16 and 20 mm on dOT effectively responded to FSH. In addition, the sample size may limit the generalization of these findings.
Wider implications of the findings: The present findings indicate that the percentage of antral follicles that successfully respond to FSH administration (FORT) is not modified by letrozole supplementation during COH when compared with conventional stimulation protocols. This is in keeping with the hypothesis that follicle-oocyte quality is not affected by the use of aromatase inhibitors.
Trial registration number: N/A.

P-492 Sphingosine 1-Phosphate does not improve mice follicle culture survival after treatment with cyclophosphamide

A. Anastácio[1], C. Poirot[2,3], K. Rodriguez-Wallberg[1,4]
[1]*Karolinska Institutet, Department of Oncology and Pathology, Stockholm, Sweden*
[2]*Université Paris VI UPMC, Université Pierre et Marie Curie, Paris, France*
[3]*CHI Poissy-St-Germain, Unité de Préservation de la Fertilité, St Germain en Laye, France*
[4]*Karolinska University Hospital, Reproductive Medecine, Stockholm, Sweden*

Study question: Does a medium enriched with Sphingosine 1-Phosphate (S1P) improve mice follicle survival in culture after administration of cyclophosphamide (CPA) *in vivo*?
Summary answer: Addition of S1P to the culture medium did not improve follicle survival in culture or follicle growth development parameters.

What is known already: Alkylanting agents including CPA are highly gonadotoxic and treatments that include such drugs induce follicle depletion and infertility. Sphingosine 1-Phosphate (S1P) is an anti-apoptotic agent that promotes cell growth and mitosis, improving not only cell proliferation but also suppressing cell death. S1P has been tested in reproductive experimental settings *in vivo* and it seems effective in improving cell survival, but no previous data on the investigation of S1P in follicle culture of treated mice with CPA are available.
Study design, size, duration: Randomized experiment. Twenty B6CBA/F1 mice, four weeks old, were randomly assigned (n = 5/group) to treatment with CPA (single injection) Group I: 100 mg/Kg, Group II: 75 mg/Kg, Group III: 50 mg/Kg, and Group IV: control. All mice were sacrificed after 72 h and secondary follicles were isolated. The follicles obtained from each treatment condition were thereafter assigned to culture media enriched with S1P (50 nM), or without. The study was approved by the ethics review board for animal experiments.
Participants/materials, setting, methods: After isolation, the secondary follicles were cultured under oil in a microdrop system for 12 days, according to the method described by Cortvrindt et al. (1996). Follicle growth was monitored daily and follicle size and morphology registered.
Main results and the role of chance: The groups of mice treated with CPA presented a 60% reduction in the number of secondary follicles that could be isolated, when compared to the control group ($p < 0.001$). However, the numbers of follicles isolated in the three CPA treated groups were similar and did not differed significantly across the different dose groups.

Follicle survival rates in culture were similar in the three groups treated with CPA, but also when compared those to the control group. Follicle growth and final follicle size were also similar between all the groups. No improvements either in survival rate or in final follicle size were observed in follicles cultured in medium that was enriched with S1P, independently of the treatment condition.
Limitations, reasons for caution: The growth of follicles *in vitro* was monitored only by established morphological characteristics. Additional investigation of molecular features would have provided further information on follicle development *in vitro*.
Wider implications of the findings: Our study shows that mice secondary follicles, previously treated with CPA, can be isolated and cultured. Despite a significant reduction in the number of follicles collected from treated CPA ovaries, *in vitro* follicle growth was similar. Addition of S1P to culture media did not improve growth or follicle survival.
Trial registration number: basic science study

PARAMEDICAL - LABORATORY

P-493 The effect of pre-warming the prepared sperm fraction for conventional IVF: a prospective sibling oocyte study

M. Abraham[1], N. De Munck[1], H. Tournaye[1], B. Desmet[1], G. Verheyen[1]
[1]*UZ Brussel, CRG, Jette- Brussels, Belgium*

Study question: This prospective sibling oocyte study evaluated whether pre-warming the prepared sperm fraction at 37°C for 1 h before IVF insemination improves fertilization and embryo development.
Summary answer: Sperm pre-warming for 1 h at 37°C does not improve fertilization and embryo quality compared to sperm kept at room temperature (control).
What is known already: Hyperactivation of spermatozoa, a process needed in order to fertilize the oocyte, is temperature dependent and faster induced at 37°C. However, preservation of capacitated sperm at 37°C during several hours before IVF insemination is discouraged because of the high energy consumption before fertilization can take place. Pre-warming the prepared sperm fraction for 1 h at 37°C could assist the spermatozoon to undergo the hyperactivation process and thereby facilitate fertilization and developmental capacity.
Study design, size, duration: A prospective sibling oocyte study was performed from September 2014 until January 2016, including 93 IVF cycles with at least 4 cumulus-oocyte complexes (COC). Semen was prepared on a 90%/45% density gradient (Spermient, COOK). The prepared sperm fraction was divided in two aliquots. In the control group, the prepared sperm fraction was kept at room temperature until insemination, while sperm was incubated for 1 h at 37°C immediately before insemination in the study group.
Participants/materials, setting, methods: The oocytes (93 cycles) were cultured in 25 µl droplets of fertilization medium (Origio). Either the oocytes of the control group or the oocytes of the study group were first inseminated, based on a computer-generated randomization list. To each droplet, 10000 progressively-motile spermatozoa were added. Inseminated oocytes were incubated overnight (16–20 h) until denudation. Statistical analysis was performed by the Chi square test, a p-value <0.05 was considered significant.
Main results and the role of chance: A total of 1064 sibling oocytes were inseminated, 533 in the control group and 531 in the study group. The fertilization rates in the control group (59.1%) and the study group (59.9%) were comparable ($p = 0.842$). On day 3, there was no difference in the proportion of excellent or the proportion of good-quality embryos between the groups ($p = 0.259$). The same observation was made for the 217 embryos (control group) and 229 embryos (study group) that were further cultured till day 5/6 ($p = 0.126$). Finally, no difference was found in the utilization rates (proportion of embryos transferred or frozen per COC) of the control and the study group (29.5% versus 29.8%, $p = 0.968$).
Limitations, reasons for caution: The overnight incubation of oocytes with sperm might have counteracted the possible effect of 1 h pre-incubation of sperm. The probability of a beneficial effect of a short pre-warming period might be higher when a short 2-h co-incubation of oocytes and sperm is performed.
Wider implications of the findings: With respect to our standard protocol of overnight co-incubation, pre-warming sperm for 1 h at 37°C seems not beneficial, thus sperm will be kept at room temperature before insemination. However, a consecutive similar study with co-incubation of oocytes and sperm during only 2 h can be considered.
Trial registration number: None

P-494 Evaluation of two different types of time-lapse embryo observation system

Y. Tsutsumi[1], J. Otsuki[1], Y. Tsuji[1], Y. Katada[1], H. Sato[1], K. Hatano[1], K. Furuhashi[1], H. Ogata[1], Y. Matsumoto[1], S. Kokeguchi[1], M. Shiotani[1]
[1]*Hanabusa Women's Clinic, Reproductive Medicine, Kobe- Hyogo, Japan*

Study question: Are there different outcomes between the two different time-lapse embryo observation systems, EmbryoScope and PrimoVision?
Summary answer: Although better outcomes are expected with PrimoVision, having a group culture system, no significant difference was detected in the time-lapse parameters and pregnancy rates.
What is known already: Since time-lapse systems became available, some parameters, such as speed and timing of embryo development were reported to predict good embryos. Group culture systems have been reported to improve embryo development rates and pregnancy rates. Closed incubator systems are considered to produce similar results, as compared to conventional open incubator systems. Although there have been reports comparing closed and open systems, there was previously no reported data which compared the culture dishes used in each system.
Study design, size, duration: Comparison of two different types of time-lapse system (EmbryoScope: a closed incubator with individual culture, PrimoVision: an open incubator with group culture). This was a retrospective cohort study involving 2,372 embryos from 270 women (<40 years old) who underwent blastocyst culture using the two time-lapse systems, and cryopreservation of their all blastocysts between September 2013 and October 2015. Patients were allocated randomly to each time-lapse system. Mouse embryo testing was performed on culture dishes.
Participants/materials, setting, methods: The time from pronuclear membrane break down (PNMBD) to 2–5 cells and 8 cells (tpnb2–tpnb5, tpnb8, from 2 to 3 cells (cc3), from 3 to 4 cells (s2), from 5 to 8 cells (s3) were compared between the two systems. Embryo development rates, pregnancy rates, and abnormal cleavage rates were compared between the two systems. The mouse

embryo test was performed in ES and PV dishes in the same open system incubator.
Main results and the role of chance: Blastocyst development rates in ES and PV were 57.7% (357/619) and 53.4% (339/633) and high quality blastocyst (≧G3BB) development rates in ES and PV were 26.5% (164/619) and 26.9% (170/633). Chemical and clinical pregnancy rates were 66.7% (58/87) and 60.9% (53/87) in ES and 61.4% (35/57) and 50.9% (29/57) in PV. Abnormal cleavage rates, including reverse cleavage and direct cleavage from 1 cell to more than 2 cells and from 2 cells to more than 4 cells were 9.2% (8/87) in ES and 8.8% (5/57) in PV. The parameters tpnb2, tpnb3, tpnb4, tpnb5, tpnb8, cc2, s2 and s3 were 27.0 ± 3.4, 37.6 ± 4.9, 38.7 ± 4.6, 50.9 ± 7.1, 58.9 ± 9.2, 10.5 ± 3.0, 1.2 ± 1.9, 8.0 ± 7.4 h in ES, and 27.5 ± 3.3, 37.4 ± 5.2, 38.2 ± 7.4, 50.7 ± 7.4, 59.7 ± 8.0, 9.6 ± 4.1, 1.2 ± 2.1, 8.7 ± 7.4 h in PV respectively. In all parameters, there was no significant difference between ES and PV. The mouse embryo test showed that the blastocyst development rate was significantly higher in PV dishes (78.1%) than in ES dishes (30.4%) ($p = 0.0011$). No significant difference was detected between the ES dish culture (30.4%) and the control (individual) culture (36.4%), whereas the blastocyst rate was significantly higher in the PV dish culture (78.1%) than in the control (group) culture (31.3%) ($p = 0.00016$).
Limitations, reasons for caution: As only patients who are younger than 40 are enrolled in this time-lapse observation, the results may not be enhanced to assist patients who are older than 40.
Wider implications of the findings: As there was no statistical difference between the two time-lapse systems, the merits in each system might counterbalance each other. A time-lapse system, which employs both a group culture system and a closed incubator system, using a less toxic culture dish, will improve ART outcomes.
Trial registration number: Not applicable.

P-495 Association of follicular fluid zinc concentration with maturation rate and fertilization rate during ovarian stimulation

F. Saji[1], N. Amano[1], M. Kobatake[1], T. Takano[1], A. Kawagita[1], M. Ishikawa[1], L.K. Young[1], M. Funabiki[1], S. Taguchi[1], Y. Nakamura[1]
[1]*Oak Clinic, Total Infertility Center and Gynecology, Osaka, Japan*

Study question: Is zinc concentration in follicular fluid obtained from women during ovarian stimulation involved in human oocyte and embryo development?
Summary answer: Zinc concentration in follicular fluid appears to be involved in human oocyte maturation and fertilization rate.
What is known already: Zinc is an essential trace element during early embryogenesis for the stabilization of DNA conformations in association with DNA repair. It also has an important role in preventing high levels of reactive oxygen species during early embryogenesis.
Study design, size, duration: A retrospective study of *in vitro* fertilization (IVF) during October 2013 to May 2015 on 117 women. Among them, 59 women were treated with GnRH agonist short protocol and 58 women with GnRH antagonist protocol. All IVF cycles were carried out with informed consent at our clinic. The primary outcomes of this study were to analyze the maturation rate of human oocytes and the fertilization rate and their association with intra-follicular concentration of zinc.
Participants/materials, setting, methods: The follicle fluid was obtained from the largest aspirated follicle without any blood contamination. Oocytes were collected from all follicles and fertilized with ICSI. The maturation rate, fertilization rate were evaluated. Zinc concentration of follicle fluid was measured using a metal assay kit. Statistical analyses were performed using *Welch's t-test* and multiple logistic regression analysis. A statistical significance was considered as $P < 0.05$.
Main results and the role of chance: Mean age of combined GnRH agonist and antagonist women was 38.2 years and the maturation rate and fertilization rate were 79.3% and 55.5%, respectively. There was no significant difference in age between GnRH agonist group (37.6 years.) and antagonist group (38.8 years., $P = 0.071$). However, a significant difference was observed between these two treatment groups in maturation rate (75.3 vs. 83.3%, $P = 0.024$) and zinc concentration (50.8 vs. 54.9 μg/dL, $P = 0.011$). Multiple logistic regression analysis indicated that the maturation rates of human oocytes were influenced by the difference of follicle stimulation protocols ($P = 0.003$) and follicular fluid zinc concentration ($P = 0.007$) regardless of the age ($P = 0.44$). The follicular fluid zinc concentration was negatively correlated with maturation rates. In contrast, the fertilization rates were influenced by follicular fluid zinc concentration ($P = 0.01$) regardless of the age ($P = 0.58$) and the difference of follicle stimulation protocols ($P = 0.69$). Our findings suggest that measuring follicular fluid zinc concentration may predict outcome of oocyte maturation and fertilization rate in women during different ovarian stimulation.
Limitations, reasons for caution: At our clinic, we commonly choose GnRH agonist short protocol during follicle stimulation for women with first IVF cycle. This may increase the risk of selection bias. Small sample size in each stimulation group in this retrospective study should be carefully considered to decide final conclusion.
Wider implications of the findings: Different stimulation protocol may be involved in variable zinc concentration of follicle fluid. In ART clinical practice, GnRH antagonist protocol may be recommended to women showing less oocyte maturation with GnRH agonist protocol. Measurement of zinc concentration in follicular fluid may help decide the selection of next ovarian stimulation protocol.
Trial registration number: None

POSTER VIEWING SESSION

PARAMEDICAL - NURSING

P-496 In-vitro fertilization with donor sperm versus social freezing in single women: the importance of family proximity

D. Garcia Garcia[1], A. Rodriguez[2], R. Vassena[2], V. Vernaeve[2]
[1]*Fundacio EUGIN, Fundacio EUGIN, Barcelona, Spain*
[2]*Clinica Eugin, Clínica Eugin, Barcelona, Spain*

Study question: Are motivations and personal characteristics of single women undergoing IVF with donor sperm (IVF) different from those undergoing social freezing (VIT)?
Summary answer: IVF women live closer to their families, and perceive to have a stronger family support than VIT women do.
What is known already: The decision to have a child might be postponed by the lack of a partner, and social freezing can afford single women more time to find a suitable companion to reach the desired family structure. Alternatively, some women decide not to postpone motherhood and to have a child on their own thorough IVF with donor sperm. Both procedures can be seen as solutions to permanent involuntary childlessness in single women, but the motivations of women undergoing one treatment or the other, and their characteristics, have never been investigated.
Study design, size, duration: This cross-sectional study includes 250 single women from 4 European countries (Spain, France, Italy, and United Kingdom) who underwent either IVF with donor sperm (192) or social freezing (58) between January and December 2015 in a large fertility center.
Participants/materials, setting, methods: Study participants were heterosexual single women; an anonymous electronic survey was sent after the women started the elected treatment. The survey consisted of 18 close-ended or multiple choice questions. The estimated time to fill in the survey was 5 min. The response rate was 49.8%. Predictors to be part of the IVF or the VIT group were analyzed following a logistic regression model. Patients' characteristics were also analyzed by logistic regression.
Main results and the role of chance: Demographic characteristics between IVF and VIT women were similar (mean age 38.5), and 3/4 reported having been single for more than one year. However, women in the IVF group lived closer to their original families than those in the VIT group, close enough to visit with family once a week (OR 3.9, 95% CI 1.9, 8.1, $p < 0.001$), and received a higher emotional and/or financial support from them (OR 2.5, 95% CI 1.1, 5.6, $p = 0.030$). We observed slight differences in education and occupation: while most participants in both groups are highly educated and have a job, more VIT hold an advanced university degree -master or doctorate- (68 vs. 33.2%, $p < 0.001$), while more IVF are employees rather than for instance self-employed (80.5 vs. 65.5%, $p = 0.017$). Regarding motivations, the most common reported reason for not having fulfilled the motherhood desire was a lack of partner (72.5% of IVF and 62.1% of VIT), as expected. However, more VIT

reported a late desire to have children (15.5% VIT vs. 6.3% IVF, $p = 0.029$), and considered having a partner more important than having a child (12.1% of vs. 0.0% IVF; $p < 0.001$). Finally, 100% of VIT knew about the possibility of IVF, while 62% of IVF knew about VIT.

Limitations, reasons for caution: Participants in the study were women who attended the center for undergoing IVF or VIT. No information was collected from women who attended an initial visit but did not follow through with treatment.

Wider implications of the findings: Our results underscore the relevance of family ties in the decision to undergo IVF as single women. Moreover, IVF women might not be fully informed about social freezing as an option to postpone motherhood. Health professionals should be aware of these differences when counseling single women on fertility choices.

Trial registration number: NA.

P-497 The effectiveness of brief mindfulness-based stress reduction program on stress, mindful awareness attention, sleep quality in infertile women: a quasi-experimental study

M.L. Hu[1], M.Y. Chang[2], M.C. Chu[2], H.S. Wang[1], H.Y. Huang[1]
[1]*Chang Gung Memorial Hospital, Department of Obstetrics and Gynecology, Guishan Districe, Taoyuan City, Taiwan, R.O.C.*
[2]*Dharma Drum Institute of Liberal Arts, Master of Community Empowerment, Graduate School of Humanities and Social Sciences, Taipei City, Taiwan, R.O.C.*

Study question: Is the 4-week Brief Mindfulness-based Stress Reduction (B-MBSR) Program effective on reducing stress and increasing mindful awareness attention and sleep quality for infertile women?

Summary answer: Four-week B-MBSR Program can decrease stress and increase mindful awareness attention and sleep quality in infertile women.

What is known already: The infertile women experienced physiological, psychological, and social stress, especially during the infertility treatment period. Mindfulness-based stress reduction program was used widely for patients with chronic disease; however, the effects for infertile women are not clear yet.

Study design, size, duration: Quasi-experimental design study was used in the study. Seventy-three subjects were included, 40 for experimental group and 33 for control group respectively. The experimental group received a 2-h B-MBSR program in every week for four weeks, and conducted daily self-practice for half hour every day. Control group kept their usual daily life style. Evaluation measurement was assessed for both experimental group and control group at baseline (pre-test), 4th week (post-test), and 8th week later (follow-up).

Participants/materials, setting, methods: Infertile women who had been treated routinely at infertility clinic, aged 2–45, understand mandarin, without hearing impairment, and willing to perform home-practice, were recruited. Purposive sampling was used to assign 73 participants into experimental and control group. The study was conducted at outpatient clinics located in northern Taiwan. Perceived Stress Scale (PSS), Mindful Awareness Attention Scale (MAAS), and Pittsburgh Sleep Quality Inventory (PSQI) questionnaires were used to assess effects of the BMSR program.

Main results and the role of chance: After the B-MBSR program, participants in the experimental group showed significantly decreased in the PSS ($B = -4.68$, $p < 0.001$) at the 4th week post-test and continuous decreased ($B = -6.14$, $p < 0.001$) at the 8th week follow-up; the MAAS significantly increased at the 4th week post-test ($B = 4.23$, $p = 0.05$) and continuous increased ($B = 7.43$, $p = 0.001$) at the 8th week follow-up; the PSQI significantly decreased at the 4th week post-test ($B = -1.22$, $p = 0–038$) and continuous decreased ($B = -2.74$, $p < 0.001$) at the 8th week follow-up. However, control group did not change significantly.

Limitations, reasons for caution: Because of clinical setting and ethical issues, randomization cannot be applied in the current study. Physiological indicators of effects, such as stress and sleep quality did not included in the study, that are recommended for next-step study in the future.

Wider implications of the findings: The B-MBSR program was confirmed to be an ideal strategic intervention to reduce stress for infertile women, and feasibility and cost-effectiveness are also setup in the study. Therefore, the B-MBSR can be applied to clinical setting for infertile women.

Trial registration number: N/A

P-498 Is hysterosalpingography really painful?

M. Fujii[1], Y. Tokura[1], M. Shiotani[1]
[1]*Hanabusa Women's Clinic, reproductive health, Kobe, Japan*

Study question: What information can be provided to hysterosalpingography patients to assist in the reduction of expected and/or actual pain levels?

Summary answer: The provision of accurate information may play a part in decreasing the pain levels of hysterosalpingography patients.

What is known already: Patients can easily obtain information from the internet and media nowadays and many of them have preconceptions about hysterosalpingography as very painful. It is known that negative perceptions regarding pain can often increase the level of pain. Thus, this study aimed to analyze the expected pain levels and postprocedure pain levels of patients who underwent hysterosalpingography.

Study design, size, duration: A questionnaire survey was conducted from April 2013 to May 2013, involving 265 patients who underwent hysterosalpingography and agreed to fill out a questionnaire. Patients were given the questionnaire immediately after they underwent the hysterosalpingography.

Participants/materials, setting, methods: The pain-level questionnaire was based on the Numerical Rating Scale (NRS), ranging from level 1 to 10. The pain was also evaluated within three categories: lower, the same or higher than expected. It was further analyzed based on the patency of oviducts. The questionnaire was handed out to patients after obtaining informed consent, including clauses regarding no invasion of privacy and a guarantee against any disadvantages if they did not wish to respond.

Main results and the role of chance: The response rate of the questionnaire was 83.3%. The rates of patients who responded that the pain was lower than expected, the same as expected, or higher than expected were 64.2% (170/265), 20.4% (54/265), and 15.4% (41/265), respectively. The average score regarding expected pain was 6.2 (±2.3) which was significantly higher than the postprocedure pain score of 4.2 (±2.6) ($p < 0.001$).

Among patients who were not found to have oviductal patency, the rates of patients who answered that the pain was lower than expected, the same as expected, or higher than expected were 47.9% (23/48), 20.8% (10/48), and 31.3%(15/48) respectively, whereas they were 67.9% (146/215), 14.4% (31/215), and 36.0% (38/215) respectively in patients who were found to have oviductal patency. A significant difference in pain levels was detected between patients with or without oviductal patency ($p = 0.029$).

Limitations, reasons for caution: As this study aimed to detect pain levels caused by misinformation and/or false preconceptions, further research is needed to confirm if patients' anxiety levels can be reduced by the provision of information based on our findings.

Wider implications of the findings: As nearly a half of patients without oviductal patency reported the pain to be lower than expected, it may be possible to reduce anxiety levels by providing precise information, especially to patients who are reluctant to undergo hysterosalpingography, due to their excessive anxiety about pain.

Trial registration number: Not applicable.

P-499 "Your Fertility" – evaluation of a health promotion program to improve awareness of factors that affect fertility

L. Johnson[1], K. Hammarberg[1], E. Crocker[1], S. Robertson[2], R. Norman[2], R. McLachlan[3], M. Deeks[4]
[1]*Victorian Assisted Reproductive Treatment Authority, Victorian Assisted Reproductive Treatment Authority, Melbourne, Australia*
[2]*Robinson Research Institute, Robinson Research Institute, Adelaide, Australia*
[3]*Monash University, Andrology Australia, Melbourne, Australia*
[4]*Jean Hailes for Women's Health, Jean Hailes for Women's Health, Melbourne, Australia*

Study question: Can a health promotion program improve awareness of potentially modifiable factors that affect fertility?

Summary answer: Data collected over five years indicate that the Your Fertility' program meets a need for targeted, evidence-based, accessible fertility-related information.

What is known already: Knowledge among people of reproductive age about the factors that influence fertility and reproductive outcomes, including ART outcomes, is generally low. The most important factors affecting fertility are parental age, smoking, obesity, and mistiming of intercourse. It

is estimated that 50% of subfertility could be avoided if these risk factors were eliminated. Initiatives to improve awareness about the limitations of the reproductive life span and the impact of health behaviours, including how fertility can be optimised by timing intercourse to coincide with the fertile window, are needed.

Study design, size, duration: Your Fertility' is a health promotion program funded by the Australian and Victorian governments which aims to improve awareness among people of reproductive age and primary health care providers about the potentially modifiable factors that affect fertility and reproductive outcomes. To identify knowledge gaps and guide program development and implementation, qualitative and quantitative formative community research was conducted at program initiation in 2011. Program reach was evaluated over 5 years.

Participants/materials, setting, methods: Collation and analysis of data collected including website activity, social media engagement, health care professionals' uptake of educational activities, and traditional media coverage.

Main results and the role of chance: The formative research revealed considerable knowledge gaps about factors that affect fertility and reproductive outcomes. Factors including age, weight, smoking, alcohol consumption and timing of intercourse were targeted in the development of information materials and informed the dissemination strategy. To optimise reach, information materials and resources were disseminated through a dedicated website, social marketing, media, public relations, and health professional organisations. The Your Fertility' website is the first non-commercial website listed in a Google search. Since its launch in 2011 the annual number of visits to the website has grown exponentially and reached more than 2.6 million in 2015. Over the five years more than 68 million people have been reached through social media campaigns and the most commonly accessed resource is a guide to when in the menstrual cycle a woman is most likely to conceive (almost 5 million views). More than 4,000 health professionals have undertaken training modules on fertility awareness and pre-conception health which are available on the website. Based on published audience figures the number of people who were exposed to information about Your Fertility' through traditional media reached over 86 million.

Limitations, reasons for caution: It is not possible to know if those who access information through the program change their behaviour and thereby improve their fertility. It is also acknowledged that factors beyond personal control affect fertility, such as medical conditions and not having a partner, and these may not be amenable to change.

Wider implications of the findings: The knowledge gaps identified in formative community research and the extensive reach and use of the resources offered by the Your Fertility' program confirm that it meets a need for public and health professional education about the impact of age and health behaviours on fertility and reproductive outcomes.

Trial registration number: Not applicable.

P-500 "The IVF nurse" in infertility care in Italy: a pilot study

M.G. Massimiani[1], C. Becattini[1]
[1]*Futura Diagnostica Medica PMA, IVF Unit, Firenze, Italy*

Study question: Nurse can represent an additional resource both for the doctor and for the couple in infertility work-up.

Summary answer: The relationship with nurse permit explanation of doubts, improve the terapeutic communication "couple – doctor – nurse", determining an appropriate and effective pathway of care.

What is known already: Nurse autonomy is a recent achievement in Italy. The idea that exist or there may be a "nurse consultation" scare the insiders and is perceveid as an illusion. In this sense, in Italy, a clear and definite "nurse moment" is not provided in infertility. As a consequence, there are only daily limited time sessions, basically telematic, regarding injection administration, but not helpful for establishing a deep communication with the couple.

Study design, size, duration: This observational cohort study of the duration of six months from January to June 2015 was conducted on 150 couples applied to "Futura Diagnostica Medica PMA" in Florence, for infertility problems.

Participants/materials, setting, methods: The 150 couples was sorted out into 2 groups: Group A: 100 couples, only standard medical consultation.

Group B: 50 couples, nurse consultation following the standard medical consultation. Couples in group B have been enrolled according to infertility nurse availability.

The nurse consultation lasted 30/40 min with slide presentation on infertility techniques and medicine administration; at the end a semi-structured questionnaire on quality's perceived by the couple was administered.

Main results and the role of chance: Assessment survey on couples of group B has demonstrated:

Empathic communication: 90%
Evidence of displayed materials: 95%
Doubts persistence: 30%
Request for additional written material: 25%.

Furthermore, the sample (A + B) was evaluated during the following IVF treatment through a retrospective analysis of clinical record regarding the following items:

Errors during therapy administration: A (2%), B (0%)

Proper competence towards medical procedures (oocyte collection, embryo transfer, testicular sperm retrieval): A (95%), B (99%)

Following telematic contact with medical staff >**2**: A (85%), B (42%)

Following telematic contact with nurse staff >**2**: A (73%), B (55%)

Limitations, reasons for caution: The study has two limitations, the modality of recruitment of patients and the limited size of the sample examined.

Wider implications of the findings: Our study shows that "nurse consultation", in infertility couples, is appreciated by the patients, reduces the rate of errors during treatment and allows optimization of human resources in the IVF centre, combining the different skills of the staff.

Trial registration number: None.

P-501 Sustainable development of nursing internet platforms in the field of reproductive medicine

M. Deng[1], L. Luo[1], Y. Liang[1], H. Qin[1], L. Zhou[1]
[1]*The First Affiliated Hospital of Sun Yat-sen University, Department of Reproductive of Medical Center, Guangzhou, Guangdong, China*

Study question: To explore whether the nurse–patient communicating online platform can improve efficiency and quality of nursing service in the field of reproductive medicine.

Summary answer: Online platforms can improve nursing efficiency and quality, and provides a new way for sustainable development of nursing system in the field of reproductive medicine.

What is known already: Network technology has been developed to an unparalleled extent in 21st century, and also healthcare industry is stepping in an informatization age. Internet platform is undoubtedly a favorable way for communication between hospital and patients. It has become a new concern for special nursing personnel in reproductive medicine area that in which way internetwork can be utilized in the new environment to carry out patient health education, promote nurse–patient communication and provide convenient, simple and effective nursing care for patients.

Study design, size, duration: A questionnaire survey was conducted with 517 follow-up patients in our reproductive medical center from May to June of 2015, in order to investigate the utilization of various internet service platforms and patients' satisfaction, aiming at providing reference for the exploration of multiform health education and other special nursing models.

Participants/materials, setting, methods: Internet service platforms were utilized since 2010 in our reproductive center, including department website, QQ (an online-chat software) groups for doctor–patient communication and public WeChat platform (a mobile APP). Major content of the questionnaire composed of 10 choice questions, including awareness and basic usage of various informationization service platforms; which platform was selected separately for appointment register as well as acquisition of assisted reproduction knowledge, satisfaction with the use of various platforms, etc.

Main results and the role of chance: The average age of participating patients was 31.4 years; the average infertility duration was 5.0 years. The survey findings revealed that patients had high awareness rate and usage rate of network service platforms already built by the reproductive center. The WeChat platform of the reproductive center held the highest awareness rate (88.6%) followed by the website of the reproductive center (84.1%). The WeChat platform had the highest usage rate, being 77.4%. Hospital visit appointment with new informationization service platforms was 49.4%, which had exceeded traditional appointment mode. A majority (62.5%) of patients obtained relevant information through the WeChat platform. This figure had far exceeded traditional method of newspaper and magazines (3.5%). Most patients thought WeChat service platform was the most convenient one to use (60.3%) and also the most useful

one for information acquisition (62.4%). In this survey, most patients expressed their satisfaction with various network service platforms of the center. The overall satisfaction rate was over 70%.
Limitations, reasons for caution: Differences in region, education degree and economy situation can result in differences in ability of using information technology, which therefore may give rise to bias of our result.
Wider implications of the findings: In China, network service platforms of the reproductive center are still in an exploratory stage. How to further use of network service platforms and encourage patients actively utilize network platforms is the focus of continuous development. Nursing in reproductive medicine should fully use network resources to realize high-quality nursing.
Trial registration number: Empty.

P-502 Poor semen quality and effect on masculinity, and on couple and family formation

R. Sylvest[1], J. Fürbringer[1], A. Pinborg[1], J. Bogstad[1], L. Praetorius[1], K. Loessl[1], L. Schmidt[2]
[1]*Copenhagen University Hospital Hvidovre, Department of Obstetrics/Gynaecology, Hvidovre, Denmark*
[2]*University of Copenhagen, Department of Public Health, Copenhagen, Denmark*

Study question: How does poor semen quality affect the masculinity, the couple and their thoughts of family formation?
Summary answer: The low semen quality was threatening the men's masculinity. The participants focused on their primary plan to conceive and have their own biologically children.
What is known already: Infertility concerns both the woman and the man. There is a limited knowledge on how male factor infertility affects the couple in fertility treatment. For men who perceive fatherhood as an important part of their masculinity, male infertility can have significant negative effect on their sense of masculinity. Fertility and masculinity seem to be closely related and to play an important role in the male identity.
Study design, size, duration: Longitudinal, semi-structured qualitative interview study including ten men with very poor semen quality undergoing ICSI-treatment. Participants were interviewed before and after their first ICSI-treatment attempt. The data collection took place between November 2014 and May 2015.
Participants/materials, setting, methods: The participants were assigned to fertility treatment at the Fertility Clinic, Hvidovre Hospital, Copenhagen, Denmark. A total of 15 men were contacted out of which five men declined participation. Ten men were interviewed before their first ICSI treatment attempt, and five men participated in the follow-up interview. The interviews were audiotaped and transcribed in full. Data were analyzed using qualitative content analysis following Graneheim and Lundman.
Main results and the role of chance: The following main themes were found: "Masculinity," "The couple as a patient," and "Different pathways for family formation." The men felt that they were not able to do what a man was supposed to do, and they felt like less of a man. They showed their masculinity by being the protecting and strong partner in their relationship. The men wanted to be addressed individually and not just as a pendant to their partner. More couples had had conflicts and discussions because the women in general wanted to talk more about infertility than the men did. However, they still had many thoughts concerning unsuccessful treatment. The men focused on the goal to have their own biological child. They wanted to push a decision of adoption or donor a side. If it later on should turn out that they would have to use donor, adoption or live without children, then it was a different chapter; a chapter they preferred to postpone. The men wished to focus on their current situation.
Limitations, reasons for caution: A limitation of the present study was the risk of selection bias. In the follow-up interview only five out of the ten men agreed to participate, mainly because it was to stressful for them to be in treatment.
Wider implications of the findings: Fertility staff should create a space and give their patients an opportunity to verbalize their concerns and questions related to male infertility and the different challenges the couple will face in the treatment. Patients need the staff to offer information about how their poor sperm quality could affect their lives.
Trial registration number: None.

POSTER VIEWING SESSION

PSYCHOLOGY AND COUNSELLING

P-503 Evaluation of the quality of life (QoL) of infertile patients in the public health sector in Chile

I. Furman[1], V. Charlin[2]
[1]*Instituto de Investigación Materno-Infantil, Hospital Clinico San Borja Arriarán, Santiago, Chile*
[2]*V.C. Consultants, Consulting, Santiago, Chile*

Study question: What is the infertility-specific QoL as perceived by patients in the Chilean public health system? Does it fluctuate according to different bio-demographic variables?
Summary answer: QoL for patients with primary infertility was significantly lower. Couples in rural areas reported better QoL regarding personal issues, but worse satisfaction with medical services.
What is known already: Infertility and its treatment are known to produce significant emotional distress and a reduction in personal well-being. The scientific literature provides substantial evidence of these negative effects. The Fertility Quality of Life Questionnaire (FertiQoL et al., 2011) was developed to measure quality of life that is specifically associated to infertility in a single international instrument and has been applied mostly in English speaking/European populations. Little is known about the quality of life of infertile patients in developing countries, where cultural norms on reproduction and family-building are presumably more traditional and access to reproductive treatment more limited.
Study design, size, duration: Descriptive, cross-sectional study conducted at the Instituto de Investigación Materno Infantil, Hospital Clínico San Borja-Arriarán, Universidad de Chile, from May through November 2015. This institution is a government-appointed national center providing first-line and assisted reproduction treatments of infertility covered by public funding. In Chile 72% of the population is under care of public health services. Participation in the study was voluntary and anonymous.
Participants/materials, setting, methods: The complete FertiQoL (in certified Spanish version) was applied to 132 patients (40 men and 92 women) upon enrollment in the *in vitro* fertilization program and prior to initiating treatment. Scoring scales range from 0 to 100, representing an increasing quality of life. In addition, bio-demographic data were collected. Subgroups were compared using independent *t*-tests and one-way analysis of variance where appropriate.
Main results and the role of chance: No significant differences were found in FertiQoL scores as a function of age, gender (though men overall scored higher), educational level, and duration of infertility. However, significant differences were observed as a function of parity and cause of infertility: patients with secondary infertility scored higher than patients with no previous children (overall mean scores 73.9 and 65.9, $p < 0.001$) and patients with combined aetiology scored significantly lower on the CORE domain (emotional and social issues) than those with other aetiologies (mean scores 63.0 and 74.4, $p < 0.01$). In addition, patients from rural areas scored significantly higher than patients from urban areas (75.6 and 68.1, $p < 0.01$) in the CORE subscale, but significantly lower (57.8 and 64.8, $p < 0.05$) on the TREATMENT subscale (satisfaction with medical issues). All groups uniformly assigned the highest score to the RELATIONAL domain (marital satisfaction). The lowest score was systematically assigned to the ENVIRONMENT domain (quality of clinical services). The correlations between domains and total scores of FertiQoL were positive and statistically significant, with the exception of ENVIRONMENT which did not correlate significantly.
Limitations, reasons for caution: The relatively moderate size of the sample may limit the generalization of results (small aetiology categories). The present data are part of an ongoing, larger scale study to be completed during 2016. These data provide no information about infertile patients' perception of quality of life in private clinics.
Wider implications of the findings: This study provides useful cross-cultural information about patients' experience of infertility and its impact on quality of life. It contributes to the validation of FertiQoL in a Latin American

Spanish-speaking country. It offers specific evidence on: men's experience, infertility aetiology, existence of previous children, and is based on clinical recruitment.
Trial registration number: N/A.

P-504 Freezing their fantasies? Linking what we know of "circumstantial (social) childlessness" with an increasing demand for social egg freezing

L. Tonkin[1]
[1]*University of Canterbury, Health Sciences, Christchurch, New Zealand*

Study question: How do women articulate their experience of loss, grieving and the impact of "circumstantial childlessness" in their daily lives?
Summary answer: "Circumstantially childless" women had vivid fantasies of themselves as mothers and the child(ren) they anticipated having, and these had significant material effects in their lives.
What is known already: The incidence of unintentional childlessness in women who have "left it too late," is rising markedly, but women's psychosocial experience of it is little researched and is not well understood. There are no known previous studies of the sense of loss these women experience, what is understood to be "lost," or the grieving and adaptations they make to the likelihood that their fantasies of motherhood and a child may not be embodied. The implications for the take-up of oocyte cryopreservation is not known.
Study design, size, duration: A qualitative psychosocial study carried out over 3 years across four sites in New Zealand. 28 "circumstantially childless" women aged between 32 and 52 were interviewed individually, and 13 of those women also took part in a semi structured group interview. The study was designed in such a way that a grief response was not presumed.
Participants/materials, setting, methods: Participants were interviewed in a variety of settings. Semi structured individual interviews, group interviews, and an innovative participant-produced drawing exercise, used as part of the group interview, were used to collect data. Narrative, thematic and visual analytical methods were employed.
Main results and the role of chance: The psychosocial methods employed were very effective at collecting data rich in affect and complexity. Central themes that emerged were loss, isolation, a sense of being marginalised, and an ongoing disenfranchised grief that pervaded their daily lives. An unexpected result was the extent to which these circumstantially childless women had often very vivid fantasies of the mother they see themselves becoming, and the child(ren) they want(ed) to have. The loss they grieved was the inability to embody these fantasies. Women had named their (hoped-for) children, bought clothes and toys for them, and planned their major aspects of their lives around their dreams of becoming a mother. The intensity and material effect of these fantasies on their daily lives has important implications for family creation, the reproductive choices circumstantially childless women make, for their take-up of technologies such as IVF or oocyte cryopreservation, for women's wellbeing, and for counselling in clinics. A further study is now in planning to investigate how women conceptualise their frozen eggs; is this a matter of "freezing time," as it is currently understood, or may these frozen oocytes be invested with the fantasies of a maternity and a child?
Limitations, reasons for caution: This was a small study, whose aim was to generate rich qualitative data. The results are not able to be generalised across a wider population.
Wider implications of the findings: The study has implications for the growing popularity and promotion of oocyte cryopreservation. How might "circumstantially (socially) childlessness" women who use (or plan to use) oocyte cryopreservation conceptualise their "frozen eggs" and what are the implications for family creation, storage and disposal of "unwanted" eggs, and women's wellbeing?
Trial registration number: Not applicable.

P-505 Attitudes towards "social egg freezing" from a socio-cultural perspective

M. Schick[1], R. Sexty[1], B. Ditzen[1], T. Wischmann[1]
[1]*Institute of Medical Psychology, Center for Psychosocial Medicine, University Hospital Heidelberg, Heidelberg, Germany*

Study question: Goal was to investigate the relationship between fertility knowledge and attitudes towards "social egg freezing" as an impact of different socio-cultural backgrounds ("milieus") in Germany.
Summary answer: There are distinct differences between attitudes toward "social egg freezing" and socio-cultural backgrounds, age cohorts, family status, education, fertility problems – but not fertility knowledge.
What is known already: The tendency to delayed parenthood is still on and driven by the availment of (early) reproductive techniques for planning parenthood in the future. The so-called "social egg freezing" stands for the cryopreservation of a woman's oocytes for non-medical purposes. Since "social egg freezing" is a relatively new and originally for cancer patient designed reproductive procedure, it stirs up many ethical, political and social debates. Until now, there are only few studies investigating social–psychological aspects and attitudes of "social egg freezing." Studies regarding fertility awareness and fertility knowledge as displayed by different socio-cultural backgrounds are missing.
Study design, size, duration: A quantitative online study was devised, approved by the Ethics Committee of the Heidelberg Medical Faculty. The study took place from April to June 2015 with $N = 643$ participants.
Participants/materials, setting, methods: Participants completed a questionnaire with items regarding fertility-specific knowledge and attitudes toward social egg freezing, partly derived from an already tested questionnaire in Belgium (Stoop et al., 2011). Furthermore, items indicating specific milieus from the German DELTA-Institute for Social and Ecological Research as various sociodemographic questions, e.g., family status or fertility problems, have been raised. Data were analyzed using correlation, regression, independent *t*-test analysis and ANOVA.
Main results and the role of chance: In total, $N = 553$ woman (Ø age: 34.2) and $N = 90$ men (Ø age: 37.8) participated in the study. Fertility problems were reported by 34.3% women and 12.5% men; 38.5% women and 33.3% men already had children. Of all participants, 69% were university graduates. The Delta milieus consist of two axes: social stratum (e.g., upper class) and basic orientation (common traditions, self-realization, self-management). The milieus "Postmaterielle," "Performer," and "Expeditive" (middle to upper class, mainly self-realization and self-management) were disproportionate high, while the delta milieus "Traditional," "Disadvantaged" and "Hedonists" (lower to middle class, mainly common traditions and self-realization) were disproportionately low distributed. There were distinct differences between attitudes toward "social egg freezing" and various age cohorts, family status, educational achievement, fertility problems and socio-cultural backgrounds. In the context of fertility specific knowledge, only 15% of all participants were able to answer correctly more than half of the questions. However, there was no correlation between fertility specific knowledge and distinct socio-cultural backgrounds or attitudes towards "social egg freezing."
Limitations, reasons for caution: Generalization of findings is limited due to the nature of online surveys, above-average existence of fertility problems and high educational background of participants as unequal participation from people of different socio-cultural backgrounds.
Wider implications of the findings: The investigated differences subject to socio-cultural backgrounds suggest a concerted research to acquire a better comprehension of notions and expectations in the field of desire of children in the German society to develop focused educational interventions. Furthermore, the little knowledge of reproductive methods indicates information deficits needful to be dissolved.
Trial registration number: No clinical trial.

P-506 Infertility related communication and coping strategies among women affected by fertility problems in Sweden

T. Sormunen[1], M. Westerbotn[1], A. Aanesen[2], K. Karlgren[3]
[1]*Sophiahemmet University, Department of Clinical Science and Education, Karolinska Institutet, Stockholm, Sweden*
[2]*Sophiahemmet Hospital, Sophiahemmet University, Stockholm, Sweden*
[3]*Karolinska Institutet, Department of LIME, Stockholm, Sweden*

Study question: The aim was to describe infertility related communication and coping strategies among women affected by fertility problems in Sweden.

Summary answer: Thirty percent of participants had difficulties discussing infertility related subjects with their husband or with close other people, and they avoided socializing with pregnant women.
What is known already: Involuntary childlessness is a reality for many reproductive aged couples and can be psychologically stressful for many of them. The inability to have children affects couples worldwide and causes psychological and emotional distress on them. Both involuntary childlessness and infertility treatment places pressure on those involved. Difficulty in marital communication and high use of active-avoidance coping are significant predictors of high fertility problem stress.
Study design, size, duration: A case control study design involving 199 Swedish women (mean age 36.3). The participants received a letter regarding information of the study including the questionnaire and a postage-paid reply envelope. Data was collected during January to May 2012. Approval from the Ethical Review Board, Stockholm (EPN 2006/1025-31; EPN 2009/5:9) was obtained.
Participants/materials, setting, methods: The population consists of women with history of primary infertility, minimum of 1 year, which sought to a fertility clinic voluntarily or was referred from other clinics. A self-administered semi structured questionnaire inspired by (COMPI) was used to collect the data. Descriptive statistical methods were used to analyse the data.
Main results and the role of chance: Response rate was 66%. Seven percent of the population did not discuss the inability to have a child, and 9% did not discuss about reasons why they were childless at all with their spouse. Seventy-five percent discussed infertility related subjects only to close other people and 20% did not discuss about the results of examinations and tests with people outside of the family. Thirty-five percent did not ask other childless individuals, friends or relatives for advice and 15% were not able to discuss about how tests and treatments affect them emotionally. Twelve percent reported that they leave the room when the subject children or pregnancies are discussed.
Limitations, reasons for caution: Participants were recruited from one infertility clinic from great Stockholm area. The population consists of 199 participants and 84% of them had postgraduate education.
Wider implications of the findings: By highlighting possible problems with infertility relating communication, physicians, midwifes and nurses at fertility clinics may become aware of this problem and therefore dare to address the question. This knowledge may ensure high quality of care, improve patient wellbeing and possibly higher treatment compliance.
Trial registration number: –

P-507 Oocyte vitrification to postpone maternity: a good medical option that is at present incompatible with social and economic conditions in Spain

M. Lopez-Teijon[1], J. Sunol[1], F. Moffa[1], V. Walker[1], E. Velilla[1]
[1]*Institut Marques, Reproductive Medicine Service, Barcelona, Spain*

Study question: The objective of this study was to ascertain whether or not fertile women attending a gynaecologist are aware that oocyte vitrification exists and would consider it personally as an option to delay pregnancy.
Summary answer: Young women would not choose to freeze their oocytes. Older women would but are too old to benefit from vitrification. Better patient advice is needed.
What is known already: When maternity is delayed the possibility of falling pregnant reduces drastically and there is an exponential increase in both the possibility of conceiving a chromosomally abnormal fetus and of needing egg donation. Until now freezing oocytes by the slow cooling method gave a low chance of oocyte survival at defrosting and of clinical pregnancy. With the development of vitrification the clinical prognosis for vitrified oocytes has become comparable to that of fresh oocytes.
Study design, size, duration: 200 patients attending a routine annual gynaecological check-up between January and April 2015 were asked to complete a survey. They were of the right age to be considered potential candidates for oocyte vitrification due to social reasons.
Participants/materials, setting, methods: Of the 200 women surveyed, 182 completed the questionnaire correctly. The age ranges were: 6.1% (18–24 years), 21.5% (25–29 years), 37.5% (30–34 years), 33.7% (35–39 years), and 1.1% (40–44 years). They were asked if they wanted to become mothers and regarding social and financial issues that could affect that decision. Although they wanted some in the future, 63.5% did not have children.
Main results and the role of chance: 68% had heard of oocyte vitrification, 16% indicated they wanted to do this (independently of whether or not they already knew of the technique) but only 22.1% said they would be willing to pay for it. 44% said they would freeze eggs between the ages of 35 and 39. The main reasons given for not having children were based on the current difficulties in finding a stable job, and the little financial help received with maternity care. Finally they also expressed difficulty in finding a stable partner.
Limitations, reasons for caution: No limitations.
Wider implications of the findings: An important discrepancy exists between medical advances and society's response: the younger women surveyed would not freeze their eggs, women who would consider it were older, and few would proceed if there were additional costs. We need more effective ways of informing women who would benefit most from this technique.
Trial registration number: –

P-508 Hope and psychological symptoms in infertile couples undergoing assisted reproduction treatment

B. Navid[1], S. Vesali[2], R. Omani Samani[2]
[1]*Tehran, Iran*
[2]*Royan, Epidemiology, Tehran, Iran*

Study question: How are hope, depression, anxiety and stress levels among three groups of infertile couples undergoing infertility treatment?
Summary answer: The level of hopelessness was higher in infertile wives than their husbands, while it was not significantly different among females or males.
What is known already: When infertility treatment takes a long time, or failure occurs, infertile patients more likely face hopelessness. The loss of hope to have a child is important because hope is one of the main psychological needs. Previous studies investigated psychological moods in infertile patients and showed that infertile women experience higher psychiatric disorders, especially anxiety, depression, stress, than their partners. Currently, there was no research to quantitatively examine the utility of Snyder's theory of hope in patients suffering from infertility.
Study design, size, duration: A cross-sectional survey was conducted on infertile couples referred to the Royan institute, a referral infertility clinic in Tehran, the capital of Iran, between 2013 and 2014.
Participants/materials, setting, methods: Participants consisted of three groups of infertile couples: 60 couples candidate for oocyte donation, 60 couples candidate for embryo donation, and 60 couples of normal infertile. The mean age was 32.94 ± 4.74 years in men, and 29.39 ± 5.09 years in women. Participants completed three questionnaires: the demographic questionnaire, the Adult Trait Hope Scale by Snyder, and Depression Anxiety Stress Scale (DASS) by Antony et al.
Main results and the role of chance: The mean score of hope was significantly higher in husbands than wives in the normal infertile group ($p = 0.046$). There was no significant difference in male patients ($p < 0.148$), as well as in female patients among three groups studied ($p < 0.735$). No significant difference was seen in the mean score of agency between wives and husbands in each group. In all groups, no significant difference was also observed in male and female patients. In the normal infertile group, the mean score of pathway was significantly higher in husbands ($p = 0.032$), and there was no significant difference in male and female patients among three groups. The distribution of depression was significantly different in male subjects among all groups ($p = 0.01$). The frequency of anxiety (normal, slight, medium, severe, and very severe) was significantly different in female subjects ($p = 0.028$). In the normal infertile group, the distribution of anxiety was significantly different between wives and husbands ($p = 0.006$). The frequency of stress (normal, slight, medium, severe, and very severe) was significantly different in male subjects ($p = 0.048$). In the embryo donation group, stress was significantly different between wives and husbands ($p = 0.002$). In the normal infertile group, stress was significantly different between wives and husbands ($p = 0.05$).
Limitations, reasons for caution: Because this study was cross-sectional, no conclusions on causality were inferred. We relied on patients coming to only one center, which is a referral clinic for infertility. This limits the generalize ability of the findings.

Wider implications of the findings: This was the first study to examine Snyder's construct of hope in special samples of infertile couples, the results suggest that hope may be important in reducing psychological symptoms in infertile couples. It is suggested to hold psychological counseling sessions (hope therapy) to all patients during assisted reproduction treatment.
Trial registration number: None.

P-509 Social oocyte cryopreservation: a portrayal of Brazilian women

E. Espirito Santo[1], F. Dieamant[1,2], C.G. Petersen[1,2], A.L. Mauri[1,2], L.D. Vagnini[2], A. Renzi[2], G.R. Oliveira-Pelegrin[2], C. Zamara[1], M. Cavagna[1,2,3], J.B.A. Oliveira[1,2], R.L.R. Baruffi[1,2], J.G. Franco Jr[1,2]
[1]Centre for Human Reproduction Prof Franco Jr, Research, Ribeirao Preto, Brazil
[2]Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil
[3]Women's Health Reference Center Perola Byington Hospital, Research, Sao Paulo, Brazil

Study question: Would childless women at reproductive age consider oocyte cryopreservation to postpone childbearing? What are their reasons for not doing so now?
Summary answer: Most participants consider safeguarding their reproductive potential. The high cost of the procedure is the main obstacle preventing an oocyte cryopreservation cycle.
What is known already: Recently, the Brazilian Ministry of Health announced that Brazilian women are having fewer children and much later in life. This is possibly due to recent media coverage about age-related infertility; women have gained substantial knowledge about the speed of fertility decline. Women who are aware of the limited female reproductive lifespan have the power to determine and plan their reproductive future. As a consequence, oocyte cryopreservation can now offer women some protection against the decline in fertility associated with aging. However, until now, no study has examined the motivations of Brazilian women with regards to social oocyte cryopreservation.
Study design, size, duration: Women at reproductive age who were randomly selected from the general population using different e-mail lists were contacted by e-mail and invited to participate in the study by completing an online web survey regarding social oocyte cryopreservation. Participants who answered yes when asked if they have had children were automatically excluded from the study. The survey was performed from May 2015 to November 2015. There was no incentive for completing the survey.
Participants/materials, setting, methods: Questionnaires from 444 childless women ($\mu = 33.5$ year; 17–44) were included. Incomplete questionnaires were eliminated. Sixty-six percent (295/444) of women were university educated. Data management and analysis were conducted using StatsDirect statistical software. A multivariate logistic regression analysis was performed to identify the factors affecting the women's decision regarding oocyte cryopreservation.
Main results and the role of chance: Although most of our responders have a partner (86.9%; 386/444) and have already planned the pregnancy of their first child (69.6%; 309/444), 85.4% (379/444) considered the potential of social oocyte freezing to improve their chances of giving birth later in life. Those that had already planned pregnancy were 2 times more likely to freeze their oocytes (OR: 1.95; 95% CI 1.06–3.60; $p = 0.03$). An increase in wage level increased the odds of oocyte cryopreservation by 24%. The most important barrier for not undergoing oocyte cryopreservation was the cost. The women who indicated that they could not currently undergo the procedure now due to cost had a 2-fold (OR: 2.1; 95% CI 1.07–4.04; $p = 0.03$) greater intension to cryopreserve their oocytes than women who thought that they would not need to delay pregnancy. The study population had negative views about receiving a sperm donation even if that were the only alternative for them to become mothers (63% not accept; 280/444).
Limitations, reasons for caution: Our study population is characterized by a higher educational level and a reasonable standard of living.
Wider implications of the findings: Brazilian women who think that they are not ready to have a family are discovering the option to cryopreserve their oocytes. Making the procedure more accessible could provide more women with the opportunity to make proactive decisions about the future of their fertility.
Trial registration number: Not applicable.

P-510 The association between the psychological assessment scores and stress biomarker levels on the clinical outcomes of women undergoing ART treatment

C.W.C. Cheung[1], S. Saravelos[1], T.Y.A. Chan[2], T.C. Li[1]
[1]The Chinese University of Hong Kong, Department of Obstetric and Gynaecology, Shatin, Hong Kong
[2]The Chinese University of Hong Kong, Department of Psychology, Shatin, Hong Kong

Study question: Are psychological assessment scores and salivary alpha amylase (sAA) levels at the time of embryo transfer (ET) procedure associated with the clinical pregnancy rate of women undergoing ART treatment cycles?
Summary answer: sAA level and psychological questionnaires were not associated with pregnancy rate. sAA levels were significantly correlated with age, Fertility Problem Inventory (FPI) and Perceived Stress Scale (PSS).
What is known already: Previous studies have shown that increased levels of the stress biomarker (sAA) are associated with a longer time-to-pregnancy and infertility in unselected women. However, although there has been data to support that psychological stress may influence ART outcomes, sAA levels have never been examined before within the ART context.
Study design, size, duration: Prospective observational study of 54 consecutive women undergoing IVF/ICSI cycles between September 2015 and January 2016.
Participants/materials, setting, methods: Sample for sAA levels were collected using dedicated Salivettes immediately before and after ET. Women also completed questionnaires on the day of ET, aimed at assessing (i) fertility stress/concerns (FPI), (ii) psychological stress [visual analog of stress (VAS-S), perceived stress scale (PSS), state trait anxiety inventory (STAI)], and (iii) general psychological health [general health questionnaire (GHQ), Beck depression inventory (BDI)]. All women were followed up for 12 weeks after the ET to determine clinical outcomes.
Main results and the role of chance: Fifty-two women successfully completed the study protocol. There were no significant differences between pregnant and non-pregnant women in the mean ± SD of the following: sAA levels (166,500 ± 115,498 versus 161,769 ± 122,482), FPI (143.7 ± 20.2 versus 136.7 ± 23.8), VAS-S (60.5 ± 21 versus 53.7 ± 24.9), VAS-P (8.6 ± 10.4 versus 8.52 ± 14.9), PSS (15.5 ± 4.8 versus 15.4 ± 3.7), STAI scores (41.2 ± 11.2 versus 42.7 ± 10.1), GHQ (25.5 ± 5.3 versus 26.7 ± 4.8).

However, there was a significant positive correlation between sAA and maternal age (Pearson Correlation 0.319, $p = 0.019$), FPI for social concern scores (Pearson Correlation 0.404, $p = 0.005$), FPI for relationship concern scores (Pearson Correlation 0.392, $p = 0.007$) and PSS scores (Pearson Correlation 0.314, $p = 0.023$).
Limitations, reasons for caution: Despite a strict study protocol for sAA sample collection, and the use of five comprehensive questionnaires, it is difficult to control for all the stressors that women undergoing ART may be exposed to, both related and unrelated to their treatment.
Wider implications of the findings: This is the first prospective observational study to examine the effect of psychological stress and biostress markers on pregnancy outcomes. Although it lacks of direct association with clinical outcomes, sAA appears to be significantly correlated to advancing maternal age, FPI scores for social and relationship concerns, and PSS scores.
Trial registration number: Not applicable.

P-511 Preferred roles in treatment decision-making, decisional conflict and depression: a longitudinal study of Chinese women making decisions on IVF treatment

C.H.Y. Chan[1], T. Chan[1], M. Tam[1], Q. Wong[1], E. Ng[2], C. Chan[1]
[1]The University of Hong Kong, Social Work and Social Administration, Hong Kong, China
[2]The University of Hong Kong, Obstetrics and Gynecology, Hong Kong, China

Study question: What is the relationship between decisional conflict and depression among women undergoing IVF treatment, and does role preference on treatment decision-making (TDM) moderate the relationship?
Summary answer: Decisional conflict at TDM led to higher-depression 3 months after decision, mediated by regret. Women preferring active TDM were less-depressed despite of conflict and regret.
What is known already: Infertility treatment is marked by open-ended nature, and patients need to decide whether to continue or terminate treatment when the current cycle fails. While there have been studies on treatment decision-making role preference among infertile women, little is known about the mental health consequences of such role preference across the time of treatment decision-making.
Study design, size, duration: A longitudinal study was conducted where infertile women indicated TDM preference at cycle failure (T0), decisional conflict when they decided on continuation/termination for next cycle (T1), and decision regret 3 months later (T2). They reported depression at 3 time points. 151 out of 246 women completed questionnaires (attrition rate: 39%). Mean age was 37.2, and they had had 1.12 cycles (range: 0–8) on average at the time of study. The study spanned for 2 years.
Participants/materials, setting, methods: The study population was comprised of Chinese female patients who failed to get pregnant in IVF treatment. They were recruited from a fertility clinic of a university-affiliated hospital in Hong Kong. Patients were approached after being notified about the negative pregnancy results. They were asked to complete scales on Fertility-Related Quality of Life and anxiety/depression across three time points and measures on role preference in treatment decision-making, decisional conflict, and regret at different time points.
Main results and the role of chance: Mediation analysis showed that the relationship between decisional conflict and depressed mood at T2 (controlling for depressed mood at T1) was mediated by decisional regret. Unstandardized direct effect between decisional conflict and depressed mood was 0.071 ($p < 0.001$), while indirect effect through mediation of decisional regret was found to be moderated by the role preference of treatment decision-making (TDM) (unstandardized indirect effect = 0.0002 and 0.0167 for passive and active TDM role preference respectively). Bootstrapping test confirmed that the mediation and moderation effects were statistically significant at 0.05 level. TDM role preference did not have significant effect on either decisional conflict or regret ($F = 0.10$ and 1.24 respectively, ns). Regret in IVF treatment can be interpreted as a consequence of preoccupation with comparing one's chosen treatment alternative to a second, non–chosen alternative. Decisional regret after making treatment-related decision becomes an important factor in addressing the psychological distress in terms of depression. Results have demonstrated another direction in healthcare communication regarding treatment decision-making.
Limitations, reasons for caution: Although there was no significant difference in age and education between those who completed the study and those who dropped out, self-selection bias remains a concern.
Wider implications of the findings: This study shows for the first time how treatment decision-making role preference leads to mental health consequences among women undergoing infertility treatment. Healthcare professionals should be aware of such preference and, when necessary, openly discuss issues of TDM conflict and possible regret regarding treatment decisions with clients.
Trial registration number: Nil.

P-512 Satisfaction with daily life and coping strategies in couple relationships and the psychoeducation of sexless couples (SLCs)

M. Hieda[1], T. Utsunomiya[1]
[1]*St.Luke Clinic, Oita, Japan*

Study question: Comparison of SLCs and a control group on satisfaction with daily and sex-lives, and the impact of stress, incorporating the results of psychoeducation for SLCs.
Summary answer: SLCs are not satisfied with their lives, lack of sex is therefore not a major problem. Psychoeducation is indicated as being effective in this situation.
What is known already: In general, Japanese couples do not consider that sex is an important part of a relationship. While this is a concept largely from social media, rather than from scientific research, the average low frequency of sex in Japan tends to support this assertion. Whenever SLC have been talked at first visit though, they say "We are satisfied with our daily life, and keep a good relationship." In fact, there is little evidence of a psychological impact on a couple's relation from the situation of no sex. However, this conflicts with the necessity to have sexual intercourse naturally to produce children.
Study design, size, duration: A questionnaire based survey was administered to 200 first visit couples seeking IVF intervention to have children at St Luke Clinic, from November 2014 to February 2015. Female patients were also given physical examinations, temperature checks, and tests for the state of their menstrual cycle. We also analyzed the frequency of sex. This is an important part of our research as it identified the sexless couples, along with the ethical considerations relating to fertility intervention.
Participants/materials, setting, methods: 200 couples were included in this investigation, which involved three kinds of questionnaire: the "GHQ-28 (General Health Questionnaire 28)," 4 items covering somatic symptoms, anxiety and insomnia, social dysfunction and severe depression; Kurosawa's "Relationship-Focused Coping for Couples (2013)," which includes 3 items for positive relations, concession and patience relations and avoidance relations; and an original questionnaire on their daily situation (22 items, about sex-lives, satisfaction, communication level, and so on).
Main results and the role of chance: 186 males and 172 females responded (response rate = 89%). Their ages were: wife (33.7 ± 4.5), husband (35.5 ± 5.7). Duration of marriage ranged from <166 months. Definition of "sexless" in this research is having sex less 1.5 times/month. This meant that 72 people (wife = 38, husband = 34) were classified as "sexless" couples. The reasons: for wives the problems were being more tired [physically ($t = 2.1$, $p < 0.05$), anxiety ($t = 2.2$, $p < 0.01$), and depression ($t = 0.6$, $p < 0.01$)] on GHQ-28, lower sexual desire (39.5%, $p < 0.01$), or a concern to have sex only to have a baby (47.1%, $p < 0.05$). SLCs were not satisfied with each other, and experienced much conflict (13.9%, $p < 0.05$). Thus, more SLCs indicated strongly that their level of sexual desire and motivation was low (26.4%, $p < 0.05$) than the control group (11.9%, $p < 0.05$). Also, SLCs do not have a positive physical relationship ($t = 18.1$, $p < 0.01$), tending to avoid ($t = 17.7$, $p < 0.05$) each other. Despite this, SLCs do not FEEL mental, or physical relationship problems (*n.s*). We stress the importance of sex at first visit, and we hold various types of seminars for patients as one of our policies, including counselling/psychoeducation for sexless couples. As a result, after 3 months the frequency of sexual intercourse increased to 3.8 times/month.
Limitations, reasons for caution: A couple's relationship and their social situation (busy) affects their sex-lives, but *sexless* may also be a mental condition. It is possible that their sex-life could recover if they have psychoeducation. However, physical sexual dysfunction may not recover using psychological means, and may be worse after IVF treatment is introduced.
Wider implications of the findings: SLCs coping ability on a number of personal dimensions is low. In this situation sex becomes work rather than pleasure. Also, SLCs do not communicate deeply even when discussing sex. We show that psychoeducation can increase the frequency of sexual intercourse even under IVF conditions, and improve their overall communication.
Trial registration number: N/A.

P-513 Depression and associated factors among Japanese women undergoing infertility treatment

Y. Akizuki[1], I. Kai[2]
[1]*Kumamoto University, Educational Department, Graduate School of Education, Kumaomto-shi, Japan*
[2]*The University of Tokyo, Department of Social Gerontology, School of Public Health, Tokyo, Japan*

Study question: This study aimed to clarify the prevalence of depression among infertile women in Japan and identify factors associated with depression among these women.
Summary answer: The prevalence of depression was higher among infertile women than other women in Japan and the associated factors differed somewhat from previous studies.
What is known already: Many previous studies have reported on the psychological health of infertile women, particularly in regards to depression. However, how depression relates to sociodemographic factors (such as age and level of education) and infertility- or treatment-related factors (such as duration of treatment, cause of infertility, and experience with IVF-ET or ICSI) has not

been thoroughly investigated. In particular, age and duration of treatment have been found to have different effects on depression in different studies. Moreover, consistent results have not been obtained regarding the effects of the cause of infertility and experience with ART on depression.

Study design, size, duration: We conducted a quantitative, cross-sectional questionnaire survey between November 2011 and January 2012. Questionnaires were distributed to 300 Japanese women who were undergoing infertility treatment at one clinic in the Kanto region of Japan. The head doctor at the clinic distributed questionnaires directly to patients and those who agreed to participate were asked to return completed questionnaires by postal mail.

Participants/materials, setting, methods: Completed questionnaires were returned by 206 women (response rate, 68.7%). Responses from patients who did not have a child and who had not been diagnosed with recurrent pregnancy loss were analyzed. Independent variables included sociodemographic factors, factors related to infertility problems and treatment, subjective feelings of stress, and attitude about disclosing infertility. The dependent variable was the score on the Center for Epidemiologic Studies Depression Scale (CES-D). Data were statistically analyzed using SPSS version 11.0.

Main results and the role of chance: The mean CES-D score was 13.19 ± 9.56, and 36% of respondents exceeded the depression cut-off of 16.0. Level of education was negatively correlated with the CES-D score. Duration of infertility treatment, the number of hospitals visited, stress associated with sex life, stress associated with schedule adjustment for treatment, and stress associated with physical malfunction were found to have significant positive correlations with the CES-D score. As a result of one-way ANOVA, attitude about disclosing infertility was found to be significantly associated with the CES-D score. Furthermore, multiple regression analysis revealed that stress associated with sex life, stress associated with physical malfunction and attitude about disclosing infertility were significantly associated with the CES-D score. Age and level of education had significant negative association with the CES-D score. However, duration of infertility treatment, the number of hospitals visited, and stress associated with schedule adjustment for treatment were not associated with CES-D in this analysis. Experience with ART and the cause of infertility were not related to CES-D in any analysis. The mean CES-D score in this study was higher than that for women in the general population, domestically and internationally. Some factors associated with CES-D in this study differed somewhat from previous studies.

Limitations, reasons for caution: Caution should be exercised when generalizing the results of this study because the response rate was only 68.7% and only infertile patients visiting a clinic were included as subjects. Therefore, it is possible that patients with poor psychological health did not participate to this study.

Wider implications of the findings: The present results suggest that in order to effectively support infertile patients, it is important for medical staff to understand the psychological status of patients and their age, level of education and perceived stress and so on.

Trial registration number: The protocol of this study was approved by the ethics review board of Shukutoku University in 2011 (approval number: N10-002).

P-514 Psychosocial counselling in donor sperm treatment: the counsellors practices

M. Visser[1], T. Gerrits[2], F. van der Veen[3], M. Mochtar[3]
[1]*Center for Reproductive Medicine Academic Medical Center, Amsterdam, Netherlands*
[2]*Sociology and Anthropology, University of Amsterdam, Faculty of Social and Behavioral Sciences, Amsterdam, Netherlands*
[3]*Center for Reproductive Medicine Academic Medical Center, Academic Medical Centre Amsterdam, University of Amsterdam, Amsterdam, Netherlands*

Study question: What do counsellors value in counselling intended parents in donor sperm treatment?

Summary answer: Counsellors combined screening and guidance, though they valued separate sessions. They raised different topics in different family types. Counsellors valued offering extended counselling after DST.

What is known already: In DST, counselling by qualified mental health counsellors is recommended to help intended parents in coping with the psychosocial implications of being a parent of donor-offspring. How counselors actually perform their counselling practices is unknown.

Study design, size, duration: We performed a qualitative study from January until September 2014 entailing 13 counsellors, who work in one of the eight Centres for Reproductive Medicine that offer DST in the Netherlands.

Participants/materials, setting, methods: We held one focus-group discussion with six counsellors and held seven individual semi-structured interviews with seven other counsellors. The focus-group discussion as well as the individual interviews were fully transcribed and analysed using the constant comparative method of grounded theory.

Main results and the role of chance: The counsellors had an average experience in counselling in DST of 8.2 years and had been trained as psychologist or as medical social worker. None had been specifically trained in DST counselling, but learned by practicing, by participating in congresses and from exchanging experiences with fellow counsellors. The policy of the clinics differed in whether or not offering counselling for heterosexual- and lesbian couples, but in all clinics but one counselling for single women was mandatory. The main topics that counsellors valued to discuss in all family types were assessment of mental health, stability of the relationship, future donor contact. Some counsellors valued to discuss in heterosexual and lesbian couples the position of the social parent. Especially in heterosexual couples they valued to discuss disclosure, and in single women their social network and economic situation. All counsellors offered intended parents extended counselling after DST, but experienced that when intended parents actually become parents, they seldom return for counselling. All counsellors felt that screening for eligibility and giving guidance and support in the same session restrained good guidance.

Limitations, reasons for caution: Limitations are the generalizability of our results, since only Dutch counsellors were studied and there is legal non-anonymity of sperm donors in the Netherlands, which is not common in all countries.

Wider implications of the findings: Our findings on what counsellors value in counselling in DST are a first step to contribute to achieve evidence based psychosocial counselling, which meets the need of (intended) parents. Whether parents wish any psychosocial guidance after treatment and childbirth and in what setting, is an essential issue needing further exploration.

Trial registration number: Not applicable.

P-515 Resilience influences on the outcome of IVF-ICSI

A.P. Llaneza[1], C. Ferrera[2], D. Llaneza-Suarez[3], M. Gonzalez[2], D. Fernandez-Garcia[4], P. De-La-Fuente[5]
[1]*Hospital Central de Asturias, Oviedo, Asturias, Spain*
[2]*Hospital Central de Asturias, Gynecology, Oviedo, Asturias, Spain*
[3]*CEFIVA, Biology Laboratory, Oviedo, Spain*
[4]*Quirinal CS, GP, Aviles, Spain*
[5]*CEFIVA, Gynecology, Oviedo, Spain*

Study question: Could women's Resilience have the capacity to improve IVF-ICSI outcomes ?

Summary answer: Higher resilience in infertile women undergoing IVF-ICSI cycles was positively correlated with women age and with Live Birth (LB) rate in IVF-ICSI cycles.

What is known already: Psychological resilience is an individual's capacity to prevent, minimize, or overcome stressful situations imposed by life adversity. Infertile women suffer from various psychosocial problems because of infertility and they adopt emotion-focused coping methods. Moreover IVF-ICSI treatments are characterized by high uncertainty and low personal control.

Resilient individuals feel confident they can overcome their emotions and resilience can be considered as an unspecific protective factor against infertility-specific distress. In addition adverse implications of couple's psychological distress for gamete biology and for IVF-ICSI outcomes has been suggested.

Study design, size, duration: A pilot cross sectional study of 75 women aged from 29 to 40 years during IVF-ICSI cycle was carried out between January and March of 2015 at the Asturias Central University Hospital (Oviedo, Spain) and *In Vitro* Fertilization Center of Asturias (CEFIVA), both affiliated with the University of Oviedo (Oviedo, Spain).

Participants/materials, setting, methods: Sixty-two infertile women were included in the study. Before starting the controlled ovarian hyperstimulation with a GnRH antagonist protocol, patients were asked to fill out an itemized general questionnaire (personal and partner sociodemographic data), the Connor Resilience Scale, the Center for Epidemiologic Studies Depression Scale (CESD-10)

and the 10 items Cohen Stress Scale. The research protocol of the study was reviewed and approved by the Asturias Ethical Committee, Oviedo, Spain.
Main results and the role of chance: Thirteen women decline to participate in the study or filled incomplete questionnaires, so the response rate was 82.7%. Oocyte retrieval mean was 8 ± 6.1 SD, fertilized oocytes mean was 5 ± 3.5 SD and single or double embryo fresh transfer were performed in 80% of cycles. Pregnancy rate was 36.8% and LB rate was 17.3%.

Total resilience values were positively correlated with women aged ($p = 0.02$). Mean resilience values were 32.4 ± 4.9 SD in women with LB and mean resilience values were 27.8 ± 4.8 SD in women with negative outcome ($p = 0.026$). In this sense, the probability of IVF-ICSI negative result was higher in women with lower resilience values OR: 2.4 (95% CI: 1.9–2.9).

Mean Cohen Stress Scale or CESD-10 questionnaires values did not show statistical differences in women with and without LB.
Limitations, reasons for caution: This is only a pilot study with a low statistical power due to the short sample size, so data must be managed carefully. Moreover the study design did not allow finding an exact explanation of the mechanism of action of resilience.
Wider implications of the findings: Our data partially agree with other research and suggest that identification of women with lower resilience values could be useful for planning the best IVF-ICSI strategy in order to obtain LB.
Trial registration number: N/A.

P-516 Self-efficacy to deal with infertility and its mediator role between anxiety, negative affect and impact on life domains

A. Galhardo[1,2], M. Cunha[1,2], J. Pinto-Gouveia[2]
[1]*Instituto Superior Miguel Torga, Psychology, Coimbra, Portugal*
[2]*Faculty of Psychology and Educational Sciences of the University of Coimbra, CINEICC, Coimbra, Portugal*

Study question: Does the perception of self-efficacy to deal with infertility have a mediator role in the relationship between anxiety, negative affect and impact on life domains?
Summary answer: The perception of self-efficacy plays a mediator role on the association between anxiety, negative affect and impact on life domains.
What is known already: The emotional impact of infertility has been widely studied but factors that may have a protective role have deserved less attention. Anxiety symptoms and negative affect are common emotional responses associated with infertility related stress, particularly when considering the dimension of "impact on life domains." The perception of infertility self-efficacy involves cognitive, affective and motivational self-regulation processes and establishes the appropriate skills for facing demanding situations. Previous studies have shown that infertile patients who show high self-efficacy tend to present more positive emotional status, persist with medical treatment or achieve a family-building resolution.
Study design, size, duration: Cross sectional study. Data were collected through self-report instruments in 4 public infertility centers and 3 private clinics between June 2010 and September 2012. Inclusion criteria were age (18 years or older), and an infertility medical diagnosis. The study was conducted in a sample of 309 infertile patients pursuing medical treatment.
Participants/materials, setting, methods: Three hundred and nine infertile patients (262 women and 147 men) completed a set of standardized self-report measures: fertility Problem Inventory, Spielberger State Anxiety Inventory, Negative Affect Scale and Infertility Self-efficacy Scale. Patients were invited to participate by their medical doctors, signed a written informed consent and were asked to fill in the questionnaires at home. Participants were also requested to return the questionnaires to the research team by mail.
Main results and the role of chance: Correlation analyses show that anxiety, and negative affect are significantly associated with infertility self-efficacy and infertility-related stress, namely the dimension "impact in life domains." A mediation analysis was conducted to examine whether the perception of infertility self-efficacy mediated the effect of anxiety and negative affect on the impact in life domains. Statistical analyses were carried out using SPSS v. 22, and path analyses were estimated in AMOS (v. 22) with bootstrap procedures (2000 samples). The model explained 40% of the impact on life domains of the infertility-related stress variance and an excellent model fit was found with a non-significant chi-square of 1.161 (df = 1, $p = 0.281$). All the paths were statistically significant and the significance of indirect mediational paths was further confirmed using bootstrap resampling method. Results indicated that negative affect predicted greater impact on life domains directly with an effect of 0.18. There was also an indirect effect of negative affect on impact on life domains ($b = 0.20$, 95% CI = 0.13 to 0.28, $p = 0.001$) through infertility self-efficacy. Anxiety predicted elevated impact on life domains fully through diminished perception of infertility self-efficacy ($b = 0.13$, 95% CI = 0.06 to 0.21, $p = 0.001$).
Limitations, reasons for caution: Although path analysis is a powerful statistical technique our findings rely on cross-sectional and self-report data. This design limits robust causal conclusions to be drawn and points to the need of future replication studies. Additionally, participants were at different stages of medical treatment and this may add confounding variables.
Wider implications of the findings: Findings point that increasing the patients' confidence levels on their own cognitive, emotional and behavioral skills related to infertility may contribute to attenuate the influence that anxiety and negative affect may exert on the patients' life domains. The study emphasizes the importance of targeting and promoting self-efficacy in infertile patients.
Trial registration number: The study was not a trial.

P-517 Infertility impact on male and female sexuality: a comparative study

C. Glina[1], L. Leis[2], C.E. Busso[1], S. Glina[3], N. Antunes Junior[1], N.E. Busso[1]
[1]*Projeto Alfa, Gynecology, São Paulo, Brazil*
[2]*Projeto Alfa, Psychology, São Paulo, Brazil*
[3]*Projeto Alfa, Urology, São Paulo, Brazil*

Study question: Is infertility impact on sexuality the same for men and women?
Summary answer: When experiencing infertility, women sexuality was significantly more affected than men's.
What is known already: Previous studies have shown that women's sexuality is more affected than their partners' when they experience infertility. However, there was no data evaluating Brazilian couples.
Study design, size, duration: Cross sectional, descriptive study. Three hundred infertile patients were included (150 men and 150 women), between January 2015 and December 2015.
Participants/materials, setting, methods: A female sexual function score and a male sexual function score (both validated for Brazilian subjects) were used. Mann–Whitney test was used for statistical analysis of sexual function scores and Fisher's Exact Test was used to compare sexual performance. Adopted $p = 0.05$ statistically significant.
Main results and the role of chance: A statistically significant difference was found when comparing sexual scores between men (median = 81.6) and women (median = 75.2) ($p < 0.001$). When sexual performance was compared, 58.7% of men reported to have a good performance while 66.7% of women reported regular performance or null performance ($p < 0.001$). Furthermore, men had less sexual desire dysfunction (6.7 vs. 14.7%; $p = 0.025$), less sexual arousal dysfunction (0.7 vs. 12%; $p < 0.001$) and less orgasm dysfunction (0.7 vs. 20%; $p = 0.001$) than women.
Limitations, reasons for caution: More studies are needed, with larger samples, to confirm these findings.
Wider implications of the findings: Infertility impact on sexuality is more important in women than in men. Health care providers that deal with infertile couples must be aware and pay special attention to this condition.
Trial registration number: Not applicable.

P-518 Actor and partner effects between gender role attitudes and fertility-related quality of life (QoL) in dyads of infertile couples

R. Sexty[1], J. Hamadneh[2], S. Roesner[3], T. Strowitzki[3], B. Ditzen[1], B. Toth[3], T. Wischmann[1]
[1]*Ruprecht-Karls University, Center for Psychosocial Medicine, Institute of Medical Psychology, Heidelberg, Germany*
[2]*Jordan University of Science and Technology, Faculty of Medicine, Department of Obstetrics and Gynecology, Amman, Jordan*
[3]*Ruprecht-Karls University, Women's Hospital, Department of Gynaecological Endocrinology and Reproductive Medicine, Heidelberg, Germany*

Study question: How are personal gender role attitudes connecting to the own and the partner's fertility-related quality of life in couples with fertility problems?

Summary answer: Instrumentality is associated mainly with own QoL for both members of the couple, while male and female partner's expressivity is beneficial only for the man.
What is known already: Previous studies suggest that gender role attitudes influence how infertile men and women cope with their fertility problems. Gender role attitudes relate to infertility stress: persons with instrumental and combined attitudes suffer less from distress caused by involuntary childlessness.
Study design, size, duration: A cross-sectional study performed from February 2012 until April 2014 in five Hungarian, one German and one Jordanian fertility centers. Couples were recruited who had primary or secondary infertility and had not been treated in the participating clinics before.
Participants/materials, setting, methods: The study sample consists of 375 couples (750 women and men) attending the first infertility consultation. They were invited by a medical assistant to fill out a questionnaire package containing the International Fertility Quality of Life Questionnaire (FertiQoL), Personal Attribute Questionnaire (PAQ) and sociodemographic questions. Data were analyzed with the Actor Partner Interdependence Model.
Main results and the role of chance: The average age of the participants is 34.4 years, their couple relationship lasts for 7.17 years and they have been wishing for a child for 3.23 years on average. A proportion of 45.8% of the participants have a higher education.

For both males and females, instrumentality has an actor effect on better global fertility-related quality of life ($ps < 0.05$). There is also a tendency for positive partner effects for both members' QoL. Fertility-related quality of life of the man is connected with their own and the female partner's expressivity ($ps < 0.05$). Expressivity of the woman has only a tendentious positive effect on her own QoL.
Limitations, reasons for caution: Cross-sectional studies are not eligible verify cause-effect relations between the examined variables so our results show only correlations between gender role attitudes and fertility-related QoL. We recommend prospective study designs to explore proper causality between personal attitudes and psychological reactions to infertility.
Wider implications of the findings: Our finding about the partner effect of female expressivity on male infertility-related QoL could be applied in the psychosocial counseling for couples with fertility problems. Counselors could help the couple to be aware of this connection and to utilize it.
Trial registration number: Not applicable.

P-519 Women's perceptions of acupuncture in relation to *in vitro* fertilisation: the body and the mind

S. de Lacey[1], E. Sanderman[1], C. Smith[2]
[1]*Flinders University, School of Nursing and Midwifery, Adelaide, SA, Australia*
[2]*Western Sydney University, National Institute of Complementary Medicine, Sydney, NSW, Australia*

Study question: How do women having *In Vitro* Fertilisation treatment perceive the role of acupuncture?
Summary answer: Women perceived acupuncture to be preparing their body through physical changes and preparing their mind through psychological changes.
What is known already: Accumulative success in IVF is but relies on women "staying the distance" through repeated treatments. Women discontinue treatment due to the physical and psychological burden of repetitive stress. Also psychological stress is known to reduce pregnancy chance. Women are increasingly seeking acupuncture parallel to IVF. Few studies are able to report an understanding of why women seek acupuncture and what perception they hold about its impact but those studies previously undertaken report that women believe it will increase their chance for pregnancy by enhancing reproductive physiology or by reducing stress.
Study design, size, duration: This study took a qualitative approach, was nested within a Randomised Controlled Trial and interviewed 50 women individually between April 2012 and September 2014.
Participants/materials, setting, methods: 50 women were recruited from an RCT of acupuncture in IVF and interviewed individually. Interviews were semi-structured and sought information about the women's perceptions of infertility, IVF and acupuncture. Data was subjected to theoretical thematic analysis to identify the attitudes and beliefs of the participants on acupuncture, what it does, how it "works" and what it feels like.
Main results and the role of chance: Two major themes emerged in the data: preparing the body and preparing the mind. Acupuncture was perceived as having an impact to the body through physical changes in the nervous, circulatory and hormonal systems thereby creating higher quality eggs, embryos and endometrial receptivity. Acupuncture was also perceived as having an impact psychologically through relaxation, mindfulness, calmness, and peacefulness. Acupuncture required stillness and this allowed women time to be still and to reflect on the meaning of embryo transfer. Themes were validated according to qualitative research standards.
Limitations, reasons for caution: Participants were drawn from only five of the nine participating RCT recruitment centres. Despite aiming to recruit as diverse a sample as possible the sample was dominated by Caucasian, well-educated women.
Wider implications of the findings: This qualitative study provides insight and deeper understanding of how women think about acupuncture in relation to their bodies in the context of IVF and infertility, and provides some insight into their reasons for engaging with this therapy.
Trial registration number: The RCT in which this study was nested is registered with the Australian and New Zealand Clinical Trial Registry 2/3/2011 (see http://www.ANZCTR.org.au/ACTRN12611000226909.aspx). ACTRN12611000226909.

P-520 Effect of religiousness on anxiety and depression in infertile women

C.E. Busso[1], L. Leis[2], J. Borges[1], N. Busso[1]
[1]*Projeto Alfa, Reproductive Endocrinology, São Paulo, Brazil*
[2]*Projeto Alfa, Psychology, São Paulo, Brazil*

Study question: To evaluate whether religiousness/spirituality affects symptoms of anxiety and depression in infertile women.
Summary answer: Religiousness/spirituality does not correlate with symptoms of anxiety/depression. However, there is a positive correlation between religiousness/spirituality and duration of infertility and number of previous treatments.
What is known already: A few studies show that religiousness/spirituality is important in coping and adaptation to infertility. However, there is no data using validated scores correlating religiousness with anxiety and depression.
Study design, size, duration: Descriptive cross-sectional study with 80 patients starting assisted reproduction treatment (timed intercourse, intrauterine insemination and *in vitro* fertilization). Data were collected from February 2015 to January 2016.
Participants/materials, setting, methods: Spirituality Self Rating Scale (SSRS) was used to evaluate religiousness/spirituality and Hospital Anxiety and Depression Scale (HADS) to evaluate anxiety and depression. Statistical analysis was performed using the Spearman correlation coefficient in the correlation of SSRS scores with anxiety and depression scores and also in correlation with the number of previous infertility treatments and duration of infertility.
Main results and the role of chance: SSRS scores do not correlate with anxiety scores ($s = 0.181$; $p = 0.108$) or depression scores ($s = 141$; $p = 0.214$). However, a significant increasing correlation between SSRS scores and duration of infertility ($s = 0.302$; $p = 0.006$) and number of previous treatments ($s = 0.330$; $p = 0.003$) was found.
Limitations, reasons for caution: Further research with larger samples and different populations are needed to confirm the results of this study.
Wider implications of the findings: Religiousness/spirituality does not seem to affect symptoms of anxiety and depression in infertile women. However, it might be an important resource in coping infertility, among patients experiencing long duration of infertility and multiple treatments for that disease.
Trial registration number: Not applicable.

P-521 Can patients verify their treatment process and its quality? Conclusions from patients monitoring over ART centres in Poland

A. Krawczak[1], E. Maciejewska-Mroczek[1], A. Damska[2]
[1]*University of Warsaw/Nasz Bocian, Institute of Polish Culture, Institute of Ethnology and Cultural Anthropology, Warszawa, Poland*
[2]*Nasz Bocian, Patients' Association for Infertility Treatment and Adoption Support, Warszawa, Poland*

Study question: Do patients have a real influence on their process of treatment: how the "patients rights" are practised and perceived by medical staff in ART centres?
Summary answer: Apart from declarative understanding of patients' rights, Polish ART centres seem not to be willing to practice patients-oriented health care.
What is known already: Reproductive medicine realizes one of the modern medical regimes described widely in the literature (Foucault, 1975; Thompson, 2005). Pregnancy, the final goal of MAR therapy, may overshadow the serious social and personal costs being paid by the patients, i.e., submission to medical authority against their own beliefs and consent to being disciplined by medical regime. Enhancing patients' voices and input into medical processes can equalize the natural dissproportion in distribution of knowledge and power. However, in the post soviet societies the dialogue between medicine and social actors seems to be often delusional with no real impact on the practice.
Study design, size, duration: In 2014–2015 Polish patients' organisation "Our Stork" led the project titled "Patients monitoring over MAR centres" with the participation of 35 MAR centres, which were visited by 13 trained social auditors. The project was based on direct observation of ART centres' daily work and structured interwievs with medical staff and patients. The conclusions deriving from the project were presented in Polish Parliament in Autumn 2015.
Participants/materials, setting, methods: 35 Polish MAR centres were audited by 13 auditors from January 2014 to April 2015. Analyses were based on: 299 civil contracts presented by MAR centres, 89 interwievs with patients, 152 interviews with doctors, midwives, receptionists and the ART centres' owners, direct observations, and on the document titled "Patients guidelines on infertility" prepared by "Our Stork" Association with the participation of 722 questionnaired patients from the Internet forum (92 thousands of registered patients).
Main results and the role of chance: Three areas of discrepancy between ART centres declarations and presented guidelines, and patients' practice were distinguished: (1) Area of procedures concerning gamete and embryo donations (i.e., lack of counselling and psychological consultation; lack of the information about general rules applied; treating the process by medical staff as purely biomedical disregarding the social aspects of the process), (2) Area of patients' rights recognition [in 299 analysed ART centres' civil contracts, 228 abusive clauses, lesser errors in legal terms discriminating patients and children (n = 74) and/or violating patients' and human rights (n = 93) were found], (3) Area of communication with patients (publishing non transparent data applied to efficiency of ART centres with no methodology disclosed; discouraging patients to SET policy; using paternalistic formulas in materials and documents distributed by centres). Apart from official declarations and legal regulations, the true relations between patient and doctors seem to be organized around biodisciplining paradigm of "obedient patient."
Limitations, reasons for caution: Before launching the monitoring, 44 ART centres which offered IVF in past 10 years were mapped, two of which had ceased activity, and seven refused to participate. Therefore, 35 ART centres out of 44 were audited, and the conclusions referred to this number.
Wider implications of the findings: Including patients' perspective into the process of health care provisions may lead to improvement in quality of services and creation of more patients-oriented health care. One of the reasons for treatment discontinuation, is the lack of patients' trust in the way the ART centres operate on area of communication.
Trial registration number: Not applicable.

P-522 Do parents with offspring following identity-release donation put their disclosure intentions into practice? Follow-up of heterosexual couples with 7-year-old donor-conceived children

C. Lampic[1], G. Sydsjö[2], A. Skoog Svanberg[3]
[1]*Karolinska Institutet, Department of Neurobiology, Care Sciences and Society, Stockholm, Sweden*
[2]*Linköping University, Department of Clinical and Experimental Medicine, Linköping, Sweden*
[3]*Uppsala University, Department of Women and Children's Health, Uppsala, Sweden*

Study question: Are disclosure intentions of heterosexual couples with children following identity-release oocyte and sperm donation put into practice?
Summary answer: The majority of parents complied with their disclosure intentions and had started the disclosing process when offspring had reached the age of 7.
What is known already: Donor-conceiving couples are increasingly recommended to share information about the donor conception with their child from an early age. While international studies report that heterosexual couples support openness and plan to disclose this information to their offspring, there is a lack of longitudinal studies investigating to what extent such disclosure intentions are put into practice.
Study design, size, duration: The present study is part of the prospective longitudinal "Swedish study on gamete donation" including all fertility clinics performing gamete donation in Sweden. Consecutive groups of recipient couples were recruited 2005–2008 and followed with individual questionnaires before and after treatment with oocyte and sperm from identity-release donors. The present study includes data from two follow-up assessments: when offspring were age 1–4 and when they had reached age 7, respectively.
Participants/materials, setting, methods: Heterosexual couples with donor-conceived children following oocyte donation (OD) and sperm donation (SD) that participated at two follow-up assessments. Among those who responded to the first follow-up, response rates for the second follow-up were 74% for OD-parents (48 of 65) and 75% for SD-parents (61 of 81). Disclosure intentions and practice were assessed individually with study-specific items. Data were analysed with chi^2-tests.
Main results and the role of chance: Among parents who at the first follow-up stated that they planned to disclose before offspring age 7 (n = 31), a majority (77%) had started the disclosure process but one in five had not realized their intention. All but one parent who had planned to disclose when the child asks questions about where babies come from (n = 11) had started disclosing at age 7. In contrast, among those who planned postponing disclosure until "the child understands" (n = 25) only one-third had started disclosing during the preschool period. In total, 66% of OD-parents and 60% of SD-parents had started the disclosure process with their offspring at age 7, a few (n = 4) were unsure or unwilling to disclose and the remaining planned to disclose in the future. There were no significant differences in disclosure practice at offspring age 7 between parents following oocyte and sperm donation.
Limitations, reasons for caution: There is risk of selection bias, with recipients preferring non-disclosure declining study participation or dropping out. Comparison of initial disclosure intentions between responders and non-responders to the second follow-up did not indicate such selection bias. Results are partly generalizable to heterosexual parents of children conceived with gametes from identity-release donors.
Wider implications of the findings: The present results suggest increasing compliance with the intentions of the Swedish legislation among parents of donor-conceived offspring. Couples building a family with donor gametes may benefit from opportunities to discuss when it is appropriate to start the disclosure process.
Trial registration number: N/A.

P-523 Stress and infertility: a pilot study measuring cortisol levels in the hair of infertile women

L. Beliveau[1], A. Vilos[1], S. Van Uum[2], C. Newton[3], K. Gideon[4], G. Vilos[5], S. Power[1], J. Hollett-Caines[1], M. Rebel[1], B. Abu Rafea[1]
[1]*University of Western Ontario, Gynecologic Reproductive Endocrinology and Infertility, London, ON, Canada*
[2]*University of Western Ontario, Endocrinology and Metabolism, London, ON, Canada*
[3]*London Health Science Centre, Clinical Psychology, London, ON, Canada*
[4]*University of Toronto, Clinical Pharmacology and Toxicology, Toronto, ON, Canada*
[5]*University of Western Ontario, Obstetrics and Gynecology, London, ON, Canada*

Study question: Is hair cortisol increased in women with infertility as compared to control subjects without infertility?
Summary answer: There was no significant difference found in overall cortisol levels in hair samples between infertile women and controls.
What is known already: Studies have shown stress has an impact in many areas of physical health. Infertility related stress is also a well-characterized entity. Chronic stress may contribute to factors such as reduced fertility and even poor pregnancy outcomes. Biomarkers for measuring acute stress have been well established but finding a "gold standard" for the measurement of chronic stress proves more difficult. Hair cortisol sampling has emerged as a

novel method for examining stress over longer periods of time and may prove clinically useful in management strategies for stress reduction in the infertility population.

Study design, size, duration: Observational case–control study. Sixty women were enrolled from April 2013 until April 2014. Thirty patients who had not conceived within the past year and were seeking IVF treatment served as the cases. Thirty age matched patients with proven fertility acted as our controls. All study patients were assessed for overall stress using the Perceived Stress Scale (PSS). In addition, infertile women were given the Fertility Problem Inventory (FPI), a survey measuring perceived infertility-related stress.

Participants/materials, setting, methods: Hair samples were taken by our clinical coordinator using a standard protocol. Each patient's sample was divided into two sections (0–3 and 3–6 cm). Hair grows on average 1 cm per month, therefore, each segment corresponded to a 3-month cortisol sample. Cortisol measurements were then attained according to the standard protocol developed in our laboratory.

Main results and the role of chance: There was no significant difference in overall cortisol levels between infertile women and controls. However, there was a significant difference between the infertile group and the controls at segment 1 ($F = 4.299$, $P = 0.043$). Interestingly, the infertility group had significantly lower cortisol levels in segment 1 compared to the controls. Mean segment 1 (0–3 cm) and 2 (3–6 cm) cortisol levels (ng/g) in the infertility group were 111 ± 135 and 121 ± 194 respectively; and in the control group were 173 ± 231 and 112 ± 147 respectively.

There was no significant relationship found between PSS and cortisol levels in either group. The infertility group, however, reported significantly higher levels of stress than controls on the PSS ($t = 2.6$, $P = 0.012$).

There was also no significant relationship found between FPI Global scores and cortisol levels in the infertility population. On the FPI, 37% of the infertility group scored above the 84th percentile compared to fertility norms, correlating with "moderately high" infertility related stress. Of these, 3.3% had scores above the 98th percentile, indicating "very high" stress. In the infertility group, there was a significant but moderate correlation between the PSS total score and the FPI Global score ($r = 0.41$, $P = 0.025$).

Limitations, reasons for caution: Cortisol levels in both groups were highly variable as shown in the large standard deviations. The small sample size may mask the true differences found in cortisol levels between the control and infertile female patients.

Wider implications of the findings: These results suggest that cortisol levels in hair might not have a simple positive linear relationship with subjective stress as has been assumed and emphasizes the need to expand this body of research.

Trial registration number: REB #103692.

P-524 Motives and considerations regarding PGD in couples carrying a structural chromosomal abnormality – a quantitative analysis

G. de Krom[1], R. Hillen[2], Y. Arens[3], R. van Golde[1], C. de Die-Smulders[3], L. van Osch[2]
[1]*Maastricht University Medical Centre, Department of Obstetrics and Gynaecology, Maastricht, Netherlands*
[2]*Maastricht University, Department of Health Promotion/CAPHRI, Maastricht, Netherlands*
[3]*Maastricht University Medical Centre, Department of Clinical Genetics, Maastricht, Netherlands*

Study question: What are motives and considerations of couples carrying a structural chromosomal abnormality deciding on preimplantation genetic diagnosis (PGD)?

Summary answer: The main reason for couples carrying a structural chromosomal abnormality to choose PGD is to increase their chances of an ongoing pregnancy.

What is known already: PGD can be offered to couples carrying a structural chromosomal abnormality to increase the chance of an ongoing pregnancy and healthy offspring. From our previous qualitative analysis we learned all couples who opted for PGD had tried to conceive spontaneously. They considered PGD because of their experience (infertility, recurrent miscarriage, termination of pregnancy, affected child). A majority of couples indicated that an important reason for them to choose PGD is wanting to increase the chance of a successful pregnancy. The present study aimed to quantify couples' motives and considerations deciding on PGD in a larger sample.

Study design, size, duration: A quantitative cross-sectional survey study investigating the motives and considerations regarding PGD or other reproductive options of couples carrying a structural chromosomal abnormality. 119 couples were included between January and May 2015. They made their reproductive choice after extensive genetic counselling on PGD.

Participants/materials, setting, methods: Couples carrying a structural chromosomal abnormality who had an informative consultation in a licensed large PGD centre between 1996 and 2012 were invited to fill out an online questionnaire on demographic and clinical characteristics and possible motives, categorized as physical, psychological, social, ethical and practical, considering PGD. Univariate and multivariate analysis was performed to investigate the relationship between couples motives and their actual choice to opt for or refrain PGD.

Main results and the role of chance: The response rate was 72.8% (131 respondents). After excluding couples who were rejected for PGD treatment 119 respondents remained for analysis. 19.3% of participants used PND before they came for the informative PGD consultation. The majority of couples chose for PGD after the PGD consultation (78.2%). 41% of couples actually started PGD treatment. Only nine participants (7.6%) regretted the reproductive choice they made, either PGD or not PGD, after the informative consultation. Respondents with a higher educational level and those who had (strong) positive feelings regarding spontaneous conception were less likely to opt for PGD. Couples who have a strong wish to prevent (further) miscarriages opt for PGD more often. Partner who carried the chromosomal translocation, presence of subfertility, number of previous miscarriages, and parity were not associated with reproductive choice.

Limitations, reasons for caution: Due to the retrospective questionnaire there is a risk of recall- and information bias. A relatively large group changed their reproductive choice over time. After counselling 78% of couples opted for PGD, in time only 41% started. We learned from our previous study main reason is a spontaneous ongoing pregnancy.

Wider implications of the findings: Couples' choice to decide on PGD is very personal. Few of the investigated motives were significantly associated with couples' reproductive choice. This information learns us it is important to personalize counselling and psychological support during the decision making process for future couples carrying a structural chromosomal abnormality.

Trial registration number: N/A.

P-525 Breaking the news to children conceived by *in vitro* fertilization: how do parents behave?

H. Creux[1], A. Tesson[1], C. Jimenez[1], S. Frantz[1], A. Papaxanthos[1], L. Chansel-Debordeaux[1], G. Rocher-Escriva[1], M.C. Dulucq[1], F. Boutges[1], C. Hocke[1]
[1]*University Hospital, Clinical Assisted Reproductive Centre, Bordeaux, France*

Study question: How parents deal with revealing to their children a mode of conception by *in vitro* fertilization (IVF)?

Summary answer: Most of parents intend to reveal to their offspring the use of IVF and many would appreciate the assistance of an informative and educational document.

What is known already: Announcing to offspring their mode of conception has been extensively studied after gamete donation or adoption. It is now commonly accepted that parents should reveal their child's origin as soon as possible because of the negative consequences of family secrets. Little is known on parental behaviour toward disclosure in case of intra-conjugal IVF. Nevertheless, despite the non missing genetic link, intra-conjugal IVF is different from a spontaneous pregnancy. Actually, many infertile patients, who needed IVF, can have negative thoughts like shame or guilt feelings, that in addition to secrecy within family, may have negative consequences on family fulfilment.

Study design, size, duration: Descriptive and prospective study from October 2013 to April 2015 in the Reproductive Centre of Bordeaux University Hospital (France).

Participants/materials, setting, methods: The study inclusion was proposed to parents who consulted for a second or third child and who already conceived by intra-conjugal IVF in the past, regardless the current age of the child(ren). If they agreed to participate, a survey questionnaire was given to both members of the couple. The participation was non-mandatory, individual, anonymous and free.

Main results and the role of chance: A total of 190 questionnaires was distributed to 95 couples, on which 92 were sent back, resulting in a response rate

of 48.4%. Thirteen per cent of parents (12/92) already revealed the mode of conception to their child(ren), 67% (62/92) thought about revealing it, 17% (15/92) were not yet decided and 3% (3/92) did not want to reveal. At the time of the survey, children born after IVF were between 9 months and 7 years old (median age: 3.2 years old). Most parents thought that the best time to disclose was "when we think our child will be able to understand"; (49%) or "when he will ask to us where do babies come from" (27%). Sixty-one percent of parents would like to dispose of a pedagogical tool. For 81% of them, the best educational material would be a children's book. Moreover, 31% of patients reported that IVF had been a psychological painful experience, with a feeling of personal failure and a sense of being different than other couples, although they gave birth to one or more children thanks to this technique.

Limitations, reasons for caution: Most people who came back for a second or third child and answered to the questionnaire had a masculine infertility (55%), which can be considered as a selection bias. As in studies about gamete donation, there could be a gap between questionnaire's answers (what people think to do) and reality.

Wider implications of the findings: Our study shows that many parents intend to reveal to their child(ren) recourse to IVF. We point out that there is undoubtedly a need for informative support. Moreover, because IVF is frequently experienced as a psychological injury, it seems essential to develop strategies to assist couples who face with infertility.

Trial registration number: Not applicable.

P-526 Impact of treatment decisions and significance of cultural beliefs in predicting quality of life of Chinese infertile women

M.Y.J. Tam[1], C.H.Y. Chan[1], H.Y.E. Ng[2], C.L.W. Chan[1], T.H.Y. Chan[1], Q.S. Wong[1], A.W.Y. Wong[1], C.K.L. Chan[1]
[1]The University of Hong Kong, Department of Social Work and Social Administration, Hong Kong Island, Hong Kong
[2]The University of Hong Kong, Department of Obstetrics and Gynaecology, Hong Kong Island, Hong Kong

Study question: What is the impact of treatment decision-making on Chinese infertile women and what factors can predict their quality of life (QOL) 3 months after the decision?

Summary answer: QOL in mind-body, social and tolerability improved but relational, environment and mental-health worsened. Believing "infertility as violation of filial piety" was identified as major predictor.

What is known already: When engaging in treatment decision making, there has been a paradigm shift to look at a patient's decision not only based on its subsequently treatment outcome or disease prognosis, but also how the decision impacts on his/her quality life. In the case of infertility, the decision of continuing or discontinuing treatment is often embedded in a midst of socio-cultural considerations such as childbearing desire and cultural attitudes towards fertility, especially in societies who regard maternity as a central milestone in adult development and childlessness will cause major disruption in women's lives by inferring with the established and desired life course.

Study design, size, duration: A longitudinal questionnaire study was conducted with 151 Chinese infertile women. Data was collected on their quality of life (FertiQOL and HADS), childbearing desires, attitudes towards infertility, and demographic details at three time-points: notification of treatment failure (T0), immediately after treatment decision making (T1) and 3 months after (T2). The study spanned 2 years.

Participants/materials, setting, methods: Participants were recruited from a fertility clinic at a university affiliated public hospital. Out of465 patients approached by the research assistant, 246 agreed to participation, and 151 completed all questionnaire (attrition rate 39%). On average, their age is 37.2 years (SD 3.27), received subfertility diagnosis for 3.8 years and had experience 1.1 IVF treatment cycle prior to the current failure. They mostly received tertiary education, non-religious, and were full-time employed.

Main results and the role of chance: Between baseline (T0) and immediately after treatment decision making (T1), no significant changes were found in the women's quality of life domains and mental well-being, except a decrease in anxiety scores [$t(150) = 6.57$, $p < 0.001$]. Three months after the treatment decision (T2), significant improvement was found for the Mind-body [$t(150) = 3.17$, $p < 0.01$], Social [$t(150) = 10.8$, $p < 0.001$], and Tolerability [$t(150) = 5.34$, $p < 0.001$] domain. However, the scores for the Relational [$t(150) = -15.53$, $p < 0.001$] and Environment [$t(150) = -4.64$, $p < 0.001$] domain, as well as the anxiety [$t(150) = 13.96$, $p < 0.001$] and depression [$t(150) = 24.15$, $p < 0.001$] scores were worsened. Regression analysis revealed the participant's identification towards the cultural saying that "infertility is biggest violation to filial piety" is an effective predictor of her anxiety level ($\beta = 0.21$, $p < 0.01$) as well as her quality of life in the emotional ($\beta = -0.22$, $p < 0.05$), mind-body ($\beta = -0.18$, $p < 0.05$), and tolerability domain ($\beta = -0.20$, $p < 0.05$) 3 months after treatment decision making.

Limitations, reasons for caution: Data was collected from a single fertility clinic, so may not be representative of all IVF patients across clinics. Although there was no significant difference in age, education, and religious background between those who completed the study and those who dropped out, self-selection bias is a concern.

Wider implications of the findings: This study showed impact of infertility treatment decisions on women's quality of life and psychological adjustments. By identifying cultural beliefs as predictor of post-decision QOL, psychosocial support may consider exploration of such beliefs with the infertile couple prior to treatment, and allow re-visiting of these conversations throughout the treatment course.

Trial registration number: Nil.

P-527 Professionals' experiences with patients undergoing e-therapy, a cohort study

A.J.C.M. van Dongen[1], J.A.M. Kremer[1], C.M. Verhaak[2], W.L.D.M. Nelen[1]
[1]Radboud University Medical Center 791, Obstetrics and Gynecology, Nijmegen, Netherlands
[2]Radboud University Medical Center 791, Medical Psychology, Nijmegen, Netherlands

Study question: What are the experiences of professionals in clinical fertility care with patients undergoing e-therapy?

Summary answer: Experiences with e-therapy were positive and it was considered useful. Before introducing e-therapy in daily clinical care, structured information should be provided to fertility staff.

What is known already: Internet-based interventions (e.g., e-therapy) are promising in reducing psychological distress. In fertility care e-therapy on psychological distress has been introduced, but the beneficial effects have to be evaluated. Furthermore, facilitators and barriers when introducing e-therapy in daily clinical practice have to be assessed. The experiences of professionals in clinical fertility care have not been evaluated before, and this could be crucial to enhance an effective introduction and implementation of e-therapy in daily clinical care.

Study design, size, duration: After conducting a prospective randomised controlled trial (RCT) aimed to reduce distress in women undergoing IVF treatment using an e-therapy program, we performed a survey to analyse the experiences of the participating professionals with patients undergoing e-therapy. A questionnaire was sent to a representative sample of fertility care professionals, i.e., nurses, physicians and secretaries ($n = 10$) and a structured interview was performed with the coaches who performed the e-therapy ($n = 2$).

Participants/materials, setting, methods: We included professionals working at the fertility care department and the coaches working at the psychology department who were involved in the RCT. In the first group questionnaires were sent, asking for professionals' experiences during the RCT, e.g., the provision of information or their time-investment. In the second group a structured interview was performed in which experiences with conducting the e-therapy were asked as well as suggestions for improvement. Results were analysed using descriptive statistics.

Main results and the role of chance: All fertility professionals stated they were well informed about the study, the e-therapy content and which patients participated. Nevertheless, 40% appreciated more information, preferable by a face-to-face presentation. All fertility professionals assessed e-therapy as useful. Assumed barriers for e-therapy, such as no face-to-face contact or Internet problems, were mentioned in 29% (all nurses). The time invested by the professionals themselves in the e-therapy program was considered as minimal.

The psychology professionals assessed the assignments as useful, with exception of the stress relaxation assignment. They suggested involving the partner during the e-therapy. The mean score of the professionals was comparable with the previously evaluated patients' score (mean score 3.73 out of 6 versus 3.79). Although the coaches preferred face-to-face contact, they assumed Internet contact could be able to replace this in specific circumstances. They grade

the program as positive and would recommend it to other professionals (mean score 7.5 out of 10 versus 6.6 in patients). When introducing e-therapy in daily clinical care, the involvement of a coach and the intake meeting with face-to-face contact were assessed as important.
Limitations, reasons for caution: The experiences of professionals could be assessed only in this centre, because e-therapy was evaluated in a single centre RCT. Generalisability could be improved by expanding e-therapy to other centres. Although we used a representative sample of clinical professionals, the uptake rate in both physicians as nurses could be higher.
Wider implications of the findings: In fertility care, this is the first study that has evaluated the experiences of professionals with patients undergoing e-therapy. Important information on professionals' experiences was obtained. This knowledge could be useful in introduction and implementation of e-therapy initiatives in daily clinical care.
Trial registration number: ClinicalTrials.gov NCT 01283607.

P-528 Mental health of mothers and fathers after successful oocyte donation treatment in pregnancy and early parenthood: a 1-year prospective study

M. Salevaara[1], R.L. Punamäki[2], L. Unkila-Kallio[3], M. Tulppala[3], A. Tiitinen[3]
[1]*Väestöliitto Fertility Clinics Ltd., Fertility, Helsinki, Finland*
[2]*University of Tampere, Psychology, Tampere, Finland*
[3]*University of Helsinki, Obstetrics and Gynaecology, Helsinki, Finland*

Study question: Is psychological wellbeing of mothers and fathers after oocyte donation (OD) treatment similar to parents after IVF/ICSI with own gametes and natural conception (NC)?
Summary answer: OD mothers showed less sleeping difficulties and symptoms of social dysfunction compared with IVF/ICSI and NC controls whereas no differences were found among fathers.
What is known already: Absence or low levels of parental mental health symptoms (depression, anxiety, sleeping difficulties and social dysfunction) have been found to be beneficial to children's psychosocial well-being. Much of the research has focused on the experience of parenting a child conceived through OD treatment. Studies have shown that the relationship with the child is comparable among couples who had undergone IVF/ICSI with own gametes and naturally conceived (NC) controls. Furthermore, studies of parents marital relations do not show differences between these groups. No data exists on OD mothers' and their partners' mental health during pregnancy and early parenthood.
Study design, size, duration: This is a prospective, longitudinal questionnaire study of couples conceived with OD treatment in five fertility clinics in Finland. The OD group consisted of 26 mothers and their matched IVF/ICSI ($n = 52$) and SC ($n = 52$) controls. The mothers and fathers filled-in the General Health Questionnaire (GHQ-36) questionnaires separately at gestational weeks 18–20 (T1), 2 months after the childbirth (T2) and when the child was 1 year old (T3).
Participants/materials, setting, methods: Matching to find controls was performed according to mother's age (≤34, 35–37 and ≥38 years), parity (primipara or multipara), type of pregnancy (singleton or twin pregnancy) and number of returned questionnaires. Full response rate (T1–T3) for OD mothers was 76.9% and for OD fathers 73.1%. The levels of mental health symptoms were compared between the OD, IVF/ICSI and NC group by MANOVAs, with Bonferroni post-hoc analyses separately for mothers and fathers.
Main results and the role of chance: At T1, the OD mothers showed less sleeping difficulties than the IVF/ICSI and NC women ($F = 3.116$, $p < 0.05$), but no significant differences were found in symptoms of depression, anxiety and social dysfunction. At T2, the OD women reported less anxiety ($F = 4.328$, $p < 0.05$) than the NC controls, less sleeping difficulties ($F = 4.358$, $p < 0.05$) and less social dysfunction ($F = 7.112$, $p < 0.005$) than the IVF/ICSI and NC controls whereas no group differences were found in depressive symptoms. One year after the delivery (T3), the OD women had again less sleeping difficulties ($F = 3.695$, $p < 0.05$) and less symptoms of social dysfunction ($F = 3.498$, $p < 0.05$) than the IVF/ICSI and NC controls but similar levels of anxiety and depression symptoms. Mental health symptoms of OD fathers did not differ from that of IVF/ICSI and NC control fathers at any time point.
Limitations, reasons for caution: The number of participating OD mothers and fathers was low and results are based on self-reported mental health. The couples in the OD group had received more psychological counselling before the pregnancy than the controls which may have improved their psychological readiness for parenthood and thus also mental health.
Wider implications of the findings: According to our small study, OD couples do not need more support in pregnancy and early parenthood compared with IVF/ICSI couples and naturally conceived couples. However, OD couples' mental health symptoms should be examined when there are child-related or social stressors in their life.
Trial registration number: None.

P-529 Identity-release egg donation in the UK: parents' disclosure decisions and thoughts about the donor

S. Imrie[1], V. Jadva[1], S. Golombok[1]
[1]*University of Cambridge, Centre for Family Research, Cambridge, UK*

Study question: Do parents who have conceived using open-identity egg donation intend to disclose this information to their children? How do they feel about the donor?
Summary answer: Most parents intended to disclose, although they did not want to know the donor's identity and felt ambivalent about the child knowing in the future.
What is known already: Less is known about egg recipient families than about families created through sperm donation. Disclosure rates amongst families in the UK with children conceived through anonymous egg donation are approximately 45%. However, nothing is known about disclosure intentions of families in the UK formed following identity-release egg donation. To date, only one European study has assessed disclosure intentions of identity-release egg recipient parents (in Sweden), and suggests that disclosure intentions amongst this group may be higher. The present study is the first study of UK families with children conceived through egg donation following the removal of donor anonymity in 2005.
Study design, size, duration: In-depth semi-structured interviews were carried out with 73 families who had a child following successful treatment with identity-release egg donation in the UK. Data were collected between December 2013 and June 2015, and form part of a larger study examining family functioning in families with infants conceived through egg donation.
Participants/materials, setting, methods: In-depth, face-to-face interviews were conducted with 73 heterosexual UK couples who had a child through identity-release egg donation. Mothers and fathers were interviewed separately (73 mothers, 57 fathers). The average age of the infants was 11 months. Data were obtained on whether or not parents intended to tell their child about their donor conception, whether they had told their family and friends about the treatment, and their thoughts about identity-release donation more broadly.
Main results and the role of chance: The majority of parents (75% of mothers, 82% of fathers) in the present study intended to tell their child about their donor conception. Eighty percent of mothers and 74% of fathers had told their own parents about the egg donation, with slightly lower numbers informing their siblings. Of the 18 families who had older naturally conceived children, half had told the older child about the donor conception. Most (83%) mothers had told more than one friend about the egg donation, although 20% expressed regrets about who they had told. The majority of couples (90%) had received counselling prior to treatment, and most had been advised to some extent by the counsellor to disclose the egg donation to the child. With regard to the donor, 69% of mothers and 62% of fathers reported a change in the frequency in which they thought about the donor since the child's birth. Most parents (40% of mothers, 57% of fathers) did not want to know the donor's identity in the future, and a further third were unsure. Just under half (43%) of the mothers in the sample expressed ambivalent feelings about the idea of the child knowing the donor's identity in the future.
Limitations, reasons for caution: There is a risk of selection bias, with families preferring non-disclosure perhaps less likely to participate in research, although this sample was recruited systematically through fertility clinics in the UK. Previous research with couples using anonymous gamete donation suggests that parents' disclosure decisions may change over time.
Wider implications of the findings: The findings suggest a trend towards greater openness in the UK amongst egg recipient heterosexual couples. That many parents raised concerns about the identity-release process in the longer term is of relevance to clinics and professionals supporting patients before, during and after treatment.
Trial registration number: N/A.

P-530 Congruence between partners' need for parenthood and its relationship to their quality of life: a dyadic approach between infertile couples

Z. Donarelli[1], L. Salerno[1], G. Lo Coco[2], A. Allegra[3], A. Volpes[3], F. Sammartano[3], D.M. Kivlighan[4]
[1]*ANDROS Day Surgery Clinic, Psychology Unit, Palermo, Italy*
[2]*University of Palermo, Department of Psychological and Educational Sciences, Palermo, Italy*
[3]*ANDROS Day Surgery Clinic, Reproductive Medicine Unit, Palermo, Italy*
[4]*University of Maryland, Department of Counseling, Higher Education and Special Education, College Park, MD, USA*

Study question: Does the congruence (i.e., agreement or discrepancy) between infertile partners' need for parenthood (NP) impact on their fertility-related Quality of Life (QoL)?
Summary answer: The increase in the need for parenthood discrepancy between men and women is related to decreasing levels of their QoL.
What is known already: Research has consistently demonstrated that dealing with infertility and Assisted Reproductive Treatment (ART) significantly impairs individuals' QoL, measured by the gold standard Fertility Quality of Life tool (FertiQoL); and that the difficulties experienced by infertile subjects are exacerbated by their attitudes towards childlessness. Moreover, recent studies have highlighted the reciprocal influence between partners undergoing ART, showing that the NP varies within the couple. However, the effects of agreement or discrepancy between partners' NP are understudied. No previous studies on FertiQoL investigated whether partners who do not agree on NP are more likely to report a decreasing QoL, during ART.
Study design, size, duration: A cross-sectional study was conducted on 520 subjects (both parties in 260 infertile couples) consecutively referred for an ART, from February 2013 to February 2015.

Polynomial regression with Response Surface Analysis (RSA) was used to examine the extent to which the couples' combination (i.e., agreement or discrepancy) of women's and men's need for parenthood (independent variables) is related to their own QoL (criterion variables).
Participants/materials, setting, methods: Both parties in couples undergoing an ART (IUI or IVF) at the ANDROS Day Surgery Clinic, Reproductive Medicine Unit in Palermo (Italy) filled in the following questionnaires before starting their treatment: the "Need for Parenthood" subscale of the Fertility Problem Inventory (FPI) and the Fertility Quality of Life tool (FertiQoL).
Main results and the role of chance: Results of polynomial regression analysis show that partners' need for parenthood accounted for 19 and 17% of variance in women and men QoL, respectively. Women's needs for parenthood [$b = -0.52$, SE = 0.07, $t(15) = -7.41$, $p < 0.001$] and the squared term for this [$b = -0.20$, SE = 0.07, $t(15) = -2.82$, $p < 0.01$] were negatively related to their QoL. Men's needs for parenthood [$b = -0.37$, SE = 0.07, $t(15) = -5.19$, $p < 0.001$] and the squared term for this [$b = -0.18$, SE = 0.08, $t(15) = -2.24$, $p < 0.05$] were negatively related to their QoL. Coefficients of the Response Surface Analysis along the line of agreement showed that if the need for parenthood is congruent and rising, both partners' QoLs decrease ($a_1 = -6.26$, $p < 0.001$ and $a_1 = -5.14$, $p < 0.01$ for women and men QoL, respectively). Moreover, the curvature along the line of disagreement shows that both partners' QoL decreases as the discrepancy between partners' need for parenthood increases ($a_4 = -4.70$, $p < 0.05$ and $a_4 = -3.79$, $p < 0.05$ for women's and men's QoL, respectively). Finally, for both partners, QoL is lower when the direction of discrepancy is such that their own need for parenthood is higher than the other partner's ($a_3 = -10.03$, $p < 0.001$ and $a_3 = 3.54$, $p < 0.001$ for female and male QoL, respectively).
Limitations, reasons for caution: There are some limitations in this study: firstly, data were obtained from one only clinical site and secondly, the cross-sectional design of the study does not allow us to explain the relationships in terms of causality.
Wider implications of the findings: Given the relationship between the NP discrepancy and QoL, specific counselling for couples undergoing ART should be considered. In order to improve their QoL, counselling should be focused on balancing individual reasons for conceiving and on achieving a congruence between partners' underlying motivations for having a child through ART.
Trial registration number: Not necessary.

P-531 The anxious 14 days – the role of spirituality in helping women during their *in vitro* fertilization result awaiting period by a self-help I-BMS model (RCT)

S. Wong[1], C.H.Y. Chan[1], M.Y.J. Tam[1], A.W.Y. Wong[1], C.K.L. Chan[1]
[1]*The University of Hong Kong, The Department of Social Work and Social Administration, Hong Kong, China*

Study question: How effective is the I-BMS self-help model in alleviating the anxiety of the women during their IVF result awaiting period?
Summary answer: The self-help model was proven effective in alleviating women's anxiety, while the role of spirituality was also an important factor to their childbearing belief.
What is known already: Many women experience complicated emotions throughout IVF treatment. Among all treatment stages, many studies have proven that their uncertainty and anxiety level peaks in the waiting period between embryo transfer and pregnancy test. The situation is especially difficult and stressful for Chinese women who bear the obligation to extend the family tree.
The introduced model adopted Traditional Chinese Medicine (TCM) as the framework aims at maintaining a harmonious balance in holistic wellbeing. It has been proven effective in alleviating anxiety, improving marital satisfaction and achieving holistic well-being of the Chinese women in face of IVF treatment.
Study design, size, duration: The study has been launched since January, 2015. In our pilot study, 38 women who were going to undergo IVF treatment were recruited in an infertility clinic in Hong Kong, and were randomly assigned to three groups: spiritual–behavioral (SB) group ($n = 19$) included a 3-h I-BMS workshop and a self-help exercise book on exercises and spiritual stories for home practicing; Spiritual (S) group ($n = 10$) received the latter with only spiritual stories; Control group ($n = 8$) received educational materials on healthy diet.
Participants/materials, setting, methods: 38 women who were going to receive IVF treatment participated in the study. They were invited to complete a set of self-administered questionnaires which comprised of Chinese State-trait Anxiety Inventory (C-STAI) and Importance of Childbearing Index on the day of embryo transfer (T1) and the day of pregnancy test (T2). The results were analyzed by ANOVA.
Main results and the role of chance: The mean age of the participants was 38.14 years old (SD: 2.26). They had married for 7.25 years (SD: 3.12) and had gone through 2.33 treatment cycles (SD: 1.45) on average. 11 out of 38 participants had experienced at least 1 previous pregnancy loss. The course of subfertility was mostly due to male factors ($n = 14$), followed by unexplained factors ($n = 5$) and female factors ($n = 3$). Some couples faced both male and female factors ($n = 2$), while some did not indicate.

Participants in SB-group showed reduction in anxiety level ($T1 = 88.50 + 14.14$, $T2 = 87.84 + 15.76$, $p < 0.001$) as measured by C-STAI in pre–post test. However, the anxiety level of the participants in S group raised ($T1 = 86.50 + 24.92$, $T2 = 88.90 + 26.42$, $p < 0.001$), while that of control group increased the most obviously ($T1 = 89.14 + 21.97$, $T2 = 92.43$, $p < 0.001$).

Apart from the anxiety level, participants in S group showed significant reduction in their childbearing belief ($T1 = 17.29 + 3.20$, $T2 = 16.56 + 3.90$, $p < 0.001$) as measure by Importance of Childbearing Index, while SB group showed slight reduction ($T1 = 15.69 + 5.04$, $T2 = 15.47 + 4.78$, $p < 0.001$). In contrast, the control group demonstrated increased childbearing belief ($T1 = 14.63 + 4.87$, $T2 = 15.63 + 7.03$, $p < 0.001$).
Limitations, reasons for caution: The sample size was limited and might not be able to generalize. Moreover, some women who experienced earlier symptoms or signs of treatment failure, such as menstruation came before pregnancy test might bring external effect to the result. Their opinions towards to model during the period were unknown.
Wider implications of the findings: The self-help intervention allows more autonomy, flexibility and privacy at lower cost to fulfill the women's special needs during the result awaiting period. It could psychologically and physically prepare them to be ready for the treatment outcomes. With limited existing psychosocial services specific for this period, it could provide another choice of support.
Trial registration number: N/A.

P-532 Inflammatory markers in depressed pregnant women

H. Toy[1], E. Türen[1], A. Toker[2], S. Herguner[3]
[1]Necmettin Erbakan University, Meram Faculty of Medicine, Obstetrics and Gynecology, Konya, Turkey
[2]Necmettin Erbakan University, Meram Faculty of Medicine, Biochemistry, Konya, Turkey
[3]Necmettin Erbakan University, Meram Faculty of Medicine, Child and Adolescent Psychiatry, Konya, Turkey

Study question: Is there a relationship between depression and anxiety levels and inflammatory markers, in pregnant women?
Summary answer: Our findings support that depression in pregnant women may be related with inflammatory process.
What is known already: In the literature, there are limited number of studies investigating the relation between depression and inflammatory markers, including cytokines TNF alfa, and IL-6. In this study, we aimed to examine the association between TNF alfa, and IL-6 levels and depression, and anxiety levels in pregnant women.
Study design, size, duration: This is a cross-sectional study with a sample of 145 pregnant in their 28–36 weeks. The current study was conducted in the Department of Obstetrics and Gynecology in an university hospital between 2013 October and 2014 November.
Participants/materials, setting, methods: We studied the plasma TNF alfa, and IL-6 levels of 145 pregnant. Inclusion criteria were (1) Being between 18 and 35 years old, (2) Having no history of psychiatric disorder. All participants filled out Prenatal Maternal Attachment Inventory, Edinburg Postpartum Depression Scale, State and Trait Anxiety Inventory. Relationships between variables was assessed by Pearson's correlation analysis. Predictors of the attachment levels and depression scores were examined by linear regression analysis. Significance at $p < 0.05$ were considered.
Main results and the role of chance: The mean age of the participants was 23.2 ± 4.5 years and mean gestation week was 32.9 ± 2.7. The group was divided into two groups, according to EPDS, Group I (EPDS ≥12) was considered as probable depression and Group II (EPDS <12) was as without depression. There were no difference between the two groups in terms of age, education, and gestational age. Women with depression had significantly higher TNF alfa, and IL-6 levels than non-depressive group.
Limitations, reasons for caution: Although we had a large sample the main limitation was we relied on self-reports instead of structured interviews. We did not consider the psychological features of fathers.
Wider implications of the findings: This study showed that 12% of the women during their trimester had probable depression. Depression had a negative relation on maternal–fetal attachment. TNF alfa, and IL-6 levels were the predictor of identifying depressive symptoms during pregnancy.
Trial registration number: This study was founded by Necmenttin Erbakan University Scientific Research Foundation. Trial registration number: 131218036.

P-533 "To whom childbearing is important?": the association between perceived childbearing importance, attitudes towards assisted reproductive technologies and psychological well-being among Chinese lesbians

P.Y. Lo[1], C. Chan[2]
[1]The University of Hong Kong, Department of Social Work and Social Administration, Hong Kong Island, Hong Kong
[2]The University of Hong Kong, Centre on Behavioral Health, Hong Kong Island, Hong Kong

Study question: What is the impact of perceived importance of childbearing and attitudes towards assisted reproductive technologies (ART) on the psychological well-being of Chinese lesbians?
Summary answer: Chinese lesbians who perceived childbearing as important to their parents or their partners but did not want to seek ART reported higher anxiety level.
What is known already: Existing research in the West shows that lesbians tend to express less childbearing desire and are less likely to become parents compared with heterosexual counterparts. For involuntarily childless couples in general, fertility treatment has implications on psychological well-being and marital relationship, as it is considered a deviation from traditional family formation. For lesbians in particular, anxiety is associated with contextual factors, namely legal recognition of parental status and neighbourhood climate. Little is known about lesbians' perceived childbearing importance, attitudes towards ART, and psychological well-being in Asia, where heteronormativity remains dominant and access to ART is restricted to heterosexual couples.
Study design, size, duration: An online cross-sectional survey of Chinese lesbians in Hong Kong was conducted from December 2014 to March 2015. A total of 438 self-identified lesbians participated in the study.
Participants/materials, setting, methods: A total of 438 Chinese lesbians in Hong Kong were recruited by bulk e-mail invitations through local lesbian, gay, bisexual, and transgender organizations and a university in Hong Kong. They completed the online questionnaire which consisted of the Childbearing Importance Index, the Hospital Anxiety and Depression Scale, and other measures and questions related to their attitudes towards ART.
Main results and the role of chance: Compared to heterosexual childless women, Chinese lesbians in our study thought childbearing was significantly less important (3.30 versus 6.00 on a 1–10 scale, $t = 14.6$). Perceived childbearing importance was also negatively associated with age ($r = -0.23$), relationship length ($r = -0.18$) and full-time employment ($F = 4.29$). Vast majority of participants (92%) supported legalizing same-sex couple's access to ART, although less than half (41%) wanted to use it themselves to have children. Among those who thought childbearing was important to their parents or their partners, not wanting ART was associated with higher anxiety level. These results were significant at $p < 0.05$.
Limitations, reasons for caution: As the lesbian community remains a hidden population in Hong Kong, snowball sampling method and anonymous online questionnaire were used, rendering it difficult to ascertain the response rate and warranting caution when generalizing the results. The cross-sectional design also limited the ability to make causal arguments regarding the observed relationships.
Wider implications of the findings: This is the first quantitative study of reproductive preferences among lesbians in Asia. The findings are helpful for healthcare professionals to address the psychological burden of Asian lesbians in relation to reproductive issues, particularly those pertaining to their perceived expectations from parents and partners concerning childbearing.
Trial registration number: N/A.

P-534 The doctor–couple communication in reproductive medicine: a pilot study on actual assisted reproductive technology (ART) visits

E. Vegni[1], L. Borghi[1], C. Becattini[2], E. Chelo[3], M. Costa[4], L. De Lauretis[5], A.P. Ferraretti[6], G. Giuffrida[7], C. Livi[3], A. Luehwink[8], A. Revelli[9], F. Tomei[10], D. Leone[1]

[6]Centro SISMER, Procreazione Medicalmente Assistita, Bologna, Italy
[7]Centro CRA, Procreazione Medicalmente Assistita, Catania, Italy
[8]Azienda Provinciale per i Servizi Sanitari, Provincia Autonoma di Trento, Centro provinciale per la PMA, Arco, Italy
[9]Ospedale Ostetrico Ginecologico Sant'Anna, Fisiopatologia della riproduzione e PMA, Torino, Italy
[10]Azienda Ospedaliera Santa Maria degli Angeli, SSD di fisiopatologia della riproduzione umana e banca del seme e degli ovociti, Pordenone, Italy

Study question: To explore communicational characteristics in ART visits and their association with patients' activation, patients' satisfaction and patients' adherence.
Summary answer: ART visits seemed highly patient-centered; patients seemed very active and very satisfied. However an association with specific verbal contents of the visit was not found.
What is known already: Communicational and relational aspects in reproductive medicine seem to be crucial for clinical decision making, retention in care and critical conversations with couples because of treatment low possibility of success. However, no studies have been realized regarding the actual interaction between the doctor and the couple in this medical context.

Study design, size, duration: A descriptive cross sectional study involving 9 Italian ART clinics where 28 clinicians and 175 patients (80 couples) signed a written consensus to be videotaped during their ART consultations. A total of 95 ART visits were collected in the period June 2014 to January 2015. 90 visits (51 first visits and 39 follow up visits) were eligible for the analysis.
Participants/materials, setting, methods: Patients filled out: before the visit the Patient Activation Measure (PAM) adapted for ART context (5-point Likert scale from 1 = totally disagree to 5 = totally agree), and after a satisfaction questionnaire (SATQ) (5-point Likert scale from 1 = poor to 5 = excellent). A 3-month telephone follow-up explored the adherence to clinician recommendations. The communication content was coded using the Roter Interaction Analysis System (RIAS), a validated and widely used coding system for categorizing verbal exchanges in the physician–patient interaction.
Main results and the role of chance: The response rate was 62.1%. Preliminary results refer to 30% of the visits. Both females and males reported high scores on the PAM (respectively $\mu = 4.25 \pm 0.38$ and $\mu = 4.21 \pm 0.43$) and on the SATQ (respectively $\mu = 4.45 \pm 0.49$ and $\mu = 4.29 \pm 0.61$). 85% of the couples declared after 3 months to have followed the clinicians recommendations; 17% of the couples declared to have asked an opinion to another ART center. As far as the communication content: physicians contributed for 63% and patients contributed for 37% of all consultation statements. The RIAS categories distributions for physicians and patients were respectively: biomedical questions (7%; 3.7%), lifestyle/psychosocial questions (1.7%; 0.8%), biomedical information (45.4%; 32.9%); lifestyle/psychosocial information (4.8%; 11.7%), emotional expressions (7.4%; 4.4%); facilitation and patient activation (13.4%; 5.7%), positive rapport (7.4%; 30.9%), negative talk (1.3%; 3.1%), social talk (0.7%; 1%), procedural talk (10.1%; 3.2%), unintelligible statements (0.8%; 2.6%). The patient-centeredness mean score was 2.5 (SD = 1.4). No correlations between physicians and patients RIAS categories and patients self-reported measures (PAM and SATQ) were found except for a positive correlation between total talk and SATQ for females ($r = 0.472$, $p = 0.008$) and a negative correlation between PAM and patient-centeredness score for males ($r = -0.462$, $p = 0.017$).
Limitations, reasons for caution: The results are preliminary and referred to the Italian context. A selection bias could be present both for accepting patients and physicians.
Wider implications of the findings: Results will allow a deeper understanding of the complexity of doctor–patient communication during ART visits, in particular concerning the engagement of the patient/couple during the encounter and its outcomes; results will be used also for tailoring the communicational training of the multi-professional team involved in reproductive medicine.
Trial registration number: The study protocol was approved by the Institutional Review Board (IRB) of the University of Milan (number 50/13) and by the IRB of the ART Centers.

P-535 Children's adjustment and perspectives in solo mother families

S. Zadeh[1], T. Freeman[1], S. Golombok[1]
[1]*Centre for Family Research, University of Cambridge, Cambridge, UK*

Study question: How do children think, feel and fare in families formed by single women using donor sperm?
Summary answer: Although children in solo mother families are generally well-adjusted and report feeling positively about family life and friendships, they have questions about father absence.
What is known already: The existing literature has identified that the adjustment of very young infants raised in solo mother families is comparable to infants in heterosexual two-parent families. However, little is known about children's experiences as they grow older. This multi-informant, multi-method study is the first to systematically examine child adjustment and children's perspectives at the age at which children are old enough to understand their family circumstances and what it means to grow up without a father. It is the only study to have elicited children's own reports about their social and familial experiences.
Study design, size, duration: A cross-sectional study of 51 solo mother families and a comparison group of 52 heterosexual two-parent families with at least one donor-conceived child aged 4–9 years. Participants were recruited from a large UK fertility clinic that routinely treats single women. Participating families were matched in terms of the age and gender of the target child, and on demographic factors including mother's educational level, perceived financial difficulties, and psychiatric problems in the last year.
Participants/materials, setting, methods: A response rate of 72% was obtained. All mothers were administered standardized questionnaires of child adjustment and parenting stress. Solo mothers completed a semi-structured interview which asked about their children's feelings about father absence, and whether or not this was a topic of family discussion. Within the solo mother families, 47 children agreed to be interviewed, 25 (53%) of whom were girls, and 22 (47%) boys. Children were asked about family life and friendships.
Main results and the role of chance: Data were analysed both quantitatively and qualitatively. There was no significant difference between family types for total scores on the child adjustment questionnaire measure. Within the solo mother families, higher levels of financial difficulties [$F(2, 41) = 5.00$, $p = 0.01$] and higher levels of parenting stress [$F(7, 36) = 2.55$, $p = 0.03$] were each associated with higher levels of child adjustment problems. Mothers mostly reported that their children had neutral (39%) or mixed (28%) feelings about father absence, and qualitative analyses of mothers' reports indicated conversations about fathers to be a prominent feature of family life. However, most children (89%) who answered a question about changing their family circumstances either expressed a desire for trivial changes (38%) or no change (51%). Children mostly (59%) reported high (19%) or very high (40%) levels of enjoyment of school. All reported having at least one friend, and most (51%) named five or more friends. The majority (63%) had not been teased at school, or had experienced trivial teasing (34%). Preliminary findings from a current follow-up study of these children in middle childhood, specifically focusing on their thoughts and feelings about their donor conception, will also be reported.
Limitations, reasons for caution: Differences between family types may not have been identified owing to the relatively small sample sizes. Not all children responded to all questions asked, possibly owing to age-related comprehension ability.
Wider implications of the findings: Findings from both mothers and children indicate that at the age at which children begin to understand their family circumstances, they continue to function well. The study offers new insights into children's perspectives and experiences in solo mother families, and the processes that determine their adjustment, as they grow older.
Trial registration number: N/A.

P-536 The decision-making process after a failed treatment cycle: understanding compliance during fertility treatment

S. Mesquita da Silva[1], J.M. Place[2], J. Boivin[1], C.S. Gameiro[1]
[1]*Cardiff University, School of Psychology, Cardiff, UK*
[2]*Ball State University, Physiology and Health Science, Muncie, IN, USA*

Study question: What characterises the decision-making process about doing more treatment after a failed cycle?
Summary answer: Patients start treatment determined to follow all the recommendations. After failure, they do not re-negotiate the decision to stop treatment and strive to remain engaged.
What is known already: After a failed cycle, couples have to decide whether to continue undergoing treatment. Previous studies shown that 22% of patients do not comply and also that compliance rates decrease with treatment failure and the main reasons for this are postponement of treatment and psychological burden (Gameiro et al., 2012). Even if the main reasons are already identified, it still remains unclear how the process of decision-making happens, who is involved in this decision and what type of influence each member of the couple might have. This knowledge is useful to provide decisional-aid.
Study design, size, duration: Cross sectional qualitative study. Data was collected in August and December 2014. One-hour semi-structured interviews were carried out separately with the two members of the participating couples. The interview' analyses were performed by two independent coders based on Interpretative Phenomenological Analysis (IPA). The data was checked for credibility, which is an effort in qualitative research to ensure trustworthy findings (Elliot et al., 1999) by presenting results to other infertility and self-regulation experts for feedback.
Participants/materials, setting, methods: Purposive sampling was used to select participants. Participants were eight Portuguese heterosexual couples who experienced a failed cycle of IVF or ICSI between 6 weeks and 1 year prior to the interview, were deciding whether or not to do another treatment cycle, and were not advised to discontinue treatment. The main subjects of the interview schedule were parenthood goal importance, failed treatment experience and individual and couple strategies to deal with it.

Main results and the role of chance: Most couples decide to do all the treatment cycles recommended at the beginning of treatment. Therefore, after experiencing a failed cycle, individuals wanted to undergo more treatment regardless of the medical prognosis for the next cycle and largely due to the high importance they attributed to parenthood. Giving up on treatment was not an option. Consequently, patients used several strategies to self-motivate to remain in treatment, such as considering each treatment cycle as a learning opportunity to acquire new skills and to avoid future regrets and, seeing the treatment process as a "game of probabilities" that required persistence to get results. A lack of communication characterized the couples as men tended to voluntarily leave the decision-making to their partners, given that women endure most of the medical procedures. Despite this, couples recognize the role partners have in the regulatory process, mostly in terms of support provision. Some patients made the decision to do more treatment in the service of secondary goals (e.g., for the partner to be happy) instead of the primary parenthood goal.
Limitations, reasons for caution: Heterogeneity is accounted for by the existence of inter-sample differences between couples who have recently started their infertility journey and those who have had multiple failed cycles. However, all participants lived in the same country and decision-making processes may reflect Portuguese cultural values and social norms instead of universal ones.
Wider implications of the findings: After a failed cycle, patients should have the opportunity to integrate the new information into their decision-making. This would allow them to make a decision about continuing treatment with the doctor based on prognosis. Patients should also be offered additional decisional support to consider wider psychosocial implications of continuing treatment.
Trial registration number: N/A.

P-537 Relationship stability among heterosexual couples following oocyte and sperm donation

G. Sydsjo[1], A. Skoog-Svanberg[2], C. Lampic[3]
[1]Faculty of Health Sciences-Linköping University, Sweden, Department of Obstetrics/Gynecology, Linköping, Sweden
[2]Department of Women's and Children's Health, Uppsala University, Uppsala, Uppsala, Sweden
[3]KI, Department of Neurobiology, Care Sciences, and Society, Karolinska Institutet, Stockholm, Sweden

Study question: Is there a difference in the relationship stability in couples having children via donated sperm or oocytes?
Summary answer: The results will be focusing on relationship dimension and also separation and custody discussions.
What is known already: Most research on couple's relationship stability following gamete donation has a short term perspective and measures relationship during treatment or shortly after treatment. The conclusions from these studies have been that the relationship stability has been found good in couples conceiving with different assisted reproduction techniques. The sample sizes are rather small in most studies.
Study design, size, duration: The present study is part of the "Swedish study on gamete donation" including all 7 clinics performing gamete donation in Sweden. All couples were consecutive recruited during 2005–2008. The couples have answered questions about their relationship three times before – at treatment and when the child was 1 and 4 years old. When the child was 7 years the men and women were again approached with question s about their relationship.
Participants/materials, setting, methods: The present study is part of the prospective longitudinal "Swedish study on gamete donation" including all fertility clinics performing gamete donation in Sweden. Parents with 7-year-old children following oocyte ($n = 53$) or sperm donation ($n = 79$) representing 75 families answered study specific questions about separations and custody. Among these families about one in six couples had separated (ORec 17%; SRec 18%).
Main results and the role of chance: For those who have been separated we found that in all but one family the parents had joint custody with the child living alternate weeks with its parents. The both the parents reported the custody situation to be functioning well. In one family following oocyte donation the mother had sole custody following a custody battle. We did not found any differences in separation frequencies in the couples.
Limitations, reasons for caution: The drop-out rate is of concern for the interpretation of the results. 45% for the SD-couples and 41% for the OD couples.
Wider implications of the findings: The couple's relationship is of interest to discuss at the treatment start and follow up.
Trial registration number: NA.

P-538 Which is the best instrument? A psychometric comparison of COMPI fertility problem stress (COMPI-FPSS), fertility problem inventory (FPI), and fertility quality of life tool (FertiQoL)

J. Pedro[1], Y. Frederiksen[2], L. Schmidt[3], H.J. Ingerslev[4], R. Zachariae[5], M.V. Martins[1]
[1]University of Porto, Faculty of Psychology and Education Sciences, Porto, Portugal
[2]Aarhus University, Department of Psychology and Behavioral Sciences, Aahrus, Denmark
[3]University of Copenhagen, Department of Public Health, Copenhagen, Denmark
[4]Aarhus University Hospital/Aarhus University, Center for Preimplantation Genetic Diagnosis/The Fertility Clinic, Aahrus, Denmark
[5]Aarhus University Hospital/Aarhus University, Department of Oncology/ Department of Psychology and Social Sciences, Aahrus, Denmark

Study question: Which infertility-related psychosocial adjustment self-report measure presents the best psychometric properties and better predicts clinically significant depression and anxiety in infertility patients?
Summary answer: While the COMPI-FPSS and the FPI presented better reliability, the FertiQoL presented better fit and discrimination of clinically relevant depression and anxiety.
What is known already: Infertility brings physical, emotional, and psychosocial challenges. About 40% of patients undergoing fertility treatments are at risk for psychological maladjustment. Several infertility-related psychosocial adjustment self-report instruments have been developed in the last decades. The most used have been the COMPI-FPSS, the FPI and the FertiQoL. This is the first study concurrently comparing the psychometric properties of these instruments and investigating their predictive validity to discriminate between patients with and without clinically relevant depression and anxiety in the same sample of patients.
Study design, size, duration: From November 2010 through July 2012, 1302 patients attending three Danish fertility clinics for fertility treatments were invited to participate. 919 patients declined to participate or did not respond (response rate = 29.4%). Ninety were further excluded because they did not meet the study's criteria. At one single moment, participants completed a questionnaire including sociodemographic questions and self-report instruments: COMPI-FPSS, FPI, FertiQoL, Beck Depression Inventory (BDI) and State-Trait Anxiety (STAI-State).
Participants/materials, setting, methods: Participants were 293 patients (161 women, 132 men). On average, participants were trying to conceive for 2.52 years (SD = 1.20) and 52.2% had already undergone one cycle of IVF/ICSI. Reliability, convergent and concurrent validity were evaluated. Confirmatory factor analyses (CFA) were performed for the three instruments. A receiver–operator curve (ROC) analysis was performed to evaluate the ability of each instrument to identify patients with or without clinically relevant depression (BDI >13) and anxiety (STAI-State ≥40).
Main results and the role of chance: The removal of a few items was performed after findings suggesting either an increase in internal consistency after removal (FPI and FertiQoL), or poor CFA model fit (loadings <0.40, FPI and FertiQoL). Subsequent analyses revealed good internal consistency in all three scales total scores (alphas between 0.89 and 0.91), with the COMPI-FPSS and the FPI subscales presenting better alphas than FertiQoL subscales. CFAs revealed acceptable fit for all final instrument models, with FertiQoL presenting a slightly better fit than the other two measures. Convergent validity was confirmed (r between 0.76 and 0.83). FPI results showed better concurrent validity indices than COMPI-FPSS and FertiQoL. In predicting clinically relevant depression, the areas under curve (AUC) were: COMPI-FPSS 0.86 (95%CI: 0.81–0.90), FPI 0.84 (95%CI: 0.79–0.89) and FertiQoL 0.88 (95%CI: 0.84–0.92). The AUC predicting clinically significant anxiety were: COMPI-FPSS 0.76 (95%CI: 0.70–0.81), FPI 0.77 (95%CI: 0.71–0.83) and FertiQoL 0.83 (95%CI: 0.78–0.88). The FertiQoL was the best instrument discriminating between patients with or without clinically relevant depression and anxiety and was able to

correctly discriminate 88% of the patients regarding clinical depression (sensitivity: 0.79; specificity: 0.81) and 83% regarding clinical anxiety (sensitivity: 0.79; specificity: 0.73) while COMPI-FPSS and FPI correctly discriminated lower percentages of patients.
Limitations, reasons for caution: These results cannot be generalized to infertile individuals not seeking treatment or without diagnosis. Because Cronbach's alpha is dependent on the number of items, the between-instrument comparability of reliability could have been affected. Further studies with repeated assessments are needed in order to evaluate responsiveness indices.
Wider implications of the findings: This study contributes to a better knowledge on psychometric properties of infertility-related psychosocial adjustment measures. This knowledge may help clinicians to decide which instrument to use in order to timely identify and refer to counseling or psychotherapy the patients who presented a greater vulnerability to develop maladjustment and emotional problems.
Trial registration number: NA.

P-539 Effect of IVF therapy on quality of sexual life

J. Brezinova[1], H. Visnova[2], R. Huttelova[3], P. Uher[2]
[1]*IVF CUBE, Prague 6, Czech Republic*
[2]*IVF CUBE, Reproductive Medicine, Prague 6, Czech Republic*
[3]*IVF CUBE, Embryology, Prague 6, Czech Republic*

Study question: Does IVF treatment affect sexual life of treated couple? What factors lead to lower quality of sexual life or its absence?
Summary answer: By 62% of respondents occurred decline of quality of sexual life. Main alteration was refusal of intercourse due to fear of negative therapy outcome.
What is known already: From psychological point of view infertility and its treatment are considered as very difficult process mostly unattended by any sexual dysfunction. The lack of sexual activity during treatment mainly by repetitive IVF cycles and fear of affecting the treatment outcome leads to emotional instability, relationship problems, sadness, anxiety, sexual alienation, etc. These issues progress at 20% of women into significant levels of depressive symptoms. Even if the routine psychological care is provided during fertility treatment, the fertility specialists do not deal with contentment in sexual life.
Study design, size, duration: The study was a retrospective questionnaire. Study duration was 7 months during 2015. There were addressed 450 participants among treated couples from the Czech Republic, Italy, Germany, Ireland and UK. The return in total was 127 (28%) filled questionnaires (84 women and 43 men).
Participants/materials, setting, methods: The participants were women and men undergoing a fresh IVF treatment or frozen embryo transfer. There was no difference between donor cycles and cycles with own oocytes and/or semen. The inclusion time was the day of HCG check-up (14 days after embryo transfer). There was no age limit by the participants; the average age was 39.5 years.
Main results and the role of chance: In 62% (79) of cases the respondents noticed deterioration of quality of their sexual life while undergoing IVF treatment, 37% (47) didn't feel any changes and 1% didn't answer the question. The most described alteration were: decrease in frequency of intimate activity 46%, decrease of sexual desire 20%, timing of intercourse only on fertile days 16%, change of sexual position 4%, change in use of erotic toys 2% and become unattractive to each other 2%. In 69% (58) of cases women didn't have intercourse after embryo transfer (ET). Reason for refusal was fear of negative result of the therapy 66%, fear of miscarriage 47%, barriers due to use of vaginal tablets 43%, tiredness 24%, pain in the lower abdomen 22%, dryness of vagina 10%. Also men didn't have intercourse after ET in the most cases (67%). In comparison to those results, 58% of women and 64% of men provided the same sexual desire as in the time with no treatment. Even 86% of women and 67% of men presented partner's interest in sex. In 34% of women and 56% of men the intercourse was compensated by non-coital activities (even with orgasm – 55%).
Limitations, reasons for caution: Main limitation was low return of completed forms and/or their general refusal due to non-anonymous sort of questionnaires. Non-anonymous processing ensured connection to patient's medical records for further analysis. Another limitation consisted in very intimate character of the inquiries and persisting general perception of the topic as a taboo.
Wider implications of the findings: Lack/absence of sexual activities, their lowered quality and fear of the impact on treatment result could negatively influence mental condition of treated patient. The situation could be worsened by repetitious IVF cycles after negative outcome. The treated couple should be openly informed about all options in sexual activities during therapy.
Trial registration number: –

P-540 "Just an egg"?: egg donors' perceptions and future expectations of being an identity-release donor

S. Graham[1], V. Jadva[1], T. Freeman[1], K. Ahuja[2], S. Golombok[1]
[1]*University of Cambridge, Centre for Family Research, Cambridge, UK*
[2]*The London Women's Clinic, London, UK*

Study question: How do UK egg donors think and feel about being an identity-release donor?
Summary answer: The conceptualisation of egg donation as "just an egg" and a recipients' chance for an "own child" influenced donors' views on anonymity, and information provision.
What is known already: Very little is known about how egg donors who have donated under an identity-release system think about their donation and future information exchange. The majority of identity-release egg donors surveyed 5–8 years after donating in a Swedish study were positive towards being contacted by offspring when they reached the age of eighteen (Isakkson et al., 2014). This is the first study of UK egg donors since the removal of donor anonymity in 2005.
Study design, size, duration: The findings were collected as part of an exploratory, in-depth qualitative study comprising of semi-structured interviews with eleven women who had attended an egg donation screening appointment at a UK clinic during a 4-month period in 2014.
Participants/materials, setting, methods: Interviews were conducted 2–6 weeks after the woman had donated or had withdrawn/been rejected from the donation process. Interviews explored egg donors motivations, experiences and future expectations of donating their eggs. Interviews were transcribed and thematic analysis performed.
Main results and the role of chance: The majority (91%) of egg donors conceptualised their donation as "just an egg," giving the recipient the chance to have an "own child." All egg donors were happy to be contacted by a child conceived through their donation, stating it was their "responsibility" to answer any questions they may have. However, the majority of participants thought contact unlikely: the child would either not be aware of their donor conception or would be comfortable with this information. In fact 45% of participants were unsure whether the removal of donor anonymity had been necessary, 36% had concerns about being an identity-release donor and only 36% provided non-identifying information about themselves at the time of donation in the form of a pen portrait and goodwill message. Concerns stemmed from empathy for the egg recipient and the possibility for donor information to make the donor's role more than "just an egg," intruding upon the recipient's "own child." All egg donors wanted information on the outcome of their donation and 64% wanted more information about the recipient(s) of their eggs in order to help them imagine the family they had helped to build through their donation.
Limitations, reasons for caution: This in-depth, exploratory study is the first study of UK egg donors since the removal of donor anonymity. However, due to its small sample size and recruitment from only one clinic, this study may not be representative of other egg donors.
Wider implications of the findings: This study highlighted the complexity egg donors experience in navigating information exchange. Further guidance should be given to egg donors when providing non-identifying information. Donors may feel more satisfied with their role as an identity-release donor if they receive more information about the outcome and recipient(s) of their donation.
Trial registration number: N/A.

P-541 The impact of disclosure versus non-disclosure on the child's well-being and on family functioning in heterosexual families with donor-conceived children: a systematic review

U. Van den Broeck[1], J. Knaeps[2], T. D'Hooghe[3]
[1]*Leuven University Hospital Campus Gasthuisberg, Department of Gynaecology/Fertility Centre, Leuven, Belgium*
[2]*KULeuven, Department of Psychology, Leuven, Belgium*
[3]*KULeuven, Department of Medicine, Leuven, Belgium*

Study question: What is the impact of (non)disclosure about donor conception on a child's psychological well-being and on family functioning in heterosexual families?
Summary answer: Overall, gamete donation families showed adequate marital, psychological and family functioning, though there are many gaps in knowledge as well as methodological shortcomings.
What is known already: The practice of gamete donation has in the past been surrounded by secrecy and concerns regarding the impact of these procedures on family functioning and the child's psychological well-being. Recent years has seen a gradual move towards more openness in society. Nevertheless, the impact of openness or secrecy on the child's socio-emotional development and family functioning remains still largely unknown.
Study design, size, duration: A systematic review was performed by searching electronic databases (PUBMED, PsycINFO, and Embase) by means of a specific search strategy followed by a snowball strategy. English language publications were screened for eligibility and subjected to a quality control using 22 criteria (STROBE). Relevant data were extracted to a structured data extraction sheet with different categories.
Participants/materials, setting, methods: Inclusion criteria: (i) only English language original empirical research with a quantitative, qualitative or mixed methodology, (ii) study participants were heterosexual couples who had used donor conception (sperm, egg or embryo) to conceive with donors who were either anonymous (unknown to recipients) or non-anonymous (known to recipients). (iii) the examination of (non)disclosure about a child's donor origin and its associated effects one of the primary aims of the study.
Main results and the role of chance: The initial search retrieved 1088 studies, dating from 1995 until 2012, of which 21 were retained for data extraction, conducted in 12 different countries, representing a diversity of disclosure customs about the child's donor origin. The majority of studies (N = 14) had a cross-sectional design whereas seven were longitudinal. Most studies used a mixed method approach, combining questionnaires with qualitative analysis (16/21). Sample sizes ranged from 7 families to 541 families, with a mean sample size of 141. An average of 14% (90/639) of DI couples had informed their child about their donor origin with an average age at disclosure of seven (SD = 3.8), as calculated over five studies (5/21), whereas 64% (409/639) of couples were non-disclosing. On the whole, the central finding of the review synthesis revealed no discrepancies between disclosing and non-disclosing families for marital relationship, child's and parents' psychological well-being, and family functioning. However, in disclosing families (15/21) both neutral as well as negative and positive reactions to disclosure were found, which appeared to be associated with age at disclosure. Concerning non-disclosure, some studies (3/21) noted that offspring showed an awareness of secrets within their families or raised questions regarding their family origins.
Limitations, reasons for caution: This review revealed several important methodological shortcomings in terms of sample size, data population and study design that may have biased the data in the studies. Therefore, data interpretation needs to take these shortcomings into account as well as several gaps of knowledge.
Wider implications of the findings: Our findings offer useful information to policy makers, professionals and prospective parents on the effects of (non) disclosure in gamete donation families. A framework of "selective disclosure" is proposed that goes beyond dichotomous thinking about (non)disclosure and focuses on the "good intentions" of parents regardless of their disclosure status.
Trial registration number: NA.

P-542 Reproduction by sperm donation and children information: a 10 years retrospective study of parent's disclosure in one French CECOS center

C. Metzler-Guillemain[1], J. Rouzier[1], S. Carez[1], A. Gnisci[1], J. Saias-Magnan[1], C. Deveze[1], J. Perrin[1], T. Lassalzede[1]
[1]*AP-HM La Conception, Biologie de la Reproduction-CECOS, Marseille, France*

Study question: To evaluate the percentage of parents that disclose their use of donated spermatozoa to their children, to know if parents disclosure is consistent with their intention before assisted reproductive techniques.
Summary answer: With a participation rate of 68%, most parents had already disclosed their use of donated spermatozoa to their children or intended to disclose it soon.
What is known already: In France, the sperm donation practice is supervised by CECOS (Centre d'Etude et de Conservation des 'ufs et du Sperme) centers. Each year, more than 2,000 couples have an ART using donated spermatozoa, and more than 50,000 children are born since the creation of the first CECOS in 1973. It seems that number of parents who intend to disclose their use of donated spermatozoa to their children regularly increase, but we have no data about the real parents attitude.
Study design, size, duration: In a retrospective study, we identified 486 pregnancies and 317 births resulting from ART with donated spermatozoa from 2002 to 2012. All couples gave their informed consent to be contacted after childbirth. We first contacted 164 couples by phone to explain the study objectives, 157 agreed to participate. We sent 157 questionnaires by mail to ask couples about their attitude and intention to inform or not their child.
Participants/materials, setting, methods: Families were recruited through our CECOS center. Participants completed a standardized questionnaire between February and March 2014.
Main results and the role of chance: Among 157 questionnaires sent, 105 couples answered and had 144 children born between 2002 and 2014. There were 41 couples that had already disclosed the donor origin to their child, and 64 (61%) who did not. Of the 41 couples (39%) who disclosed the donor origin to their child, 39 intended to before ART, but 2 (5%) did not want to before ART. Among the 64 couples (61%) who did not inform their child, 42 (66%) plan to inform their child soon, but 20 (31%) want to keep the sperm origin secret. Of the 20 couples who want to keep the origin secret, 3 intended to disclose the donor origin before ART.
Limitations, reasons for caution: This is a retrospective study. Although a good participation rate, the lack of response from 52 couples may induce a risk of selection bias.
Wider implications of the findings: This study shows that after childbirth the majority of parents disclose or intend to disclose the donor origin to their child, which is higher than reported in the international literature. Moreover, they are consistent with their intention before ART even if 5% of couples changed their intention after childbirth.
Trial registration number: No clinical trial.

P-543 Factors risk of infertility: what information patients receive before ART?

N. Chevalier[1], G. Charlotte[1], P. Rusudan[1], S. Pierre[1], M. Mathilde[1], Q. Guillaume[1], L. Christophe[1], R.V. Gilles[1]
[1]*Centre de Gynécologie Obstétrique Tour Polygone, Service Médecine de la Reproduction Centre AMP Saint-Roch, Montpellier, France*

Study question: What information is known couples before their treatment in ART and how they receive this information.
Summary answer: Many couples followed in ART are overexposed to infertility risk factors (smoking, overweight, alcohol, …) and often have a lack of information on the subject.
What is known already: In our modern society, changes in lifestyle increase exposure to certain factors affecting fertility and contribute to fertility decline (smoking, overweight, unhealthy diet, alcohol, …). The correction of these risk factors may allow patients to recover their potential natural fertility and improve outcomes in Assisted Reproductive Technologies (ART). When couples consult with ART, they have often not started to change these risk factors. At present where many means of communication are developed, couples can be informed but the target is not often achieved.
Study design, size, duration: We performed a descriptive epidemiological study, quantitative, with a self anonymous questionnaires offered to infertile couples consultant at the center AMP Saint-Roch in Montpellier on paper and the members of certain patient groups across the French territory by a questionnaire online from December to April, 2015.
Participants/materials, setting, methods: Three hundred and seventeen questionnaires women and 153 men were included. We asked in the first part of the questionnaire if they were exposed to various toxic or risk factors that may be involved in fertility. And in a second part of the questionnaire, the couples met on their knowledge and the means of communication that allowed them to be aware of these risk factors for infertility.
Main results and the role of chance: The average age of women is 34.5 years and men 36.3 years. The social level of patients is quite high with over 67% with a higher level of education. Most couples (75%) were already in ART: 75%

of patients accumulate between two and five risk factors. Addictions (tobacco, cannabis, alcohol) and stress are most evident for patients. Weight, diet and sedentary, although very common in our population are insufficiently known patients, especially men who are often the most exposed. Other factors (caffeine, toxic, testicular heat) are unknown to patients, but less frequent. Women seem better informed than men. The main source of information is the media and internet to more than one third of couples. The doctors only come in third position (15% by the gynecologist and 8.5% by the general practitioner) behind friends and family.

Limitations, reasons for caution: The survey by self-administered questionnaire can result in selection bias because they are the most involved patients who respond to the questionnaire. Patients already being in an IVF course, the information received may be considered retrospectively. Finally some questionnaires were incomplete.

Wider implications of the findings: The couples consulting for a problem of infertility, appear overexposed to risk factors and there is a lack of information for many factors. The sedentary lifestyle and stress are the main. Websites are the preferred means of patients, should be strengthened reliably, accurate and accessible.

Trial registration number: None.

P-544 Children's, parents' and donors' perspectives on family communication about sister-to-sister oocyte donation: a multi family member interview study

H. Van Parys[1], V. Provoost[2], I. Stuyver[3], G. Pennings[2], P. De Sutter[3], A. Buysse[1]
[1]*Ghent University, Psychology and Educational Sciences, Gent, Belgium*
[2]*Ghent University, Bioethics Institute Ghent, Gent, Belgium*
[3]*Ghent University Hospital, Department of Reproductive Medicine, Gent, Belgium*

Study question: How do family members (parents, children and the donor) experience family communication about the donor conception in sister-to-sister oocyte donation families?

Summary answer: Family communication about the donor conception was subject of careful consideration for both recipients and donors and was rather limited.

What is known already: In intra-familial medically assisted reproduction, familial closeness between donor and recipients raises questions about how family relationships are shaped and experienced before, during and after the donation. Studies on the recipient couples' experiences mainly focus on their disclosure decisions and the relationship between recipient couples and donors. The ways in which this donor conception is discussed and family members' individual experiences of the disclosure process do not receive much research attention.

Study design, size, duration: As part of a larger qualitative research project on family members' perspectives on social and genetic parenthood, semi-structured interviews were conducted with heterosexual couples, their oocyte donors and one of their children. Participants were recruited via the Department of Reproductive Medicine of the Ghent University Hospital.

Participants/materials, setting, methods: Couples eligible for the study were contacted by their counsellor 7–10 years post treatment. Two couples, one mother, three oocyte donors and three children were interviewed separately. Interviews were analysed using Interpretative Phenomenological Analysis, followed by an analysis within families and a comparison across families.

Main results and the role of chance: The three participating families all had disclosed the nature of conception to their (oldest) child. The parents held the belief that the way they spoke about the donation would impact their child's evaluation of this conception method. In this respect, carefully selected messages were given to the child and this was also what the child remembered of the story when they were asked about it in the child interview. Furthermore, disclosure processes in the recipients' and donors' families seemed to be coordinated as both the recipients and the donor wanted to avoid the children finding out in an inappropriate way. In general, there was only limited discussion about the oocyte donation between all family members. It is striking that some children expressed a wish to talk about the oocyte donation to the donor or the donor's children but refrained from doing so.

Limitations, reasons for caution: Our analysis was based on a small sample and does not intend to produce generalizable findings. Moreover, it was based on a specific subset of families in which the donor conception was disclosed to the child and parents felt comfortable with their child being interviewed.

Wider implications of the findings: This is found to be the first study linking children's, donors' and recipients' perspectives on family communication about the intra-familial donor conception. Consistent with recent process-oriented disclosure studies, this study pointed at the complexity of this dialogical process and to various meanings that can be attached to the donor conception.

Trial registration number: N/A.

P-545 Fertility preservation to transmen: learning the needs of a new patient group

G. Armuand[1], C. Dhejne[2], J.I. Olofsson[3], K. Rodriguez-Wallberg[1]
[1]*Karolinska Institutet, Department of Oncology-Pathology, Stockholm, Sweden*
[2]*Karolinska Institutet, Department of Clinical Neuroscience, Stockholm, Sweden*
[3]*Karolinska Institutet, Department of Clinical Science, Intervention and Technology, Stockholm, Sweden*

Study question: How does healthcare professionals at an academic fertility clinic experience transmen as a new patient group and adapt existing clinical fertility preservation (FP) program?

Summary answer: Learning the needs of transmen, a new patient group, was a challenging process. Through increased knowledge, training and patient collaboration, professionalism grew over time.

What is known already: Earlier research shows that FP may negatively impact transmen's gender dysphoria, as the procedures are closely linked to the female identified body parts the men strive to leave behind. Trans people have reported negative experiences of healthcare encounters, both within general health care as well as in reproductive care, where they have experienced discrimination and even been refused care. No studies have investigated healthcare professionals' experiences of caring for transmen who undergo FP. Research among general healthcare providers' shows that the professionals felt that they lacked knowledge about trans-specific healthcare needs and available resources.

Study design, size, duration: Healthcare providers working at an academic reproductive medicine clinic providing FP for transmen were invited to participate in semi-structured interviews. As we wanted to capture the experiences of meeting transmen throughout the chain of care, we also included administrative staff. The interviews lasted 17–53 min (mean 34 min). The interviews were digitally recorded and transcribed verbatim. Inclusion started in January 2016 and is still ongoing.

Participants/materials, setting, methods: Hitherto, 10 health care providers (2 physicians, 4 midwifes and 4 administrative personnel) have participated in the study. The interviews covered two areas: the preparation, education and planning for this new patient group which took place prior to the new patient group being counselled for FP, and personal experiences of caring for transmen that underwent counselling and FP. Data was analysed using thematic content analysis.

Main results and the role of chance: Preliminary analysis resulted in three themes: *preparations*, *encounters* and *practicalities*. The first theme is about how the clinics preparations, such as presentations and meetings, helped the health care providers to understand the transmen's specific needs. The second theme is about experiences of meeting the transmen who underwent FP procedures. The most challenging part in the encounters was how to know what name, pronoun and which terminology to use. Fear to upset or irritate lead to holding back on communication. One way to solve this was to ask about preferred pronouns and words and being responsive to any signals. The healthcare providers noted that they became more skilled over time. The physicians and midwifes were particularly cautious when performing pelvic exams, as they were considered to be distressing. The third theme is about practicalities that sometimes functioned as a barrier to optimal care, such as the printed patient information material not being adjusted for the new patient group. Additionally, IT system issues when recording new personal identity number following the patients changing their legal sex were encountered. These problems were all solved over time, but caused distress not only for the transmen but also for the health care providers.

Limitations, reasons for caution: As in all qualitative research the results are based on an interpretation of the interviews. So far, only ten providers have been interviewed and some caution is advised when interpreting the results.

Wider implications of the findings: The findings of the study provide an insight into what facilitators and barriers that may be present when introducing a new patient-group at a reproduction clinic; transmen undergoing FP. This in

turn may help other clinics to prepare for the patient group in order to optimize the care.
Trial registration number: Not applicable.

P-546 Does having a child impact infertile couples' relationship satisfaction? A longitudinal study with men and women who did and did not achieve a live birth

M.P. Sobral[1], M.E. Costa[1], M.V. Martins[1]
[1]*Faculdade de Psicologia e de Ciências da Educação, UP de Consulta Psicológica, Center for Psychology at University of Porto, Porto, Portugal*

Study question: Does having a child impact infertility patients relationship satisfaction?
Summary answer: Having a live birth seems to increase relationship satisfaction 5 years after a couple seeks treatment.
What is known already: Literature suggests that the infertility process (i.e., infertility diagnosis, fertility treatments) and the inherent psychological phenomena (e.g., common goal, complicity) can bring marital benefit to infertile couples. However, some scholars argue that such marital benefit may fade with time and/or discontinuation of treatments. Furthermore, transitioning to parenthood has a negative impact on couple's relationship satisfaction. The challenges that accompany taking care of a newborn seem to push the members of the couple away from each other. There is no long-term evidence on how this transition affects infertility patients.
Study design, size, duration: Participants were drawn from a consecutive sample of patients attending a fertility center in 2010/2011 (T1), who were contacted via telephone in 2015 (T2). Each woman was asked to report current relationship status, fertility treatments outcome, reproductive decision, and relationship satisfaction. If the couple was not divorced/separated, men were then contacted to report his relationship satisfaction as well.
Participants/materials, setting, methods: Exclusion criteria were being divorced or separated, having previous children and having adopted. The final sample was composed of 107 couples (81 had achieved a live birth, 26 had decided on a child-free lifestyle). Patients responded to the satisfaction subscale of the *Perceived Relationship Quality Components Inventory* at both assessment points. Reproductive decisions (T2) were assessed via a brief semi-structured interview. Paired-sample *t*-tests were performed for males and females separately.
Main results and the role of chance: No baseline differences were found on relationship satisfaction between couples who would and would not achieve a live birth after treatments ($p > 0.05$). No differences between satisfaction in T1 and T2 were found for men ($M_{T1} = 5.48$; $SD_{T1} = M_{T2} = 5.57$; $SD_{T2} =$) or women ($M_{T1} = 5.51$; $SD_{T1} = 0.688$; $M_{T2} = 5.67$; $SD_{T2} = 0.688$; $p > 0.05$) who decided on a child-free lifestyle. For those who had a live birth between the two assessments, an increase in relationship satisfaction was found both for men ($M_{T1} = 5.34$; $SD_{T1} = 0.667$; $M_{T2} = 5.64$; $SD_{T2} = 0.676$; $p = 0.005$) and women ($M_{T1} = 5.33$; $SD_{T1} = 0.778$; $M_{T2} = 5.57$; $SD_{T2} = 0.680$; $p < 0.001$).
Limitations, reasons for caution: Although this study extended the evaluation of relationship satisfaction almost to 5 years after having started treatment, we still do not know whether marital benefit persists over a longer period. Findings cannot be generalized to patients who transitioned to parenthood through adoption.
Wider implications of the findings: The increased marital satisfaction that infertile patients experience from transitioning to parenthood is encouraging, and fertility staff can use this information in preventing treatment discontinuation. Further studies are needed to elucidate if and how infertile couples enjoy infertility marital benefit by assessing pre-treatment levels.
Trial registration number: N/A.

P-547 Surrogate families in Spain: difficulties perceived of doing the process abroad, perception and relationship with the surrogate and decision over disclosure

M. Roca[1], C. Negre[2]
[1]*Hospital Quiron Barcelona, Psychology, Barcelona, Spain*
[2]*Centre APROP, Psychology, Barcelona, Spain*

Study question: Psychosocial experience of surrogacy in Spanish families who have done the process aboard.
Summary answer: Spanish surrogate families also have to face issues related with living the distance and the lack of proximity with the surrogate mother.
What is known already: No studies have been done about surrogacy in Spanish population. Due to the illegality of the process in Spain, as in many other European countries, families have to look for a commercial surrogacy that implicates emotional, economic, cultural, social and family issues.

Findings in other countries, where national surrogacy is allowed, suggest that surrogate families maintain good relationships with the surrogate mother over time, report a positive arrangements experience and show disclosure intention.
Study design, size, duration: Data were collected from January to November 2015 in a cross sectional study in Spain. We enrolled 35 men and women, couples and single, who had done a surrogacy process aboard.
Participants/materials, setting, methods: The sample is composed by heterosexual and homosexual couples, as well as single gay men and women in Spain, who had at least one surrogacy child older than 6 month.

Semi-structured, open-ended and auto administrated questionnaire relating to motivations, experiences, relationship with de surrogate mother, support, knowledge, information, concerns, legality, genetic link and disclosure, were sent by e-mail to the families, previous telephone contact.

Participant where recruited through surrogacy agencies and intended parents national associations.
Main results and the role of chance: Results show 46.7% of the sample would modify some aspect of the surrogate process, especially those related to legal (16.7%) and administrative aspects, registers and information (16.7%). Parents describe positive aspects of surrogacy as (1? y 2?) (29.9%), and the negative ones are related to legal aspects (43.5%), distance, lack of information and the economic cost (13.5%). The main difficulties these families have had to face are economic (66.5%), job (26.6%) and language (26.6%). Having done the surrogation in their own country would have allow them to have much more implication during the process (53.2%) and establish a closer relationship with de surrogate mother (49.9%). After meeting more than one possible surrogate mother (80%) intended parents established a close relationship with her, describing her as nice, affective or self confident. Contact between the intended parents and the surrogate mother decreased over time. 13.8% of the parents have informed their children about surrogacy and 82.7% of them show disclosure intention as their children get older. Narrative about the surrogacy process includes, in 51.7% of the cases information and data about the process and 34.5% of them manifest gratitude toward the surrogate mother. 58.6% of the surrogate children have met their surrogate mother.
Limitations, reasons for caution: Limitations: the sample size is relatively small due to the difficulty to identify those families and the legal situation they face. Confounders: infertility problems, genetic link, marital status, gender, motivations, sexual orientation, economic status.
Wider implications of the findings: Distance is the most important surrogacy stressor, generating anxiety, fear, lack of control and economic issues. Results are consistent with the literature, in the perception of the surrogate mother and the disclosure intention. Data show great ignorance about how and when disclosure. Contact with the surrogate mother decreased over time.
Trial registration number: x.

P-548 Can pre-treatment emotional health predict pregnancy rates after IVF?

V. Tamhankar[1], G. Jones[2], P. Magill[2], R. Jacques[3], M. Metwally[4], J. Skull[4], W. Ledger[5]
[1]*Sheffield, UK*
[2]*University of Sheffield, Academic Unit of Reproductive and Developmental Medicine, Sheffield, UK*
[3]*University of Sheffield, Medical Statistics Group, Sheffield, UK*
[4]*Sheffield Teaching Hospitals NHS Trust, Department of Reproductive Medicine, Sheffield, UK*
[5]*University of New South Wales, Department of Obstetrics and Gynaecology, Sydney, NSW, Australia*

Study question: Can pre-treatment emotional health predict pregnancy rates after *in vitro* fertilization (IVF) treatment?
Summary answer: Pre-treatment emotional health does not predict pregnancy rates after IVF.

What is known already: The emotional burden of infertility is increasingly becoming a significant priority. Studies on psychological interventions suggest a link between emotional health improvement and IVF outcome. The evidence from existing literature demonstrates higher levels of anxiety and depression in IVF patients, but the effect this has on the conception rates is inconclusive. Existing studies have methodological limitations due to use of generic tools to assess emotional health which cannot capture the complex nature of fertility specific distress. There is a need for large cohort study to examine this relationship using a fertility specific tool.
Study design, size, duration: The aim of this study is to investigate if emotional health of patients can be used to predict IVF outcome. The study was designed by recruiting a prospective cohort of 414 women undergoing IVF between June 2011 till February 2015. The treatment cycle of 35 women were cancelled at different stages due to medical reasons. 379 patients completed the treatment cycle. An intention to treat analysis was performed.
Participants/materials, setting, methods: Women undergoing IVF were asked to complete a set of patient-reported outcomes at the start of the cycle which included Emotional Health in Infertility Questionnaire (EHIQ), Perceived Stress Scale, Positive and Negative Affect and Fertility Problem Inventory. Clinical pregnancy rates and live birth rates were compared between women with low, average and high emotional health. We then used logistic regression to see if pre-treatment emotional health can predict the probability of pregnancy.
Main results and the role of chance: 414 women undergoing IVF were divided into three tertiles according to their emotional health profile: poor emotional health (EHIQ 13.13–56.88; n = 140), average emotional health (EHIQ 57.5–71.88; n = 139) and high emotional health (72.5–97.50; n = 135). The three groups were similar with regards to female age, BMI, previous live births and proportion of patients having their first IVF. The overall pregnancy rate is this study group was 31.4%. Clinical pregnancy in patients with low emotional health was statistically similar to patients with high emotional health (27.9 vs. 31.1% p = 0.597). The clinical pregnancy rate was lowest (27.9%) in women with poor emotional health, but the highest pregnancy rates were found in women with average emotional health (36.2%). This difference was not statistically significant (27.9 vs. 36.2% p = 0.199). Logistic regression showed that EHIQ scores did not predict the clinical pregnancy in this study group.
Limitations, reasons for caution: Some patients who declined to participate, cited stress about the treatment outcome as the main reason. This indicates selection bias as some patients with poor emotional health have not been included.
Wider implications of the findings: Our study has helped to identify a group of patients with poor emotional health at the start of IVF, who are at risk of significant psychological distress following a failed cycle. Psychological interventions may be indicated in this group and help reduce dropout rates.
Trial registration number: Not a randomised control trial. Regional Ethics Committee reference number: 10/H1308/46.

POSTER VIEWING SESSION

QUALITY AND SAFETY OF ART THERAPIES

P-549 A comparison of dual triggering by administration of GnRH agonist plus HCG versus HCG in normal responders in ART outcomes

M. Farid mojtahedi[1], M. Eftekhar[2], S. Miraj[3]
[1]*Research and Clinical Center for Infertility, Shahid Sadoughi University of Medical Sciences, Tehran, Iran*
[2]*Research and clinical center for infertility, Shahid Sadoughi university of Medical Sciences, Yazd, Iran*
[3]*Research and clinical Center for infertility, Shahid Sadoughi University, Yazd, Iran*

Study question: Question: does the mode of triggering final oocyte maturation influence the ART (artificial reproductive technology) outcome in normal responders?
Summary answer: It seems that we can improve the ART outcome by adding GnRH agonist to standard dose of hCG in normal responders.
What is known already: Several studies in high responders showed significant improvement in IVF outcomes when a dual trigger was used without a significant increase in the OHSS rate. As we know that GnRH-a causes both FSH and LH release like a physiologic natural cycle and according to the fact that gene expression pattern and downstream signaling of LH receptors is different between hCG and GnRH-a triggered patients, several investigators intended to study the effect of coadministration of GnRH-a and hCG triggering to improve ART outcomes.
Study design, size, duration: This double-blind randomized controlled trial was performed at the Research and Clinical Center for Infertility, Shahid Sadoughi University of medical Sciences between April 2014 until February 2015. A total of 223 patients were assessed for eligibility.
Participants/materials, setting, methods: The inclusion criteria were tubal or male infertility, BMI < 32, age ≤42 years, absence of major endocrinologal pathology, first, second and third IVF cycle.

All patients began ovarian stimulation with flexible antagonist protocol. When at least two leading follicles had reached 17 mm in diameter, final oocyte maturation was triggered by either 6500 IU hCG alone, or by 6500 IU hCG plus 0.2 mg of triptorelin.
Main results and the role of chance: A total of 184 cycles were analysed. We found no statistically significant differences in the total recombinant FSH dose, duration of stimulation, duration of GnRH-antagonist treatment, serum E2 and on the day of trigger. Although mean number of oocytes retrieved and mature metaphase II (MII) oocytes and obtained embryos were higher in the dual-trigger group compared with the controls (10.85 versus 9.35 and 8.80 versus 7.98), the observed differences were short of reaching statistical significance (p-value: 0.009 and 0.12). Also the difference of OHSS rate between the two groups were not statistically significant (p-value = 0.06).

Our results was not significantly different except a trend toward higher oocyte and embryo yield and also clinical and ongoing pregnancy rates in dual trigger group (26.3 versus 22.6% and 24.2 versus 22.5) (p-value: 0.3 and 0.77) (p-value = 0.3).
Limitations, reasons for caution: We think that this new concept require more study before becoming a universal COH protocol in IVF practice. Certainly, extending the study population will help to get a better result.
Wider implications of the findings: The results of our study did not confirm the favorable effect of dual-triggered oocyte maturation with a GnRH-agonist and a standard dosage of hCG that was shown by Lin et al. (2013)[9] as an effective strategy to optimize pregnancy outcome for normal responders in GnRH-antagonist cycles.
Trial registration number: The study was registered under IRCT2015031221420N2.

P-550 The long-term alterations of myocardial remodeling associated genes from birth to old age in assisted reproductive technology mice and mechanism involved

Q. Wang[1], F. Zhang[1], M. Hu[1], L. Wang[2], F. Jin[2]
[1]*Women's Hospital-School of Medicine-Zhejiang University, Obstetrics and Gynecology, Hangzhou, China*
[2]*Women's Hospital-School of Medicine-Zhejiang University, Center of Reproductive Medicine, Hangzhou, China*

Study question: Could assisted reproductive technology (ART) have adverse effects on cardiovascular long-term health? Besides, what are likely mechanisms involved in these alterations?
Summary answer: The expression of myocardial remodeling associated genes are significantly up-regulated in offspring conceived by ART compared with the naturally conceived offspring.
What is known already: There is evidence to suggest that ART can increase the risk of cardiovascular birth defects and high blood pressure in offspring. However, the long-term effects of ART on cardiovascular system and molecular mechanisms remain unclear.
Study design, size, duration: C57BL/6J female and male mice were used in this study. They were randomly divided into *in vivo* group, IVF group and ICSI group. Institute of Cancer Research (ICR) female mice that were at least 8 weeks of age were used as pseudopregnant recipients to get their offspring. All treatment protocols involving the use of animals were approved by the Zhejiang University Animal Care Committee according to the Institutional Guidelines for Animal Experiments (No. ZJU2009101007Y).

Participants/materials, setting, methods: The body weight, blood pressure and heart rate were detected from birth to the age of 1.5 year in control group, IVF group and ICSI group. At the same time, the myocardium of mice offspring was respectively detected at 3 week, 10 week and 1.5 year. The expression of myocardial remodeling associated genes (COL1, COL3, CTGF, Myh7), AT1, AT2 and Akt were detected by real-time quantitative PCR, Western blot, immunofluorescence and pyrosequencing.
Main results and the role of chance: The results showed that the expression of COL3 and CTGF were significantly up-regulated both in myocardium of IVF group and ICSI group compared with control group ($P < 0.05$ and $P < 0.01$ respectively) at the age of 3 week. At the age of 10 week, the expression of COL1, COL3 and CTGF were significantly up-regulated in IVF group and ICSI group ($P < 0.01$, $P < 0.05$ and $P < 0.05$ respectively). When the mice reached the age of 1.5 year, the expression of COL1, COL3, CTGF and Myh7 were significantly up-regulated in IVF group and ICSI group compared with control group ($P < 0.01$, $P < 0.05$, $P < 0.05$ and $P < 0.05$ respectively). What is more, there was obvious different in the expression level of these genes between IVF group and ICSI group in old age ($P < 0.05$). Besides, DNA methylation rates of these genes were also different among three groups ($P < 0.05$). Furthermore, the AT1, AT2, Akt and p-Akt expression in myocardium were significantly different among three groups ($P < 0.05$) which had correlation with expression of myocardial remodeling associated genes.
Limitations, reasons for caution: The advantage of this study is that the long-term cardiovascular conditions can be observed in ART mice, especially in old age. Although we observed gene alterations in myocardium of ART mice compared with controls, further studies are urgently needed to confirm this observation and determine the cause of this phenomenon.
Wider implications of the findings: In this study, we report an association between ART and myocardium remodeling which could be a reflection of adverse effects of *in vitro* culture conditions. Meanwhile, ART offspring would be more vulnerable in cardiovascular diseases in the long term.
Trial registration number: This study is not clinical trial.

P-551 Neurodevelopmental and cardiometabolic outcome in 4-year-old twins and singletons born after *in vitro* fertilization

D. Kuiper[1], A. Bennema[1], J. Seggers[1], P. Schendelaar[1], M. Haadsma[2], A. Hoek[3], M.J. Heineman[4], M. Hadders-Algra[1]
[1]*University Medical Center Groningen, Department of Paediatrics Division of Developmental Neurology, Groningen, Netherlands*
[2]*University Medical Center Groningen, Department of Genetics Division of Clinical Genetics, Groningen, Netherlands*
[3]*University Medical Center Groningen, Department of Obstetrics and Gynaecology, Groningen, Netherlands*
[4]*Academic Medical Center, Department of Obstetrics and Gynaecology, Amsterdam, Netherlands*

Study question: Do cognitive development, neurological condition, anthropometrics and blood pressure (BP) of 4-year-old *in vitro* fertilization (IVF) twins differ from those in 4-year-old IVF singletons?
Summary answer: Four-year-old IVF twins had lower sequential intelligence quotient (IQ) and higher systolic blood pressure (SBP) than IVF singletons after adjustment for confounders and effect mediators.
What is known already: Twin pregnancies are associated with worse perinatal outcome than singleton pregnancies. This also holds true for IVF twin pregnancies: IVF twin pregnancies are associated with an increased risk of obstetrics complications, such as preterm birth, low birthweight, caesarean section and perinatal mortality. Despite the high number of multiple births in IVF pregnancies and the increased risk of obstetric complications in IVF twins, limited knowledge is available on the cognitive development, neurological condition, anthropometrics and cardiometabolic health of IVF twins compared with IVF singletons.
Study design, size, duration: A prospective assessor blinded follow-up study of two studies: the Groningen assisted reproductive technology (ART) cohort study and the Preimplantation genetic screening (PGS) Follow-up study. In total 151 children born following controlled ovarian hyperstimulation IVF (COH–IVF) were assessed. Overall attrition rate was less than 15%. Information on socioeconomic status, the prenatal, perinatal and neonatal period was collected two weeks after birth on standardized charts. The follow-up examination took place at the age of 4 years.
Participants/materials, setting, methods: Participants were 4-year-old singletons ($n = 103$) and twins ($n = 48$) born following COH–IVF as part of the Groningen ART cohort study and the PGS Follow-up study. Primary outcome was Total IQ, evaluated with the Kaufman Assessment Battery for Children, second edition. Secondary outcomes were neurological condition (evaluated with the Hempel assessment), anthropometrics and BP. After univariable analyses, multivariable regression analyses were used to adjust for effect modifiers, such as gestational age, and additional confounders.
Main results and the role of chance: Parental characteristics, fertility parameters and child characteristics were similar, but birth characteristics differed between twins and singletons. Twins had, for example, a lower birthweight ($p < 0.001$) and lower gestational age at birth ($p < 0.001$). Total IQ (twins [mean 94.96, SD 10.91] and singletons [mean 99.24, SD 11.86]), sequential IQ, simultaneous IQ, and knowledge IQ scores of twins were lower than those of singletons. Learning IQ scores of twins were similar to those of singletons. Also weight and height of twins were significantly lower than those of singletons (16.9 ± 2.1 vs. 18.6 ± 2.8 kg and 105.8 ± 3.4 vs. 108.7 ± 5.3 cm, resp.). But triceps and subscapular skinfold thickness in the two groups were similar. The neurological condition of twins did not differ from that of singletons. In the unadjusted analysis SBP (regression coefficient [B]: 0.53, 95% confidence interval [95% CI] [2.32 −3.40) and diastolic blood pressure (DBP) of twins were similar to those of singletons. Most differences between twins and singletons disappeared after adjustment for confounders. Yet, the multivariable regression analyses revealed that twins differed in two ways from singletons: twins had a lower sequential IQ, (B: −5.98, 95% CI [−11.27 to −0.68]) and they had a higher SBP (B: 4.67, 95% CI: 0.64–8.71), ($p = 0.024$) than singletons.
Limitations, reasons for caution: We did not distinguish between monozygotic and dizygotic twins. Monozygotic twins might contribute to the increased risk for unfavourable outcome of the twin group. However, the majority of IVF twins was probably dizygotic due to dual embryo transfer. Another limitation is that both BP measurements were performed on 1 day.
Wider implications of the findings: Our study suggests an IVF twin effect on short-term memory and SBP. It is conceivable that twin pregnancies are associated with increased levels of fetal stress, originating from maternal psychological stress and physiological stress related to less favourable uterine conditions for twins. IVF may add to the risk or stress.
Trial registration number: M09.074824.

P-552 Factors affecting birthweight after single frozen-thawed embryo transfer

T. Habara[1], H. Rei[1], K. Noriko[1], K. Yukiko[1], T. Sanae[1], Y. Nanako[1], H. Nobuyoshi[1]
[1]*Okayama Futari Clinic, Private Clinic, Okayama, Japan*

Study question: Does blastocyst grade affect birthweight after frozen-thawed embryo transfer (FET)?
Summary answer: Birthweight of the singleton born after FET was not associated with blastocyst morphology but related to maternal body mass index (BMI) and smoking habits.
What is known already: A previous study (Fertil Steril 2015 103: 382) demonstrated that greater birth weight was associated with a higher inner cell mass grade after standard *in vitro* fertilization (IVF) and FETs. However, it is still a controversial topic and no consensus on whether blastocyst grade affects fetal growth.
Study design, size, duration: A retrospective analysis was performed for 1145 singleton neonates born after FET cycles between April 2008 and March 2014.
Participants/materials, setting, methods: The examined factors affecting birth weights of singletons born full-term after FET cycles included quantitative variables like gestational age, cryopreservation period, maternal age, BMI, and endometrial thickness and qualitative variables like newborn gender, parity, ovarian stimulation and insemination methods, maternal smoking habits, embryonic stage, and blastocyst morphologic parameters. All blastocysts were cultured in same culture Media (Cleavage and Blastocyst Media Cook®). The blastocysts were graded according to the Gardner grading system.
Main results and the role of chance: A total of 1145 deliveries resulting from single blastocyst transfers were analyzed. A correlation analysis revealed that the quantitative variables including gestational age ($r = 0.399$, $P < 0.0001$) and BMI ($r = 0.177$, $P < 0.0001$) significantly correlated with birthweight. No

significant differences were observed for birthweight and ovarian stimulation and insemination methods. There was no significant difference in the average birthweight between the high grade blastocysts ($n = 923$: 3125.7 ± 385.9 g) and the low grade blastocysts ($n = 222$: 3102.4 ± 357.7 g). Stepwise logistic regression indicated gestational age, newborn gender, BMI and maternal smoking habits as effective factors to predict birth weight. After correction using these variables, a multivariate regression analysis resulted in significant *F*-statistic values for expansion ($F = 0.085$, $P = 0.968$), ICM ($F = 0.379$, $P = 0.685$), and TE ($F = 0.810$, $P = 0.445$). Therefore, blastocyst morphologic parameters were suggested to be ineffective factors to predict birth weight.

Limitations, reasons for caution: As this study was retrospective, blastocyst selection was based on existing selection criteria. We were not able to adjust the analyses for paternal BMI, maternal weight gain during pregnancy and quality of diet due to limited database information. Further studies are needed to clarify this issue.

Wider implications of the findings: Birthweight of low grade blastocyst is similar to that of high grade blastocyst. Our findings suggested that maternal factors affected the birthweight more than embryonic factors.

Trial registration number: Not applicable.

P-553 ART laboratory disinfectants are not "embryosafe" and should always be used with caution

S. Catt[1], S. Howie[1], H. Ghazala[1], M. Khoeun[1], A. Tran[1], P. Chen[1], M. Pangestu[1], P. Temple-Smith[1]
[1]*Monash University, EPRD, Department Obstetrics and Gynaecology, Melbourne, VIC, Australia*

Study question: To evaluate the effects of six laboratory disinfectants simultaneously when used in close proximity to sperm and embryos using a variety of assays.

Summary answer: All six disinfectants demonstrate toxicity in at least one assay and all should be used with caution.

What is known already: As ethanol is a known volatile organic compound (VOC), non-VOC disinfectants have been promoted for use in ART labs, with varying ingredients and actions: Oosafe® (sparMED) and Fermicydal D2® (Labotect) contain quaternary ammonium compounds (QACs) whereas Fertisafe™and Fertisafe Plus™ (Research Instruments) are chlorine and silver dihydrogen citrate based respectively. 3% hydrogen peroxide (H_2O_2) is also used in ART laboratories. There has been no previous cytotoxic testing comparing all 6 disinfectants simultaneously.

Study design, size, duration: 1-cell mouse embryo and human sperm assays (*direct contact*: 1% v/v disinfectant in media, or *atmosphere:* incubators/chambers cleaned with disinfectants just prior to use, and *residue:* culture dish with dried-rinsed disinfectant residue (embryos only) were used to test all disinfectants against controls.

Participants/materials, setting, methods: Embryos were randomly distributed to each disinfectant scenario (3 replicates, $N = 528$). Development and survival was assessed daily to the blastocysts stage. Sperm (4 replicates) was centrifuged through a density gradient, diluted and divided between *direct contact* (0.5 ml, capped tubes), *atmosphere* (0.5 ml uncapped tubes in disinfectant cleaned, un-gassed chambers) and controls. Motility was assessed at 24, 48 and 72 h. Sperm motility loss was the difference of total motility at time 0 and the assessment time.

Main results and the role of chance: For *direct contact* and *residue*, lysis and/or no cleavage was observed with the H_2O_2, Oosafe, Fermicidal and Fertisafe Plus groups, whereas, limited blastocyst rates were observed in Ethanol [r*esidue*: 4/13 (31%), *direct contact* 2/31 (6.5%)] and Fertisafe [residue 1/20 (5%) and *direct contact* 1/16 (6.25%)], all except ethanol *residue* were significantly different to controls [$P < 0.05$, 35/59 (59.3%)]. For the embryo *atmosphere* trials, H_2O_2 and Fertisafe groups showed the lowest development to blastocysts (1/18 and 0/44 respectively, $P < 0.001$) while Fermicidal (17/32, 53%) was the only group not different from the controls [35/59 (59.3%)]. For *direct contact* there was significant sperm motility loss after 24 h ($P < 0.01$) in all treatment groups (>90% loss) compared to the control (<35% loss), and for *atmosphere,* significant sperm motility loss was only observed in the Ethanol, Fertisafe Plus and H_2O_2 groups ($P < 0.01$). Paired Chi square and Dunnets multiple comparison *post-hoc* tests were used on embryo development and sperm motility respectively.

Limitations, reasons for caution: Treatment conditions used are representative of worse-case scenarios thus, in ART laboratories all these disinfectants may be safe to use in some circumstances. Also, *atmosphere* conditions are hard to standardise: disinfectants were rotated through bench-top incubators (confined space but continual gas-flow) and traditional CO_2 incubators (large space, reduced gas movement).

Wider implications of the findings: Despite concern with Ethanol, its quick evaporation and apparent reduced toxicity implies that moderate use maybe acceptable. QACs in *atmosphere* had reduced toxicity, but lethal if any contact occurred. H_2O_2 proved lethal in all testing scenarios. This research leads to a greater awareness of disinfectant toxicity.

Trial registration number: Not applicable

P-554 Comparison of birthweights in patients randomly assigned to fresh or frozen-thawed embryo transfer

B. Shapiro[1], S. Daneshmand[2], C. Bedient[2], F. Garner[2]
[1]*Fertility Center of Las Vegas, Las Vegas, NV, USA*
[2]*Fertility Center of Las Vegas, Reproductive Endocrinology and Infertility, Las Vegas, NV, USA*

Study question: Are fresh and frozen-thawed embryo transfers (FET) associated with different birthweight in resulting infants?

Summary answer: Birthweights following fresh transfer were significantly less than those following FET.

What is known already: Multiple prior studies of national registries have found significantly reduced birthweight in fresh transfer when compared to frozen-thawed embryo transfer. Reported differences in mean birthweight observed in registry studies have ranged from 40 to 250 g, with a median reported difference of 145 g. However, registry studies are inherently vulnerable to confounding effects of non-randomized treatment assignment and unknown/uncontrolled variation in treatment protocols.

Study design, size, duration: This follow-on study included 134 patients that had live birth after being randomly assigned to fresh transfer or FET. Pregnant subjects were followed through childbirth. No subject was lost to follow-up.

Participants/materials, setting, methods: All patients underwent ovarian stimulation with both hMG and rFSH at a private fertility center. Immediately following oocyte collection, patients were randomly assigned to either fresh blastocyst transfer or else cryopreservation (conventional slow freezing) of the entire cohort at the bipronuclear stage followed by thaw of the entire cohort and culture to the blastocyst stage before transfer. Identical culture conditions were used in both groups and all transferred embryos were primary (not supernumerary) blastocysts.

Main results and the role of chance: After adjusting for potential confounding variables, including gestational age at birth, number delivered, and presence of a vanished twin, the adjusted mean birthweight was 166 g less following fresh blastocyst transfer when compared to FET ($P = 0.0094$) (95% CI 42–291 g).

Limitations, reasons for caution: This data set is much smaller than those used in registry studies of birthweights. The specific causal mechanism (embryonic or uterine) cannot be discerned from this study design.

Wider implications of the findings: The birthweight differences between patients randomized to fresh transfer or FET are consistent with previous registry studies, suggesting the previous findings were not caused by potential confounding resulting from non-randomized patient allocation or uncontrolled protocol variation, including culture conditions, stage of transfer, and/or use of supernumerary embryos.

Trial registration number: ClinicalTrials.gov registration numbers NCT00963625 and NCT00963079.

P-555 Failure mode and effect analysis as a proactive method to prevent risks in assisted reproduction technology (ART): a more than 1000 cycle-laboratory experience

G. Intra[1], A. Alteri[1], L. Corti[1], A. Quagliariello[1], E. Rabellotti[1], E. Papaleo[1], L. Restelli[2], M. Candiani[1], P. Viganò[1]
[1]*IRCCS San Raffaele Scientific Institute, Obstetrics and Gynecology, Milan, Italy*
[2]*Ospedale Maggiore Policlinico, Infertility Unit, Fondazione Ca' Granda, Milan, Italy*

Study question: Is failure mode and effects analysis (FMEA) a useful and effective method of risk assessment in the ART laboratory?

Summary answer: The analysis of the potential failures, their causes and effects has allowed to improve the safety strategies already adopted in the clinical practice.
What is known already: Over the years, there have been numerous reports of misidentification resulting at best in a deleted cycle if the mistake was identified before embryo transfer, or in a tragedy if realized after the embryo transfer. Therefore, approaches that systematically supervise the whole process and identify the causes of all errors are needed. FMEA represents a strategy to identify and eliminate known and/or potential failures before they occur.
Study design, size, duration: FMEA represents a proactive risk evaluation technique used to identify and eliminate known and/or potential failures. The project was conducted in a large ART center that performs more than 1000 "fresh" cycles and about 400 "frozen/thaw" cycles per year and it was applied between August 2013 and August 2014.
Participants/materials, setting, methods: Processes were analyzed to identify and score the potential failure modes, using the risk priority number (RPN) scoring system. The magnitude of the RPN, by multiplying 3 factors, occurrence, severity, detection (graded 1–5), denotes the priority of the failure mode. The final step of FMEA is to optimize the single procedure according to the RPN score. Finally, FMEA was repeated after 8 months and the improved RPN after the corrective actions was calculated.
Main results and the role of chance: In total, 11 individual steps in our ART laboratory were identified and mapped. All the steps had multiple failures and sixty-eight different potential failure modes were identified. The highest ranked failure modes with an RPN score of 25 encompassed 17 failures and pertained to "patient mismatch" and "biological sample mismatch". The maximum reduction in risk with RPN from 25 to 5 was mostly related to introduction of double checks by a second operator. The critical failure modes about sample processing have been improved by 50% in RPN focusing on the training in order to correct technical errors of the staff. Three indicators of FMEA success based on technical skill, competence and traceability have been evaluated after FMEA implementation. The monitoring of these three indicators represented a substantial proof that the corrective actions applied exerted a positive influence on daily work. Double witness by a second human operator should be introduced in the lab as the main control measure used to avoid sample mix-ups.
Limitations, reasons for caution: This study is subjected to the general limitations of the FMEA method, such as subjective experiences of the individual participants for which failures may be unrecognized ("missed"), underestimated or exaggerated. Other limitations were seen such as its time-consuming nature, the difficulty with the scores and its partial validity and reliability.
Wider implications of the findings: The goal of the method of risk assessment should be to completely eliminate risk of mismatching. FMEA is capable of producing a wealth of information about the potential vulnerabilities within the process and consequently provides systematic guidance for development of risk-reduction interventions.
Trial registration number: Not applicable.

P-556 Fresh versus frozen-thawed embryo transfers: a systematic review and meta-analysis of obstetric outcomes

M. Roque[1], M. Valle[2], A. Kostolias[2], M. Sampaio[3], S. Geber[3], M.A. Checa[4]
[1]*ORIGEN, Center for Reproductive Medicine, Belo Horizonte, Brazil*
[2]*ORIGEN, Center for Reproductive Medicine, Reproductive Medicine, Rio de Janeiro, Brazil*
[3]*ORIGEN, Center for Reproductive Medicine, Reproductive Medicine, Belo Horizonte, Brazil*
[4]*Universitat Autónoma de Barcelona, Department of Obstetrics and Gynecology, Parc de Salut Mar, Barcelona, Spain*

Study question: Are there differences in the risks of obstetric outcomes in IVF/ICSI pregnancies when comparing fresh to frozen- thawed embryo transfers (FET)?
Summary answer: The results of this systematic review and meta-analysis suggest that pregnancies from FET have an overall better obstetric outcomes when comparing to fresh embryo transfer.
What is known already: Although fresh embryo transfer is currently the norm in assisted reproductive therapies (ART), there are increasing concerns regarding the adverse effects of controlled ovarian stimulation (COS) upon the endometrial and uterine environment. In contrast, FET is performed in a more "physiological" environment and this could be related to better outcomes after FET when compared to fresh cycles. It has been suggested that ART pregnancies are related to poorer obstetric outcomes when compared to natural conceptions. However, the obstetric outcomes observed in pregnancies arising from ART may differ among fresh and FET cycles.
Study design, size, duration: We conducted a systematic review and meta-analysis of observational studies published in English, comparing obstetric outcomes in singleton pregnancies after fresh and FET. An electronic search was performed within the PubMed, EMBASE and Cochrane databases, through October 2015. We also searched the references of the relevant articles.
Participants/materials, setting, methods: Original studies reporting obstetric outcomes for singletons pregnancies after ART that compared fresh to FET outcomes were included. Studies including only frozen and donor oocytes were excluded. The main outcomes were ectopic pregnancy and preterm birth (delivery <37 weeks of gestation). The secondary outcomes were pregnancy-induced-hypertension (PIH), pre-eclampsia, placenta previa, placenta accreta, and placental abruption. Adjusted odds ratio (aOR) was used to calculate the estimated effect of outcomes, with the exception of ectopic pregnancy.
Main results and the role of chance: The search yielded 915 articles, 43 of these met inclusion criteria, reporting on obstetric outcomes of over 1,000,000 pregnancies. When comparing pregnancies arising from FET to fresh embryo transfer, there was a decrease in the risk of obstetric complications in pregnancies from FET when compared to fresh embryo transfer: ectopic pregnancies (all embryo developmental stages – including 929,431 pregnancies) – odds ratio (OR) 0.80, 95% confidence interval (CI) 0.67–0.95; ectopic pregnancies after cleavage stage – OR 0.73, 95% CI 0.65–0.81; ectopic pregnancies after blastocyst stage – OR 0.52, 95% CI 0.42–0.64; preterm birth (219,356 singletons pregnancies evaluated) – aOR 0.90, 95% CI 0.84–0.96); and placental abruption (59,450 singleton pregnancies evaluated) – aOR 0.65, 95% CI 0.45–0.94. There were no significant differences in the risk between FET and fresh groups when evaluating: pre-eclampsia (59,450 singleton pregnancies evaluated) – aOR 1.11, 95% CI 0.77–1.59; and placenta previa (69,486 singleton pregnancies evaluated) – aOR 0.70, 95% CI 0.46–1.08. The following outcomes were increased in the FET group: PIH (48,926 singleton pregnancies evaluated) – aOR 1.82, 95% CI 1.24–2.68); placenta accreta (48,158 singleton pregnancies evaluated) – aOR 3.51, 95% CI 2.04–6.05.
Limitations, reasons for caution: Although this is the largest study to date comparing the obstetric outcomes of pregnancies arising from FET and fresh cycles, it is based on observational studies and therefore subject to bias. Further studies are needed to better understand the effects of COS and cryopreservation upon mothers and offspring health.
Wider implications of the findings: It is necessary to balance the pros and cons between FET and fresh cycles. However, if the potential benefit of FET over fresh cycles regarding obstetric outcomes is confirmed in more studies, it will be feasible to change the routine of IVF/ICSI treatments.
Trial registration number: PROSPERO CRD42015029800

P-557 Is trial registration an indicator of risk of bias in fertility trials?

C. Farquhar[1], M. Showell[1], E. Showell[1], P. Beetham[1], N. Baak[1], S. Mourad[2], V. Jordan[1]
[1]*University of Auckland, Obstetrics and Gynaecology, Auckland, New Zealand*
[2]*Radboud University Medical Centre, Obstetrics and Gynaecology, Groningen, Netherlands*

Study question: Are there differences in the methodological quality and epidemiology of unregistered and registered trials of fertility treatments?
Summary answer: Registered fertility trials were considered low risk for randomisation, allocation concealment, and for non-reporting the prestated primary outcomes.
What is known already: The International Committee of Medical Journal Editors stated that from 2005 all trials should be registered. This resulted in an increase in the number of registered trials. However unregistered trials are still being published and biased, low quality publications remain problematic for systematic reviewers. It has been suggested that unregistered trials are of lower methodological quality than registered, and therefore should not be included in systematic reviews in order to increase validity. However there is no published evidence that unregistered trials negatively impact on the quality of evidence. Another issue is whether excluding unregistered trials increase the likelihood of publication bias.

Study design, size, duration: A search was performed in the Cochrane Gynaecology and Fertility Group's specialised register for all full text, English language and subfertility trials from 2010 to 2014. 706 were included in the study while 232 were excluded. We checked for registration firstly in the paper, the clinical trials registries and then by contacting the authors. Data were then extracted, the variables collected included country of primary author, fertility topic, sample size, funding and the journal where published.
Participants/materials, setting, methods: A random selection using a computer generated list of trials stratified by year (2010–2014) of 25 unregistered and 25 registered in each year was undertaken, 250 in total. Trials were assessed using the Cochrane risk of bias tool where the domains of randomisation, allocation concealment, blinding, attrition, and selective reporting were classified as low or high/unclear risk (combined) and odds ratios with 95% confidence intervals were reported. Authors were contacted for additional information where necessary.
Main results and the role of chance: The top 10 fertility journals saw an increase in registered trials from 46% to 58%. Although in the two leading journals the rate in 2014 was 90%. Of the included trials 44% were registered. For each year there were more unregistered trials published in journals than registered. Registered trials were more likely to have low risk of bias for randomisation (OR 2.47 95% CI 1.42–4.28), allocation concealment (OR 2.23 95% CI 1.30–3.83) and for non-reporting the prestated outcome from the protocol (OR 57.69 95% CI 19.94–166.87). There was no evidence of difference between registered and unregistered trials in low or high risk categories for blinding or incomplete outcome data. Unregistered trials were more likely to have a high/unclear risk of bias in selective reporting of expected outcomes (OR 0.50 95% CI 0.30–0.83). The six countries publishing the greatest number of trials were Iran (n = 113), USA (n = 76), Egypt (n = 73), Italy (n = 61), China (n = 56) and Turkey (n = 52). The proportions for registered and unregistered trials are; Iran (63%/37%), USA (58%/42%), Egypt (44%/56%), Italy (21%/79%), China (34%/66%) and Turkey (15%/85%). Funding sources were not stated in 70% of unregistered trials and 47% of registered trials.
Limitations, reasons for caution: We were unable to contact all authors for additional information. Trials were not assessed to discover if unregistered trials were more likely to have positive results. Sample sizes were low so we analysed only the 10 most frequently occurring journals in our sample and we only included English language trials.
Wider implications of the findings: Inclusion of unregistered trials in systematic reviews may affect the methodological quality of systematic reviews. However, a significant proportion of trials are still unregistered and their exclusion will reduce the number of trials that are included in a meta-analysis. Journals should insist on manuscripts that have trial registration.
Trial registration number: Not applicable.

P-558 Cumulative live birth rate following IVF and ICSI: a population-based cohort study

Study question: What is the cumulative live birth rate following *In Vitro* Fertilisation (IVF) cycles compared with Intracytoplasmic Sperm Injection (ICSI) cycles?
Summary answer: ICSI resulted in a similar live birth rate to IVF for couples with male factor infertility but was lower for couples with non-male infertility.
What is known already: The ICSI procedure was developed for couples with male factor infertility. There has been an exponential increase in the use of ICSI regardless of the cause of infertility. Cycle-based statistics show that there is no difference in pregnancy rates between ICSI and IVF when the subfertility is not due to a male factor. However, evidence indicates that ICSI is associated with increased risk of adverse perinatal outcomes. There is little patient-based population data on the cumulative live birth rate for ICSI compared to IVF when the subfertility is not due to a male factor.
Study design, size, duration: A population-based cohort of women who had their first stimulated cycle between July 2009 and June 2013 in Victoria, Australia was evaluated retrospectively. Characteristics and treatment outcomes for women undergoing IVF cycles (n = 3730) and ICSI cycles (n = 7153) were compared. Treatment and clinical outcomes were recorded for the first autologous stimulated cycles and associated thaw cycles women had until June 2014, or until a live birth was achieved.
Participants/materials, setting, methods: Demographic and treatment related information was obtained from the Victorian Assisted Reproductive Treatment Authority, a statutory authority which records details of all ART treatments undertaken in the state of Victoria, Australia. A generalized estimating equation model was used to compare the cumulative live birth rate between the two groups. Adjustment was made for maternal age, cause of infertility, parity, number of oocytes retrieved and number of embryos transferred.
Main results and the role of chance: The 3730 women undergoing IVF cycles and 7153 women undergoing ICSI cycles had 5938 and 11153 embryo transfer cycles, which resulted in 1382 and 2493 live deliveries, respectively. The mean age of women in the IVF group was 35.1 ± 4.7 years and 34.8 ± 4.9 years for those in the ICSI group ($p < 0.05$). For couples with known cause of infertility, male factor infertility (male factors only or combined male/female factors) was reported for 35.9% in the IVF group and 62.7% in the ICSI group. Non-male factor infertility (female factor infertility only or unexplained infertility) was reported for 64.1% in the IVF group and 37.3% in the ICSI group ($p < 0.01$). Fertilisation rate per oocyte treated was higher in the ICSI group (70.1%) than in the IVF group (60.3%) ($p < 0.01$). The cumulative live birth rate within six cycles was 36.9% for IVF the group and 34.8% for ICSI group. Among couples with male factor infertility, ICSI resulted in a similar cumulative live birth rate (Adjusted odds ratio (AOR): 0.88, 95% confidence intervals (CI): 0.73–1.06) compared with IVF. For couples with non-male factor infertility, ICSI resulted in a significantly lower cumulative live birth rate (AOR: 0.76, 95% CI: 0.64–0.90) compared with IVF.
Limitations, reasons for caution: The reported causes of infertility were based on the treating clinician's classification and criteria may have varied between clinicians. Details of infertility diagnosis and indication for ICSI were not available. Residual confounders might have impacted the findings of this study since not all potential confounders were collected in the dataset.
Wider implications of the findings: This population-based study found a higher cumulative live birth rate following IVF compared with ICSI among couples with non-male factor infertility. It suggested that ICSI offers no advantage over IVF in terms of live birth rate for couples with non-male factor infertility.
Trial registration number: NA.

P-559 Development of an external quality assessment (EQA) scheme for embryo morphology using the UK standard embryo grading scheme

J.D. Critchlow[1], G. Horne[1], P. Goddard[1], J. Hartley[1], R. Deol[1], D. Shearden[1], H. Hunter[1]
[1]*St.Mary's Hospital, Reproductive Medicine, Manchester, UK*

Study question: EQA for embryology morphology launched in 2011 as part of the UK National External Quality Assessment Service (UK NEQAS) for Reproductive Science.
Summary answer: Currently 60 UK laboratories (>80% of licensed assisted conception units) and 30 international laboratories participate in the EQA scheme for embryo morphology.
What is known already: The primary aim of UK NEQAS is educational, with 390 pathology schemes operating (not for profit) from 26 centres. EQA scheme participants receive independent, objective and impartial reports on their performance, enabling them to identify weakness and take appropriate action. UK NEQAS Reproductive Science includes EQA for Andrology launched in 1994 (currently with 200 UK and 90 international participants). EQA for embryology followed as an on-line scheme in 2011 with all participants using the UK embryo grading scheme (Cutting et al., 2008).
Study design, size, duration: Data was taken from EQA scheme participants for inter-laboratory comparison of embryo morphology assessment between April 2011–December 2015. In addition, a survey of UK embryologists in January 2016 asked for feedback on: (i) participation in the EQA scheme; (ii) routine use of the UK embryo grading scheme; (iii) the need for review/update

of the UK embryo grading scheme and (iv) interest in EQA for time-lapse imaging annotation.

Participants/materials, setting, methods: Laboratories assessed embryo images four times per year on line (Gamete Expert website). A single set of results (from one "assigned" embryologist per lab) was submitted for each distribution; including four each of day 2, 3 and 5 stage embryos (1 min "rolling" embryo videos); plus 2 time lapse videos from 1 cell to blastocyst stage. Target values were derived from an all laboratory consensus and an EQA performance report was produced for each laboratory.

Main results and the role of chance: Between April 2011–December 2015, a total of 264 embryo images (152 day 2/3 videos and 112 day 5 videos) were distributed over 19 occasions. Least agreement between laboratories was found for blastocyst inner cell mass grading with a consensus (used to derive target values) reached for only 70% (78/112) of embryos; 80% of blastocysts reached consensus for expansion and 96% for trophectoderm grading. Consensus was reached for 99% of day 2/3 embryos assessed for degree of fragmentation, 95% for cell number and 90% for evenness/cell size.

78 UK embryologists responded to the embryo grading survey; 87% (68/78) participated in the EQA scheme; 44% (30/68) of those in the scheme also participated with individual logins; 59% of respondents routinely used the UK grading scheme for cleavage stage embryos and 65% for blastocysts; the remainder mainly used "in-house" grading schemes. The majority of respondents (88%) would like to see a review of the UK standard grading scheme. Although only 41% (32/78) of respondents routinely used time-lapse imaging, 82% (56/68) of those in the EQA scheme were interested in EQA for time-lapse annotation and 6/10 labs not already participating would join the scheme if this was offered.

Limitations, reasons for caution: Alternative methods to derive "target values" for comparison of inter- laboratory performance could be considered. Only around 20% of the ACE membership responded to the embryo grading survey and the results may not be representative of all UK embryologists.

Wider implications of the findings: Increasing the number of EQA participants would provide a larger data set for inter-laboratory comparisons, allowing for further development/improvement of the scheme and ultimately grading standardization. The interest shown in EQA for time lapse annotation merits its inclusion in the scheme and a pilot study is planned.

Trial registration number: Not applicable.

P-560 Perinatal death after fertility treatment; a 7-year national cohort study in New Zealand on contributory factors and potential avoidability

S. Mourad[1], C. Farquhar[2], L. Sadler[2]
[1]*Radboud University Medical Center, department of Obstetrics and Gynaecology, Nijmegen, Netherlands*
[2]*University of Auckland, department of Obstetrics and Gynaecology, Auckland, New Zealand*

Study question: What are the causes of and contributory factors to perinatal death after fertility treatment in New Zealand, and how many deaths were potentially avoidable?

Summary answer: Main causes of perinatal death were congenital abnormalities and specific perinatal conditions. Contributory factors were found in 10%; 4% of cases were considered potentially avoidable.

What is known already: Available international data on perinatal mortality from large population based fertility treatment cohorts, provides information on common risk factors such as obesity, smoking and fetal growth restriction. Very few studies however provide data on the underlying causes of death or potentially avoidable deaths.

As fertility pregnancies are "planned pregnancies," the causes of death may differ, and it is important to know if any of the deaths were potentially avoidable and if there were modifiable causes such as specific treatment regimens.

Study design, size, duration: All perinatal deaths in New Zealand (i.e., fetal death from 20 weeks gestation and neonatal death up to 27 days) are centrally collected by the Perinatal and Maternal Mortality Review Committee (PMMRC). We undertook a retrospective, 7-year cohort study (Jan 2007–December 2014) to analyse all perinatal deaths in New Zealand of babies conceived after fertility treatment including ovulation induction (OvI), intra uterine insemination (IUI) and *in vitro* fertilisation (IVF) and intra-cytoplasmatic sperm injection (ICSI).

Participants/materials, setting, methods: A multidisciplinary PMMRC local panel reviewed each perinatal death and identified the cause of death, contributory factors and potential avoidability. We analysed characteristics for all mothers, deceased babies and singleton and multiple gestations conceived after OvI, IUI or IVF/ICSI. Substandard factors directly related to the fertility treatment, or related to the fact that this was a "planned" pregnancy, were collected.

Main results and the role of chance: In total, 261 perinatal deaths from 234 pregnancies in 232 mothers were included. There were 168 singleton deaths and 93 deaths from 66 multiple gestations (55 twins, 8 triplets and 3 quadruplets). Most pregnancies were conceived by IVF/ICSI (71%, including 6% after oocyte donation) followed by clomiphene (22%) and IUI (7%). Most multiples derived from IVF/ICSI (n = 50, 75%) followed by 12% after clomiphene, which also accounted for most high-order gestations. Maternal risk factors such as BMI >32, alcohol drug or tobacco abuse, were low. 53% were born <24 weeks gestation, followed by 14% <27 weeks; 33% were small, 6% large and 45% appropriate for gestational age. 22% of deaths were terminations of pregnancy, 54% stillbirths and 25% neonatal deaths. Main causes of death were congenital abnormalities (26%), specific perinatal conditions (24%, e.g., cervical incompetence, twin to twin transfusion or complication of intra-uterine procedures), spontaneous preterm labour (15%), antepartum haemorrhage (10%).

In-depth local case review reported contributory factors in 24 pregnancies (10%, 16 singleton, 8 multiples), mainly relating to "personnel" and "organisation & management of care." 15 deaths (4%) were considered potentially avoidable. For 7 cases, avoidability was related to fertility treatment and concerned high-order multiples.

Limitations, reasons for caution: Retrospective analysis of perinatal mortality data does not provide insight into "near-miss" cases, substantial morbidity or infant death beyond 27 days. Moreover, the denominator for some substandard factor analyses is unknown, as non-fatal cases are not included in a New Zealand registry.

Wider implications of the findings: To our knowledge, this is the first nationwide confidential review into perinatal deaths after fertility treatment. Recognition of contributory factors is important to increase understanding of perinatal death after fertility treatment. It could facilitate feedback to professionals and education of the public on, e.g., the risks of multiple pregnancies.

Trial registration number: Not applicable

P-561 Assisted reproduction causes reduced fetal growth associated with downregulation of paternally expressed imprinted genes that enhance fetal growth

S. Chen[1], B. Li[1], X. Xiao[1], J. Huang[1], H. Zhang[1], C. Liu[1], B. Kang[1], X. Wang*[1]
[1]*Tangdu Hospital, The Fourth Military Medical University, Obstetrics and Gynecology, Xi'an, Shaan'xi, China*

Study question: Whether manipulation of embryo affects genomic imprinting and developmentally relevant genes in mouse placenta and resulted in fetal reduced growth at E10.5.

Summary answer: ART placentae exhibited perturbed genomic imprinting and the expression of developmentally relevant genes and functional genes for nutrition transport was also affected.

What is known already: ART affects placental nutrient transport and results in lower fetal weight and placenta overgrowth at E18.5 in mice. ART placentae also exhibited histomorphological alterations with defects in placental layer segregation and abnormal migration of glycogen cells at E18.5 in mice, and perturbed genomic imprinting may contribute to these problems.

Study design, size, duration: Mouse blastocyts were produced by (1) embryo culture *in vitro* after *in vivo* fertilization (IVC) or (2) *in vitro* fertilization (IVF), and (3) *in vivo* fertilization and development and then transferred to the uteri of pseudopregnant females. The fetal crown-rump length, placental weight, methylation level of *H19*, *KvDMR1* and *SNRPN*, expression level of multiple imprinted genes and genes that important for placental development were compared between the *in vivo*, IVC and IVF groups at E10.5.

Participants/materials, setting, methods: Virgin 6- to 8-week-old CD1 female mice, adult CD1 males were used. DNA bisulfite treated using the EpiTect Bisulfite Kit (Qiagen). DNA methylation was analyzed by MassARRAY platform (Sequenom). Real-time PCR was performed using the CFX96 real-time PCR instrument (Bio-Rad). Data were subjected to analysis of variance test for assessing any significant difference. The least significant difference post hoc

test was used to examine any significant difference between groups. *P*-values <0.05 were considered significant.

Main results and the role of chance: ART procedures could reduce fetal and placental growth at embryonic day 10.5. Moreover, ART lead to decreased methylation levels at *H19*, *KvDMR1*, and *SNRPN* imprinting control regions in placentae ($P > 0.05$), instead of fetuses. Furthermore, in the placenta, ART resulted in the downregulation of a majority of parentally expressed imprinted genes (*Dlk1*, *Igf2*, *Kcnq1ot1*, *Ndn*, *Peg3*, *Plagl1*, *Sgce*, *Peg10*, *Peg11*, *Zdbf2* and *Sfmbt2*), whereas it resulted in the upregulation of a majority of maternally expressed genes (*Cd81*, *Cdkn1c*, *Dcn*, *Gnas*, *H19*, *Mash2*, *Gatm*, and *Phlda2*). Additionally, the expression of genes (*Gcm1*, *Syna*, *Synb, Prl8a8, Tpbp*a, *Pcdh12, Hand1, Gys2*, *Gbe1, Hif1*a, *Hsd11b2, Mapk14* and *Stat4*) that regulate placental development was also affected by ART. Last but not the least, ART resulted in the downregulation of a majority of placental nutrient transporters (*Slc38a1, Slc38a4, Atp2a3, Atp1a1, Slc1a3, Slc6a6, Slc19a2, Slc26a7, Slc22a3* and *Slc22a18*).

Limitations, reasons for caution: This study was carried out using a mouse model. Whether ART affects the development and function of human placenta, and influences the growth of fetus in early pregnancy need further study.

Wider implications of the findings: The results from this study suggest that ART disrupts epigenetic reprogramming events and perturbs developmental gene expression in the mouse placenta that may affect the placental development and function, which may affect fetal growth and reprogramming.

Trial registration number: no

P-562 Am I ready for ICSI? Individualized training for laboratory technicians and assessment of learning curves

M. Durban[1], D. Garcia[2], A. Obradors[1], V. Vernaeve[1], R. Vassena[1]
[1]*Clinica EUGIN, Clinica EUGIN, Barcelona, Spain*
[2]*Fundacio EUGIN, Fundacio EUGIN, Barcelona, Spain*

Study question: Can an individualized ICSI training, tailored in realtime to the trainee performance, allow technicians with no experience in embryo manipulation to perform ICSI effectively?

Summary answer: Learning ICSI requires a variable number of attempts; however, following training with the proposed system, technicians can perform real ICSI as proficiently as senior embryologists.

What is known already: ICSI is widely used and central to the efficiency of ART cycles. ICSI is also operator-dependent, and no standardized training and evaluation of competence achievement for technicians is currently available. Although most laboratories establish internal training schemes to learn ICSI, they are not tailored to the trainee and do not allow individualized assessment of proficiency. Moreover, the vast majority of training schemes are not validated against clinical results. The present study aims to establish an individualized ICSI training for ART technicians without previous experience in micromanipulation, and to evaluate their training performance.

Study design, size, duration: Prospective study including 5 laboratory technicians. ICSI training consisted of 1 theoretical phase common to all technicians, and 1 individualized. The individualized part consisted in performing ICSI with latex microsphere (LM) on discarded oocytes. Injected oocytes outcomes were recorded and analyzed in real time in order of injection. Learning curve-cumulative summation (LC-CUSUM) curves were used to monitor in real-time when ICSI competence was achieved. Post-training performance against senior embryologists was assessed by Student' *t*-test.

Participants/materials, setting, methods: The LM inside the oocyte 24 h post injection was considered a successful ICSI. A lysed oocyte, or the LM placed outside of the plasmalemma, were considered failures. In a LC-CUSUM graph, each success moves the learning curve towards the decision limit, while each failure moves it back towards the *x*-axis. The trainee is not proficient until the learning curve crosses the decision limit. A trainee was considered trained when his failure rate remained within 5%.

Main results and the role of chance: Four technicians trainees became proficient at ICSI after a variable number of LM injections, ranging from 35 to 80. This allowed for the lab to move trainees to clinical practice after different times spent training, while all achieved the same level of proficiency. One trainee did not achieve competence after 80 LM injections and was retrained under the supervision of a senior embryologist. All technicians that achieved proficiency with LC-CUSUM, whatever the number of ICSI with LM necessary to do so, went on to perform ICSI with human gametes in a clinical setting as proficiently as senior embryologists, measured by their lysis, fertilization and rate of number of viable embryos available for ET in the first 50 real cases post-training. LC-CUSUM based, personalized training was therefore validated against clinical cases and senior embryologists. All trainees were women and all has some experience in simple ART techniques such as washing semen samples, but never handled oocytes or used a manipulator.

Limitations, reasons for caution: In this study, ICSI competence is acquired after a specific training through a structured theoretical and practical course followed by personalized learning curve. The observed results cannot be generalized to other training programs. The proposed system can be applied widely given the absence of animal gametes and human fertilization.

Wider implications of the findings: A variable number of ICSI are needed to achieve proficiency; conventional ICSI trainings might undertrain technician, undermining cycle efficiency for the patients. A tailored and continuous individualized assessment of training optimizes both training time and resources, and identifies technicians that cannot learn effectively.

Trial registration number: NA

P-563 Separated double embryo transfer represents a novel method in assisted reproductive technology treatment to prevent multiple pregnancies

T. Hasegawa[1], K. Nakagawa[2], M. Kaneyama[2], E. Tonouchi[2], K. Ehara[2], M. Oba[2], R. Sugiyama[2], H. Ito[1], *N*. Kuji[1], K. Isaka[1]
[1]*Tokyo Medical University, Obstetrics and Gynecology, Tokyo, Japan*
[2]*Sugiyama Clinic, Division of Reproductive Medicine, Tokyo, Japan*

Study question: Does a novel embryo transfer method in which two embryos are separately transferred (s-DET) prevent multiple pregnancies than does conventional double-embryo transfer (c-DET)?

Summary answer: The incidence of multiple pregnancy rates in the s-DET group was significantly lower than that in the c-DET group.

What is known already: Previous studies have reported that transferred embryos remain localized to the areas in which they were initially transferred. Furthermore, approximately 80% of the embryos implant into the direct area in which the catheter tip was placed, as determined by the ultrasonic observation of air bubbles from the catheter following embryo transfer. Moreover, the implantation rate of DET with two morphologically good embryos (MGEs) has been shown to be significantly lower than that of SET with only one MGE. These data suggest that embryos may interfere with each other when several embryos are trying to implant within the same restricted space.

Study design, size, duration: This was a prospective cohort study. A total of 231 patients with a history of two or more failed implantations after fresh or thawed ET cycles were consecutively enrolled between May and December 2015. This study was approved by our Institutional Review Board, and all patients provided informed consent upon enrollment.

Participants/materials, setting, methods: A total of 137 patients underwent s-DET (s-DET group, in which two embryos were transferred separately), whereas 94 patients underwent c-DET (c-DET group, in which two embryos were transferred together. In both groups, either fresh or frozen-thawed embryos were used. A range of reproductive outcomes were compared between the groups, including gestational sac development, clinical pregnancy, implantation, multiple pregnancy, and miscarriage rates.

Main results and the role of chance: The average age of the s-DET group was 39.2 ± 3.2 (mean ± SD) years, which was comparable to that of the c-DET group (39.1 ± 3.9 years). The history of pregnancy and delivery in the s-DET group was similar to that in the c-DET group. The number of previous ET attempts in the s-DET group was 3.7 ± 3.4 (mean ± SD), which was comparable to that in the c-DET group (2.6 ± 2.5). Clinical pregnancy and implantation rates in the s-DET group were 25.3 and 15.1%, respectively, which were comparable to those in the c-DET group (27.6 and 17.5%, respectively). Multiple pregnancy rate was significantly lower (2.9%) in the s-DET group than in the c-DET group (25.0%; $P < 0.01$).

	s-DET	c-DET	*P* value
Number of cycles	137	94	
Age, years	39.2 ± 3.2	39.1 ± 3.9	
Number of previous ET attempts	3.7 ± 3.4	2.6 ± 2.5	
Number of transferred embryos, *n*	274	188	
Number of clinical pregnancies, *n* (%)	35 (25.3)	26 (27.6)	NS

GS, *n*	36	33	NS
Implantation rate, %	15.1	17.5	NS
Number of multiple pregnancies, *n* (%)	1 (2.9)	7 (25.0)	0.009
Number of miscarriages, *n* (%)	5 (14.2)	6 (23.1)	NS

Limitations, reasons for caution: The small sample size of the s-DET group represented one potential limitation. Furthermore, implantation is believed to be dependent upon an intimate relationship between the embryo and uterine tissues mediated by locally secreted factors. Determining the mechanism underlying these findings requires further research.
Wider implications of the findings: An embryo that implants first may attempt to maintain an appropriate distance from its neighbor to prevent overlap, thus interfering with the other embryo's ability to implant. This could explain the significantly higher multiple pregnancy rate in the c-DET group than in the s-DET group.
Trial registration number: None

P-564 Is transfer on blastocyst stage related to a higher risk of pregnancy complications?

E. Marbán Bermejo[1], A.B. Garrido Quijano[1], L. García de Miguel[1], E. Santiago Romero[1], A. García Enguídanos[1], P. Caballero Peregrín[1], R. Núñez Calonge[2], V. De Lucas Domínguez[3], M. Ruano García[3], A. Guijarro Ponce[4]
[1]*Clínica Tambre, Gynaecology, Madrid, Spain*
[2]*Clínica Tambre, Biology, Madrid, Spain*
[3]*Clínica Tambre, Nurse, Madrid, Spain*
[4]*Hospital Virgen de la Luz, Gynaecology, Cuenca, Spain*

Study question: To determine whether the obstetrical complications are more frequent after blastocysts stage transfer (day 5 or 6) versus embryo transfer on day 2 or 3.
Summary answer: The main factor for the appearance of obstetrical complications (i.e., gestational diabetes, pregnancy induced hypertension or premature rupture of membranes) is transfer on blastocyst stage.
What is known already: The blastocyst stage transfer (day 5 or 6) is a relatively new technique with theoretical advantages over day 2 or 3 transfer: it is more physiological as it is more similar to what happens in natural conditions, the implantation rate is higher as only the viable embryos reach the blastocyst stage, it allows a good selection of the best embryo to transfer and there is a better embryo-endometrium synchrony.

Despite the known advantages of day 5 or 6 embryo transfer, the effect on the pregnancy and the new born development remains unclear.
Study design, size, duration: This is a cross sectional study where pregnancies obtained after *in vitro* fertilization (IVF) or donor oocytes cycles were included. The study period of time was 2013 and 2014.

A total of 374 pregnancies were included. 217 of them were obtained after donor oocyte treatment and 157 after IVF. In 123 cases, the embryos were transferred on blastocyst stage and in 251 cases on day 2 or 3.
Participants/materials, setting, methods: χ^2 test was performed to compare the obstetrical complications in blastocyst stage transfer and non- blastocyst stage one. The obstetrical complications studied were: gestational diabetes, pregnancy induced hypertension and premature rupture of membranes.

We used a multivariate logistic regression model to avoid confounding factors in the obstetrical outcomes such as age, type of treatment, transfer on blastocyst stage and twin pregnancy.
Main results and the role of chance: In our study group, we found statistically significant differences between transfer on blastocyst stage and some of these obstetrical complications: gestational diabetes (11.5 versus 4.9 p 0.008), pregnancy induced hypertension (16.7 versus 7.4 $p = 0.002$) and premature rupture of membranes (16.7 versus 7.1 $p = 0.001$)

When we analyzed confounding factors such as age (<38 years old versus >38 years old), type of treatment (IVF versus donor oocytes treatment), single pregnancy versus twin pregnancy and transfer on blastocyst stage or not, the only factor found with a statistically significant relation with the appearance of the studied pregnancy complications was the transfer on blastocyst stage with an Odds Ratio (OR) 2.34 ($p < 0.001$).

Regardless of age, type of treatment or the presence of twin pregnancy, transfer on blastocyst stage increases the risk for obstetrical complications.
Limitations, reasons for caution: Due to the statistical design, more studies are needed to advice suitably our patients about the transfer on blastocyst stage implications
Wider implications of the findings: In the study patients, we found a higher risk of obstetric complications such as gestational diabetes, pregnancy induced hypertension and premature rupture of membranes in those patients with day 5 or 6 embryo transfer.

More studies are needed to confirm our findings.
Trial registration number:

P-565 Prevalence of ovarian hyperstimulation syndrome (OHSS) and hypercoagulability in patients triggered by GnRH agonist for excessive follicular response: a systematic follow-up

M. Lobert[1], M. Peigné[2], S. Jonard-Catteau[1], V. Tintillier[3], D. Dewailly[1]
[1]*Universtité de Lille 2, Hôpital Jeanne de Flandre, Lille, France*
[2]*Université Paris VII, Hôpital Bichat Claude Bernard, Paris, France*
[3]*Universtité de Lille 2, Institut D'hématologie Transfusion CHRU Lille, Lille, France*

Study question: In patients with excessive follicular response after ovarian stimulation with antagonist protocol, does GnRH agonist triggering and "freeze-all" strategy prevent the occurrence of OHSS?
Summary answer: Triggering by GnRH agonist and "freeze-all" strategy does not fully prevent the occurrence of OHSS, but limits its duration.
What is known already: In the literature, the risk of moderate to severe OHSS is 3 to 6% and reaches 31% in high risk populations 9 days after oocyte triggering with hCG. Many studies report no or a markedly decreased risk of OHSS after triggering ovulation with a GnRH agonist. However, criteria to define OHSS are rarely explained and OHSS itself is not thoroughly asserted. It is well known that OHSS is associated with hypercoagulability. However, no study after triggering with a GnRH agonist assessed haemostasis in these high-risk patients with high circulating estradiol levels.
Study design, size, duration: In a French academic reproductive medicine centre, a systematic prospective observational follow-up of all patients triggered by GnRH agonist for excessive follicular response was conducted. 52 patients were included from January 2014 to July 2015.
Participants/materials, setting, methods: All patients undergoing antagonist protocol and at high risk of OHSS (estradiol level ≥3000 pg/mL and/or more than 20 follicles ≥11 mm on the day of triggering) were triggered by GnRH agonist. No luteal phase support and a "freeze-all" strategy were performed. On the day of oocyte retrieval (T0), at 48 h (T1) and at day 7 (T2), OHSS and hypercoagulability were systematically assessed. Haemostasis data were compared to the initial status of each patient.
Main results and the role of chance: The prevalence of moderate to severe OHSS was respectively 26.9% (T0) (14/52), 15.38% (T1) (8/52), and 7.6% (T2) (4/52). As a whole, 18 patients had moderate to severe OHSS during follow-up (34.6%). Only 1 patient had severe OHSS requiring hospitalisation. No difference in clinical or ovarian stimulation parameters was observed between the patients who experienced OHSS and the others. Hypercoagulability was evidenced at each stage of the follow-up but no thromboembolic event happened. A rapid decrease of estradiol and progesterone levels was observed, reaching basal levels at T2. Finally, pregnancy rate by oocyte retrieval was 26.9%.
Limitations, reasons for caution: OHSS classification is not precise. Subjective criteria are included and the number of criteria necessary to move from one stage to another is not well described, which could lead to misevaluation of OHSS and difficulties of comparison to the literature.
Wider implications of the findings: OHSS prevalence is much higher than expected. The occurrence of one case of severe OHSS is consistent with the fact that GnRH agonist triggering does not completely prevent from OHSS. Hypercoagulability appears after GnRH agonist triggering for excessive follicular response and a thrombosis prophylaxis must be discussed.
Trial registration number: CPP Nord-Ouest 4: CPP16/03

P-566 Perinatal outcome of children born after vitrification of blastocysts (9480 cycles with 3143 babies in 16 years experiences)

T. Mukaida[1], C. Oka[2], K. Takahashi[1], K. Tanaka[1], M. Hagaba[1]
[1]*Hiroshima HART Clinic, Hiroshima, Japan*
[2]*Tokyo HART Clinic,., Tokyo, Japan*

Study question: We analyzed perinatal information in infants born after vitrified blastocysts transfer including congenital problems after 13 weeks of gestation, and the rate of monozygotic twinning (MZT).
Summary answer: The perinatal results of 2849 births with 3143 babies, rate of congenital defect and perinatal complication (1.9%) confirm the safety of vitrified BL program.
What is known already: Since vitrification approach has been widely recognized as an established method for human oocyte and embryo cryopreservation, better clinical outcome than the one of classical slow cooling method has been often reported. Recent attention has been paid to the safety of this vitrification approach.
Study design, size, duration: Between 2000 and 2014, a total of 14370 vitrified BLs from 9480 cycles were warmed and 13748 survived (95.7%). In 9363 vitrified BLs transfers, 4447 resulted in pregnancy (47.5%). A total of 12665 vitrified BLs were transferred and 4815 were implanted (38.0%). In 2849 births 3143 babies (1655 boys & 1488 girls) were born.
Participants/materials, setting, methods: Vitrification involved the exposure DMSO and EG during the cooling step, and 0.25/0.5 M sucrose solution for warming. The blastocoelic cavity was collapsed before vitrification, and after warming, zona hatching was carried out with laser pulse. MZT was defined the number of FHB was more than that of embryos transferred.
Main results and the role of chance: Fifty two clinical pregnancies were confirmed as MZT (1.8%). Forty six cases had either congenital birth defects or perinatal complication (1.5%), including eight chromosomal abnormalities (two 18 trisomy, six 21 trisomy), nine multiple anomalies, one stillbirth due to hydropus, seven stillbirths of unknown causes during delivery (25, 29, 30, 32, 37, 38, 39 weeks of gestations), two anencephaly, one spina bifida, eleven congenital heart or major vessel malformations and three minor anomalies in hands and/or feet, one congenital esophageal obstruction, one biliary duct obstruction, one Cornelia de Lange syndrome (CdLS), and one Treacher Collins syndrome. No statistical difference was seen in the mean gestational days of between fresh BT (272.5 days) and vitrified BT (273.8 days). However, significant difference was observed in the mean birth weight of full term birth with fresh BT (2998 ± 371.5) and vitrified BT (3097 ± 406.2).
Limitations, reasons for caution: Results of vitrified BLs program were compared with the one of fresh BT program in the same period. However, background of both groups may not be completely same due to private clinical set-up the program.
Wider implications of the findings: Also, the high implantation rate encourages us to establish single BL transfer. Further investigation of developmental competence of childrens born after vitrified BL will be necessary.
Trial registration number: None

P-567 Behavioural, cognitive, and motor performance of children born after intracytoplasmic sperm injection with testicular sperm at the age of five

A.M. Meijerink[1], L. Ramos[1], A.J.W.M. Janssen[2], N.M. Maas-van Schaaijk[3], A. Meissner[4], S. Repping[4], M.H. Mochtar[4], D.D.M. Braat[1], K. Fleischer[1]
[1]Radboud University Medical Center, Obstetrics and Gynaecology, Nijmegen, Netherlands
[2]Radboud University Medical Center, Rehabilitation–Physical Therapy, Nijmegen, Netherlands
[3]Radboud University Medical Center, Medical Psychology, Nijmegen, Netherlands
[4]Amsterdam Medical Center, Centre for Reproductive Medicine, Amsterdam, Netherlands

Study question: What is the frequency of behavioural, cognitive, motor or physical problems of children born after intracytoplasmic sperm injection with testicular sperm (TESE-ICSI) at the age of five?
Summary answer: Five out of 86 children (5.8%) had developmental problems based on two or more of behavioural, cognitive and motor assessments, or based on previous diagnosis.
What is known already: A number of studies described pregnancy and neonatal outcome, focussing mainly on congenital malformations in children born after TESE–ICSI up until two years of age. No studies have been performed on behavioural, cognitive and motor performance of children born after TESE–ICSI above the age of two.
Study design, size, duration: We performed a prospective longitudinal cohort study including 378 live born children after TESE-ICSI. Data were collected between March 1st, 2008 and January 1st, 2016 in the fertility centres of the Radboud university medical center in Nijmegen and the Academic Medical Center in Amsterdam, The Netherlands. In this period, 108 children reached the age of five. In total 86 children were part of the "5-years-old cohort" while 22 (20.4%) were lost to follow up.
Participants/materials, setting, methods: Questionnaires were sent at birth, and at one and four years of age. Five-year-old children were invited for assessment. Behavioural performance was assessed using the Child Behaviour Checklist for parents and teachers. Cognitive performance was assessed using the Wechsler Preschool and Primary Scale of Intelligence test, third version. Motor performance was assessed using the Movement Assessment Battery for Children, second version. We performed also a physical examination.
Main results and the role of chance: Of the 108 five-year-old children, 79 children were completely assessed and seven were partially assessed at the age of five. Behaviour was in the normal range: the child behaviour checklist of the mothers, fathers and teachers reported behaviour in the normal range in 73/80 (91.3%), 77/80 (96.3%) and 65/74 (87.8%), respectively. Intelligence level was also in the normal range: the total IQ was mean 111.1 with a standard deviation of 11.7. In 62/80 (77.5%) we found a normal motor performance. The mean total test score for motor performance was 9.5 with a standard deviation of 3.1. Five children (5/86; 5.8%) of the five-years-old cohort had developmental problems. Two of them were previously diagnosed with a form of autism (Pervasive Developmental Disorder-Not Otherwise Specified). Three children had developmental problems based on two or more of our behavioural, cognitive and motor assessments.
Limitations, reasons for caution: In this study we found that five children had developmental problems. This study is small to draw conclusions about the relation between the mode of conception and the developmental problems.
Wider implications of the findings: Our findings seem can inform couples who consider TESE-ICSI treatment about the development of children born after this procedure.
Trial registration number: None

P-568 "Economic evaluation of single versus double embryo transfer in IVF/ICSI: a systematic review"

M. López-Regalado[1], A. Clavero[1], M. Gonzalvo[1], P. Navas[1], I. Sanchez[1], A. Guzman[1], L. Martinez-Granados[1], H. Rodriguez[1], M. Navarrete[1], L. Martínez[1], J. Mozas[1], J. Fontes[1], M. Onieva[2], E. Hernández[3], J.A. Castilla[1]
[1]Unidad de Reproduccion, UGC Laboratorio y UGC Obstetricia y Ginecologia, CHU Granada, Unidad de Reproduccion, Granada, Spain
[2]UGC Interniveles de Salud Publica, CHU de Granada, Salud Pública, Granada, Spain
[3]Subdirección de Control de Operaciones, CHU de Granada, Estadística, Granada, Spain

Study question: Is elective single-embryo transfer (eSET) more cost effective than double embryo transfer (DET)?
Summary answer: Cost-effectiveness studies of different embryo transfer strategies present diverse levels of quality. Taking into account only high-quality studies, an eSET strategy is considered more cost-effective.
What is known already: Multiple pregnancies lead to complications and provoke high costs. eSET is the most effective strategy to reduce the multiple pregnancy rate in IVF/ICSI. In terms of cost-effectiveness, eSET could counteract the decreased live birth rate by reducing the rate of multiple pregnancies. Current opinion is that eSET success rates depend on two factors: suitable patient selection and the efficiency of the embryo cryopreservation technique.
Study design, size, duration: The protocol design followed the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) guidelines for reporting systematic reviews and meta-analyses. The search was performed during January 2015 by two independent reviewers, applying as inclusion criterion that studies should describe a full economic evaluation. Drummond's checklist of 10 items was utilised to determine whether the method in each study was methodologically adequate for the objectives proposed and whether the results were valid
Participants/materials, setting, methods: The search for economic evaluations to be included in this eSET vs. DET review was conducted using the following databases: Medline, EMBASE, NHS Centre for Reviews and

Dissemination Database of Abstracts of Review of Effectiveness (NHS CRD DARE), NHS Centre for Reviews and Dissemination Health Technology Assessment (NHS CRD HTA), NHS Centre for Reviews and Dissemination Economic Evaluation Database (NHS CRD EED), the Cochrane Library and the US clinical trials registry.
Main results and the role of chance: Out of 137 non-duplicate studies, 126 were excluded. Thus, 11 studies met the eligibility criteria and had extractable data, and were included in the systematic review. Among these 11 studies, 18 different scenarios were analysed. The cost-effectiveness results obtained are expressed as a relative percentage. Overall, the studies reported relative reductions of 10% in the live birth rate and 15% in costs when eSET was performed. The reduction in effectiveness was not modified by differences in the quality of the studies, the perspective analysis adopted or the inclusion of cryotransfers in the studies. Neither was the cost reduction related to the perspective analysis adopted or to the inclusion of cryotransfers in the study design. However, a greater reduction was reported in "top quality" studies than in other categories (−31.8% vs. −3.8% $p < 0.05$). This direct relationship between the quality of the study and the cost reduction achieved with eSET was also observed when only studies that took cryotransfers into account were analysed (−29.0% vs. −2.7% $p < 0.05$).
Limitations, reasons for caution: For a full economic evaluation to be considered of high methodological quality, it should include an analysis from a social perspective, apply discount rates, base its findings on the incremental cost-effectiveness ratio, incorporate a probabilistic sensitivity analysis and address a long time horizon.
Wider implications of the findings: A repeated eSET strategy can minimise the risk of multiple pregnancy in couples undergoing IVF/ICSI and reduce costs, without substantially reducing the likelihood of achieving a live birth. Most studies of this question included young women with a good prognosis.
Trial registration number: No trial registration number.

P-569 Therapeutic effect of acupuncture on the outcomes of *in vitro* fertilization: evaluated by an updated systematic review and meta-analysis

Y. Qian[1], Y. Meng[1]
[1]*The First Affiliated Hospital of Nanjing Medical University, Nanjing, China*

Study question: This study aim to evaluate the effect of acupuncture on *in vitro* fertilization (IVF) outcomes.
Summary answer: Acupuncture improves CPR among women undergoing IVF based on all the studies.
What is known already: Although *In vitro* fertilization (IVF) increases success rate, its repeated cycles does not only cause enormous economic pressure on the patients and their families, but also invasive and time consuming. Therefore, new therapies which can improve reproductive outcomes are highly desirable. Acupuncture as one of the oldest, most commonly used medical procedure in the world, while the effect of acupuncture on IVF-ET outcomes still remain to be explored.
Study design, size, duration: This study is systematic review and meta-analysis. Patients are women undergoing IVF in randomized controlled trials (RCTs) who were evaluated for the effects of acupuncture on IVF outcomes.
Participants/materials, setting, methods: And the treatment groups were used by traditional, electrical, laser, auricular and other acupuncture techniques. The control groups were consisted of no, sham, and placebo acupuncture. The major outcomes were biochemical pregnancy rate (BPR), clinical pregnancy rate (CPR), live birth rate (LBR), ongoing pregnancy rate (OPR). Heterogeneity of the therapeutic effect was evaluated with a forest plot analysis. Publication bias was assessed by a funnel plot analysis.
Main results and the role of chance: Thirty trials (a total of 6,344 participants) were included in this review. There were no significant publication biases for most of the comparisons among these studies. The pooled CPR (30 studies) from all of the acupuncture groups was significantly greater than that from all of the control groups. The pooled CPR from all acupuncture groups was significantly higher than the controls. Subsequently, the pooled CPR, LBR, BPR and OPR results were significantly higher in the acupuncture group than in the controls when acupunctures are conducted during controlled ovarian hyperstimulation.
Limitations, reasons for caution: The effect of acupuncture on IVF-ET is still remain to be seen based on more trails.
Wider implications of the findings: However, optimized positive effects could be expected using acupuncture in IVF during controlled ovarian hyperstimulation.
Trial registration number: No.

P-570 Do internal audits increase pregnancy rates?

A.D. Deenadayal[1], L. Mettler[1], S. von Otte[1]
[1]*UKSH, Reproductive Medicine, Kiel, Germany*

Study question: Does a time consuming internal audit in real ART Practice improve pregnancy rates?
Summary answer: Yes, internal audit holds a mirror up to us for us to clearly identify the problem areas and rectify them.
What is known already: Several published papers are available on analysis of factors predicting live birth rate, logistic regression analysis of multiple variables that affect ART outcome and identification of individual predictors of pregnancy. All these studies are over a period of several years and with more than 1000 treatment cycles. There is also software available for the analysis of cycles of an ART Practice. But, there appears to be no published study if such an analysis internally plays a role in the improvement of an ART Practice. Our study question is aimed at a small ART Practice with 250 cycles per year.
Study design, size, duration: The study was a prospective cohort study of 327 cycles in 2014 compared to 365 cycles in 2015. The outcome of an ART cycle depends on a multitude of determinable and indeterminable variables. We evaluated the maximum possible determinable variables. The entire clinical profile (15 variables), ovarian stimulation details (18 variables) combined with the laboratory data (27 variables) of the ART cycle of each patient was entered into the statistical data analysis software and analyzed.
Participants/materials, setting, methods: All patients undergoing an ART Cycle at the Universitaeres Kinderwunshzentrum in Kiel, Germany in 2014 and 2015 were included. The data of the patients was entered into the SPSS Statistical software sheet and analyzed. The 1st analysis was made in January 2015 and the second analysis in January 2016. After the 1st analysis, the effect of the changes in the clinics and in the lab and was reanalyzed in the 2nd analysis.
Main results and the role of chance: 60 variables (e.g., Stimulation protocols, number of ultrasounds/blood tests done, time of ICSI/embryo transfer, lab/clinical personal performing a procedure, etc) were evaluated against different end points (e.g., number of oocytes, percentage of mature oocytes, fertilization rate, grade A/B/C embryo rate, blastocyst conversion rate and biochemical/clinical pregnancy rate). Using SPSS, a multiple logistic regression analysis was conducted with regard to each end point taking into account the confounding factors from a clinical and laboratory point of view of each variable. In both the clinical and laboratory analysis there were many variables of insignificance and a few with significance after the 1st analysis. After a significant result, a discussion regarding the possibilities of role of alteration of our protocol followed. Few examples after the 2nd analysis are: A significant improvement in blastocyst conversion rate was seen when earlier ICSI was performed followed by single drop culture of embryos. Aliquoting of media in the lab significantly increased the rate of grade A embryos. An increase in biochemical pregnancy rate was seen after change in the embryo transfer catheter but it was not significant. There was a 10% increase in pregnancies from Blastocyst transfer compared to the previous year.
Limitations, reasons for caution: The sample size was small for any definitive conclusions. A combination of meticulous data collection, statistical prudence and "outside the box" analysis was necessary. The improvements seen after the modifications as a result of the audit could have been either due to only one change or a combination of changes.
Wider implications of the findings: End points other than pregnancy rates need to be analyzed. A regular audit of the procedures and protocols in an ART Practice is the way of the future. It is through audit that a practice can continue to do what is beneficial and change what it finds to be damaging.
Trial registration number: For this analysis, a registration was not required.

P-571 Blastocyst biopsy in PGD/PGS cycles does not increase the neonatal risk when compared to intracytoplasmic sperm injection cycles

H. He[1], S. Jing[1], Y.Q. Tan[1,2], K.L. Luo[1,2], D.H. Cheng[1,2], F. Gong[1,2], G.X. Lu[1,2,3], G. Lin[1,2,3]
[1]*Institute of Reproductive and Stem Cell Engineering, Central South University, Central laboratory, Changsha, Hunan, China*

[2]Reproductive and Genetic Hospital of CITIC-Xiangya, Reproductive Centre, Changsha, Hunan, China
[3]Key Laboratory of Reproductive and Stem Cell Engineering, Ministry of Health, Central laboratory, Changsha, Hunan, China

Study question: To investigate whether blastocyst biopsy in preimplantation genetic diagnosis (PGD)/screening (PGS) increase the risk of adverse neonatal outcomes.
Summary answer: Blastocyst biopsy did not add extra risk to neonatal outcomes.
What is known already: Blastocyst biopsy is becoming more popular in PGD/PGS because of potential better pregnancy outcome and the availability to obtain more biopsy material for detecting entire chromosome complement. However, the safety of the offspring after this strategy is still to be determined.
Study design, size, duration: This is a retrospective cohort study including all children born after blastocyst biopsy combined with frozen embryo transfer (487 singletons and 91 twins) and frozen blastocyst transfer after intracytoplasmic sperm injection (ICSI, 501 singletons and 153 twins) from January 2011 to March 2015 in Reproductive and Genetic Hospital of CITIC-Xiangya.
Participants/materials, setting, methods: All patients who received blastocyst biopsy with frozen embryo transfer (biopsy group) or frozen blastocyst transfer after ICSI (non-biopsy group) and delivery at least a live baby were enrolled in this study. Patients using donated oocytes or sperm or multifetal reduction during pregnancy or testicular sperm aspiration were excluded. In addition, all triplets were not included in the statistical analysis because of the small sample size. All embryos were applied with ICSI in PGD/PGS cycles.
Main results and the role of chance: No differences were observed in both the absolute gestational age (GA)/birthweight (BW) and the GA/BW adjusted for maternal age, BMI, etiology, arrested intrauterine pregnancy, source of sperm, fetal sex of the newborns between biopsy and non-biopsy groups. The sex ratio, rate of birth defects, preterm birth (PB), very preterm birth (VPB) as well as the rate of low birthweight (LBW), very low birth weight (VLBW) and macrosomia were all comparable between the two groups no matter in singletons or twins. Meanwhile, the neonatal outcomes including GA, BW, rate of PB, VPB, LBW, VLBW did not differ between different number of biopsy cells groups (≥10 and <10). The association between number of biopsy cells and GA/BW was also not statistically significant (spearman rank correlation coefficient: $r = 0.014$, $P = 0.911$/$r = -0.025$, $P = 0.843$).
Limitations, reasons for caution: Our study is limited to the retrospective design and small sample size. There was no information available on normal control from natural conceptions.
Wider implications of the findings: Our study offers some insights into the safety of blastocyst biopsy. There were no significant differences in the neonatal status between the biopsy and non-biopsy groups.
Trial registration number: NA

P-572 Perception of pain during the follicular puncture and post-operative (48 h) under paracervical block and conscious sedation, a prospective study

B. Prieto Molano[1,2], R. Mendoza Hourtouat[1], T. Jauregui Perez[1], A. Exposito Navarro[1], R. Matorras Weinig[1,2], L. Martinez Indart[3]
[1]Cruces University Hospital, Human Reproduction Unit, Baracaldo-Vizcaya, Spain
[2]Basque Country University, Medical Surgical Specialties, Baracaldo-Vizcaya, Spain
[3]Cruces University Hospital, Statistics, Baracaldo-Vizcaya, Spain

Study question: Study the level of pain perceived by patients during and 48 h after the oocyte retrieval under local anesthesia and sedation, a prospective study
Summary answer: 83.3% of women reported a high degree of acceptability and satisfaction associated with this method during the oocyte retrieval
What is known already: There are different types of anesthesia that may be used for transvaginal follicular aspiration and oocyte retrieval. Conscious sedation is the most commonly used in IVF because it is relatively safe and does not require the presence of an anesthesiologist when opioids or benzodiazepines are used. Propofol is the preferred anesthetic agent, but should be used by specially trained personnel.

It is easy to administer in cooperative and motivated patients and is safe in healthy individuals; it has a relatively low risk for adverse effects on oocytes, embryo quality and pregnancy rates.

Study design, size, duration: A prospective cohort study of 250 patients. From October 2014 to March 2015, 239 patients answered anonymously the questionnaire, 12 declined and 1 was lost. The study was not performed when oocyte retrieval was done under general anesthesia.
Participants/materials, setting, methods: An anonymous survey was proposed to all patients undergoing IVF/ICSI cycles.

To catalog pain level an scale (0–10) is used, the cut is set to 7 (<7 tolerable pain, intolerable pain ≥7)

To compare the different variables with pain (<7 and ≥7) chi-square test was used and to compare the immediate and postoperative pain nonparametric McNemar test was applied.
Main results and the role of chance: Mean age of patients was 35.4 ± 3 and sterility time was 4.3 ± 2 years. From all the patients 52.8% were from first cycle, and from the ones which had previous cycles in 29% was with general anesthesia

83.3% of women reported a high degree of acceptability and satisfaction associated with this method during oocyte retrieval and 75.3% in the postoperative.
During the oocyte retrieval, the high level of pain was compared in patients who had previous abdominal surgery, gynecological surgery, endometriosis, psychiatric illness, nervous personality, habitual use of analgesics, dysmenorrhea, previous children, compared to patients who did not.

High levels of pain were found in patients with endometriosis (31.3%) comparing to patients with no endometriosis (13.8%), ($p = 0.013$). Also patients with habitual use of analgesics showed higher levels of pain (28.5%) that the ones that do not take analgesics (12.6%) ($p = 0.005$)

Relating to **Postoperative pain** no statistical significance was not found when comparing the same parameters. 52% of the patients who had high pain level in the oocyte retrieval, continued to have it in the postoperative while 23% of patients who had low pain level began to have high level of pain in the postoperative.
Limitations, reasons for caution: it would be interesting to know how many patients have postoperative pain when general anesthesia is performed
Wider implications of the findings: High levels of women´s satisfaction were reported from conscious sedation and paracervical block. However general anesthesia should be offered in patients with endometriosis and in analgesics users. It`s necessary a good analgesia guideline in postoperative pain control.
Trial registration number: CEIC E14/51

P-573 Letrozole use for infertility and the risk of congenital malformations: a systematic review and meta-analysis

E.M. Dahdouh[1], J. Balayla[2], M.S. Brochet[3]
[1]Assisted Reproduction Center CHU Sainte-Justine and Procrea Clinics, Department of Obstetrics and Gynecology, University of Montreal, Montreal, QC, Canada
[2]University of Montreal, Department of Obstetrics and Gynecology, Montreal, QC, Canada
[3]CHU Sainte-Justine, Department of Pharmacy, University of Montreal, Montreal, QC, Canada

Study question: Does the use of letrozole (LTZ) in infertility increase the risk of congenital malformations relative to clomiphene citrate (CC)?
Summary answer: When used for ovarian stimulation in polycystic ovary syndrome (PCOS) patients and for unexplained infertility, LTZ does not increase the risk of birth defects.
What is known already: LTZ is used as an off-label drug for ovulation induction in PCOS patients as an alternative to CC, and it has been associated with higher ovulation rates and higher live birth rates (LBR) when patients' BMI is >30. In addition, LTZ is used for ovarian stimulation coupled with intra uterine insemination (IUI) for unexplained infertility with equivalent results to CC in terms of LBR. However, LTZ remains contraindicated for use in infertility by many world health authorities because of its potential teratogenic risk. But whether LTZ truly increases the risk of birth defects remains a matter of debate.
Study design, size, duration: A systematic review and meta-analysis of observational studies (OS) and randomized controlled trials (RCTs) on LTZ and the risk of congenital anomalies published before February 2016 was performed. Only studies reporting congenital malformations with LTZ vs. CC were

included. The clinical outcomes of interest included in the meta-analysis are congenital malformations rates. 1015 live births following treatment with LTZ were compared to 1120 live births after treatment with CC.

Participants/materials, setting, methods: We searched Medline, Cochrane Central, EMBASE, Scopus, Web of Science, Google Scholar, as well as related articles from relevant authors on the subject. Studies were only eligible if they compared LTZ to CC for infertility and if they reported the number of congenital malformations. The three authors independently screened for eligibility, and assessed the quality of the studies.

Main results and the role of chance: Out of 526 citations identified, 120 articles met initial eligibility criteria and were further analyzed. Of these, only 6 studies met full inclusion criteria, allowing direct comparison of LTZ to CC and reporting congenital malformations. 3 OS and 3 RCTs were included in the meta-analysis. LTZ has been used either for ovulation induction in PCOS patients or coupled with IUI for the treatment of unexplained infertility. Treatment with LTZ is associated with equivalent risk of congenital malformations when compared to CC. The risk is 1.87% in the LTZ group vs. 3.03% in the CC group, with an odds ratio [OR] of 0.68 [95% CI: 0.33 – 1.40].

Limitations, reasons for caution: Primary outcomes in all the reported studies were clinical pregnancy outcomes and not congenital malformations, which may introduce selection bias and may underestimate the true risk of birth defects. Therefore these results must be interpreted with caution for the time being and patients should be counseled accordingly.

Wider implications of the findings: More data reporting congenital malformations after LTZ use are needed. Ideally, future RCTs powered to detect the birth defect rates are needed to resolve this debate. These may further clarify the safety of this medication.

Trial registration number: NA

P-574 Low immunogenicity potential of follitropin delta, a recombinant FSH preparation produced from a human cell line: Results from phase 3 trials (ESTHER-1 and ESTHER-2)

B. Buur Rasmussen[1], B. Mannaerts[2], B.M. Klein[3], L. Helmgaard[2], J.C. Arce[2], &. ESTHER-1 and ESTHER-2[4]

[1]Ferring Pharmaceuticals, Bioanalysis – Global Clinical R&D, Copenhagen, Denmark

[2]Ferring Pharmaceuticals, Reproductive Health – Global Clinical R&D, Copenhagen, Denmark

[3]Ferring Pharmaceuticals, Biometrics – Global Clinical R&D, Copenhagen, Denmark

[4]On Behalf of the ESTHER-1 and ESTHER-2 Trial Group, Evidence-Based Stimulation Trial with Human rFSH in Europe and Rest of World, Copenhagen, Denmark

Study question: To assess the incidence of anti-FSH antibodies in patients undergoing controlled ovarian stimulation with follitropin delta (FE 999049; recombinant FSH preparation produced from the human cell line PER.C6®) in up to three stimulation cycles.

Summary answer: The incidence of treatment-induced anti-FSH antibodies with follitropin delta was similar to the incidence of pre-existing anti-FSH antibodies and did not increase with repeated exposure.

What is known already: Several factors can influence the immunogenicity of therapeutic proteins, including molecular structure, product purity and formulation, duration of treatment and route of administration. The assessment of antibodies to gonadotropins is not routine in clinical practice, and there are no adequate epidemiological data on the prevalence of antibodies towards FSH in the general population.

Study design, size, duration: Randomised, controlled, assessor-blind trial in patients undergoing controlled ovarian stimulation with follitropin delta or follitropin alfa for IVF/ICSI (ESTHER-1), with a subset of patients undergoing additional assessor-blinded stimulation cycles (ESTHER-2): a total of 1,326 patients in cycle 1, 513 in cycle 2, and 188 in cycle 3. The distribution of patients treated with follitropin delta and follitropin alfa was balanced in all three cycles. Patients with pre-existing or treatment-induced anti-FSH antibodies could be re-exposed.

Participants/materials, setting, methods: In all treatment cycles, blood samples for anti-FSH antibody analyses were collected at stimulation day 1 (pre-dosing) as well as 7–10 days (first post-dosing) and 21–28 days (second post-dosing) after the last gonadotropin dose. The testing strategy was tiered: a screening assay followed by a confirmatory assay and, if applicable, titre, cross-reactivity and neutralising antibody assays.

Main results and the role of chance: The incidence of anti-FSH antibodies prior to exposure to follitropin delta, i.e., pre-existing anti-FSH antibodies, was 1.4% (9/665). After treatment with follitropin delta, the incidence of anti-FSH antibodies was 1.1% (7/665) in cycle 1, 0.8% (2/252) in cycle 2 and 1.1% (1/95) in cycle 3, indicating no increase in anti-FSH antibodies during repeated exposure to follitropin delta. Furthermore, these incidences were similar to those observed for follitropin alfa. In cycle 1, the anti-FSH antibodies observed after treatment with follitropin delta had maximum titres below those detected in patients with pre-existing anti-FSH antibodies. In cycles 2 and 3, all positive anti-FSH antibody samples after treatment with follitropin delta had titres below the limit of quantification. No treatment-induced anti-FSH antibodies in follitropin delta patients were of neutralising capacity (0% in all 3 cycles). Interestingly, repeated treatment with follitropin delta in patients with pre-existing or treatment-induced anti-FSH antibodies did not increase the titre, was not associated with decreased ovarian response, and did not induce immune-related adverse events.

Limitations, reasons for caution: Immunogenicity testing was performed in accordance with current guidelines from the European Medicines Agency (EMA) and the Food and Drug Administration (FDA). All assay cut-points were derived statistically and designed to minimise the risk of false negatives, but a low incidence of false positives cannot be ruled out.

Wider implications of the findings: There is no increased immunogenicity risk following controlled ovarian stimulation with follitropin delta, a recombinant FSH preparation from the human cell line PER.C6®, neither in the first treatment cycle nor after exposure in repeated cycles. The findings indicate an overall low immunogenicity potential of follitropin delta.

Trial registration number: NCT01956110 and NCT01956123

P-575 Birthweight according to hypertensive disorders in pregnancy and conception method – exploring the excess risk of large babies and hypertension following cryopreservation of embryo

S. Opdahl[1], A.K. Henningsen[2], A. Tiitinen[3], C. Bergh[4], A. Pinborg[5], U.B. Wennerholm[4], M. Gissler[6], R. Skjærven[7], L.B. Romundstad[1]

[1]Norwegian University of Science and Technology, Department of Public Health and General Practice, Trondheim, Norway

[2]Rigshospitalet, Copenhagen University Hospital, Fertility Clinic, Copenhagen, Denmark

[3]Helsinki University Central Hospital, Department of Obstetrics and Gynaecology, Helsinki, Finland

[4]University of Gothenburg, Sahlgrenska University Hospital, Department of Obstetrics and Gynaecology, Gothenburg, Sweden

[5]Copenhagen University Hospital, Department of Obstetrics and Gynecology, Hvidovre Hospital, Copenhagen, Denmark

[6]National Institute for Health and Welfare, THL, Helsinki, Finland

[7]University of Bergen, Department of Global Public Health and Primary Care, Bergen, Norway

Study question: Is the increased risk of hypertensive disorders in pregnancies following embryo cryopreservation associated with the increased risk of large-for-gestational-age (LGA) offspring after cryopreservation?

Summary answer: The risk of LGA offspring is higher in cryopreservation pregnancies with hypertensive disorders compared to both normotensive cryopreservation pregnancies and spontaneously conceived (SC) normotensive pregnancies.

What is known already: Pregnancies following assisted reproductive technology (ART) carry a higher risk of hypertensive disorders and small-for-gestational-age (SGA) offspring compared to SC pregnancies. More recently, ART pregnancies following cryopreservation have been shown to carry a higher risk of both hypertensive disorders and LGA offspring, compared to both SC and fresh ART pregnancies. Although the causes remain unknown, sibling studies indicate that these excess risks after cryopreservation may not entirely be attributed to parental characteristics or infertility per se.

Study design, size, duration: Population based cohort study with nationwide data from health registers in Sweden, Denmark and Norway from 1988 to 2007. All registered ART singleton pregnancies with gestational age ≥22 weeks

(n = 47,088) and a sample of SC pregnancies (n = 268,599), matched on parity and birth year, were included.
Participants/materials, setting, methods: We compared birthweight in 255,925 normotensive and 12,674 hypertensive SC pregnancies, 37,640 normotensive and 2282 hypertensive fresh ART pregnancies, and 6044 normotensive and 455 hypertensive frozen-thawed ART pregnancies. We used linear regression to compare mean birthweight and logistic regression to compare odds of SGA and LGA outcomes (-/+ 22% according to Marsal's formulas). All analyses were adjusted for parity, maternal age, country, child sex, birth year and gestational age.
Main results and the role of chance: Mean birthweight was lower in SC (−91 g, 95% confidence interval (CI) 100 g to −82 g) and fresh ART (−105 g, 95% CI −126 to −83 g) pregnancies with hypertensive disorders compared to normotensive SC pregnancies. In hypertensive pregnancies following frozen-thawed ART, mean birthweight was 18 g lower than in normotensive SC pregnancies (95% CI −66 g to 29 g). In SC normotensive pregnancies, the risk of being born SGA was 3.9%, whereas the risk was higher in all groups of hypertensive pregnancies, with hypertensive fresh ART pregnancies showing the highest absolute risk of 15.0% (OR 4.4, 95% CI 3.9–4.9). The risk of being born LGA was higher in hypertensive pregnancies, regardless of conception method, but highest in hypertensive pregnancies after cryopreservation with an absolute risk of 8.0% compared to 4.0% in SC normotensive pregnancies (OR 2.1, 95% CI 1.5–3.0). In normotensive pregnancies after cryopreservation, the risk of being LGA was 5.6% (OR 1.4, 95% CI 1.3–1.6).
Limitations, reasons for caution: The number of cryopreservation pregnancies with hypertensive disorders was limited. Residual confounding from parental factors cannot be excluded. We had no information on specific cryopreservation procedures or additional treatment.
Wider implications of the findings: The link between hypertensive disorders and LGA offspring in pregnancies after cryopreservation raises the question of a common underlying pathophysiology for these two complications in frozen-thawed cycles. Improved understanding may open opportunities for prevention.
Trial registration number: Observational study, no trial registration number.

P-576 Ongoing and cumulative pregnancy rates after cleavage stage embryo transfer: impact of the day of cryopreservation of the supernumerary embryos

I. De Croo[1], K. Tilleman[1], S. De Gheselle[1], A. Van de Velde[1], B. Heindryckx[1], F. Vandekerckhove[1], E. Van den Abbeel[1], P. De Sutter[1]
[1]*Ghent University Hospital, Department for Reproductive Medicine, Ghent Fertility and Stem cell Team G-FaST, Ghent, Belgium*

Study question: What is the ongoing cumulative pregnancy rate after day 3 transfer in combination with either day 5 vitrification or day 3 slow freezing of supernumerary embryos?
Summary answer: The cumulative ongoing pregnancy rate of day 3 transfers in combination with vitrification is higher than day 3 transfer cycles in combination with slow freezing.
What is known already: A Cochrane analysis demonstrated that in terms of live birth rates there was a slight benefit for fresh blastocyst transfer as compared to day 3 transfer. The cumulative live birth rate showed a benefit for day 3 transfer. However, most of the studies used slow freezing for blastocyst cryopreservation and these protocols proved to be suboptimal. With the introduction of vitrification of blastocysts, better results are obtained in terms of live births It is hypothesized that vitrification at the blastocyst stage might not only increase the cumulative live birth rate after day 5 but also after day 3 fresh transfers.
Study design, size, duration: Retrospective analysis over a period between July 1st 2010 and December 31st 2014 in a group of patients having between 5 and 9 zygotes available on day 1 and with fresh embryo transfer on day 3 (n = 1102). The cumulative ongoing pregnancy rate was defined as the ongoing pregnancy rate obtained after fresh transfer on day 3 in combination with maximum 3 subsequent thawing/warming cycles.
Participants/materials, setting, methods: In 433 patients, the surplus embryos were frozen on day 3 with a slow freezing protocol (Cook, Australia) (group 1) and in 669 patients, the surplus embryos were vitrified at the blastocyst stage (Irvine, USA) (group 2). Continuous variables were compared using the independent Student's t-test and categorical variables were compared using Chi-Square test. The significance level was set at 5% ($p < 0.05$).
Main results and the role of chance: In group 1 and 2, mean female age (32.0 years ± 4.6 years vs. 31.9 years ± 4.7 years; NS) and number of zygotes obtained (6.9 ± 1.4 vs. 6.8 ± 1.4; NS) was similar. The mean number of embryos frozen was significantly higher in group 1 compared with group 2 (2.8 ± 1.5 vs. 2.3 ± 1.3) ($p < 0.0001$). The ongoing pregnancy rates after fresh day 3 transfer were comparable in both groups (27.7% (120/433) for group 1 and 29.0% (194/669) for group 2; NS). The transfer rate after thawing/warming was significantly lower in group 1 (63.6% (246/387) as compared to group 2 (86.3% (550/637) ($p < 0.0001$). The ongoing pregnancy rates after a maximum of 3 consecutive thawing/warming cycles was 15.5% (60/387) in group 1 and 24.3% (153/637) in group 2 ($p = 0007$). The cumulative ongoing pregnancy rate in group 1 was significantly lower (41.6% (180/433) as compared to group 2 (52.2% (347/669) ($p < 0.0001$). Interestingly, the number of patients with an ongoing pregnancy after the first thawing/warming cycle was significantly higher in group 2 (19.0% (121/637) as compared to group 1 (10.3% (40/387) ($p = 0.0002$).
Limitations, reasons for caution: This study is limited by its retrospective design. Our results are conditioned by the lower survival rate of slow freezing of day 3 embryos in group 1.
Wider implications of the findings: These findings suggest that for patients with 5–9 fertilized oocytes, the time to pregnancy can be shortened when the surplus embryos are vitrified on day 5 compared to slowly frozen on day 3. Furthermore, a fresh blastocyst transfer can be suggested whenever there are at least 5 zygotes available.
Trial registration number: Not applicable

P-577 Evaluation of congenital anomalies in 3747 children born after *In Vitro* fertilization (IVF), intracytoplasmic sperm injection (ICSI) or frozen embryo transfer (FET) in France

A.A. Beltran Anzola[1,2], M. Gervoise-Boyer[1], D. Montjean[1], V. Pauly[2], A. Amar-Hoffet[1], V. Lubin[1], B. Pfister[1], P. Tourame[1], D. Bautrant[1], N. Berdah[1], C. Geoffroy-Siraudin[1], P. Boyer[1]
[1]*Hopital Saint Joseph de Marseille, Service de Medecine et Biologie de la Reproduction, Marseille, France*
[2]*Université Aix-Marseille, Laboratoire de Santé Publique et Maladies Chroniques, Marseille, France*

Study question: Is the prevalence of congenital anomalies comparable in the three procedures of Assisted Reproduction Technologies (ART) routinely used in our center?
Summary answer: The prevalence of the congenital anomalies is not different when comparing children born after IVF, ICSI and FET.
What is known already: Congenital anomalies (≈2.6% in EUROCAT Database) are one of the main criteria used for assessing children health. The risk for these children to develop such anomalies may vary with factors such as the cause of infertility and different aspects possibly related with Assisted Reproductive Technologies procedure such as ovarian stimulation treatment, culture media composition, embryo culture duration, freezing and thawing cycles and hormonal environment at the time of implantation. It was recently described that subfertile couples are more likely to give birth to children showing abdominal wall defects, hypospadias, right ventricular outflow tract obstruction, and methylation defects causing imprinting disorders.
Study design, size, duration: This study is a retrospective descriptive analysis of congenital anomalies in 3747 children born after IVF, ICSI or FET between 1994 and 2014. Three groups were analyzed: IVF group (1319 children), ICSI group (1563 children) and FET group (575 children).
Participants/materials, setting, methods: Data compiled of congenital anomalies were collected by maternity hospitalization report, a copy of the child health record or an auto-questionnaire filled by parents. Congenital anomalies were coded by a medical doctor using International Classification of Diseases and classified with European Concerted Action on Congenital Anomalies and Twins classification. Variables were described by proportions N(%) and means (SD). Student's t-test was used to compare quantitative variables and Pearson-Chi-Square or Fisher's Exact Test was used for qualitative variables.
Main results and the role of chance: 3457 children were enrolled in the analysis, 1698 boys, 1758 girls and 1 undetermined (2429 singleton, 995 twins and 33 triplets). 290 children were excluded because data could not be verified by a medical report. 142 children [4.1%] were diagnosed with a congenital

anomaly. There are no statistical difference in congenital anomalies prevalence [$p = 0.7$] between the three groups (IVF group: $n = 54$ [4.1%]; ICSI group: $n = 68$ [4.4%]; FET group: $n = 20$ [3.5%]), and between girls ($n = 62$ [3.5%]) or boys ($n = 79$ [4.7%]) [$p = 0.1$]. 3.0% of the children have a congenital anomaly and 1.1% children have more than one. The five main categories of congenital anomalies in our study were: congenital heart defects with 44 cases (1.3%), limb defects with 30 cases (0.9%), genital malformations with 29 cases (0.8%), urinary malformations with 27 cases (0.8%), and 15 cases (0.4%) in the class of genetic syndromes, microdeletion and sequences. Do not report any case of imprinting disease.

Limitations, reasons for caution: This descriptive study does not permit to establish a causal link between these three ART procedures and the congenital anomalies prevalence. However our preliminary results are in line with the epidemiological studies which have shown an increased genetic risk in infertile couples.

Wider implications of the findings: The evaluation of congenital anomalies of children born after IVF, ICSI and FET can be used as a support to assess informed consent to couples enrolled in an infertility treatment program.

Trial registration number: None

P-578 Cortisol levels and diurnal patterns of 9–10 year old children born after ART (IVF/ICSI)

M. Vänskä[1], J. Lindblom[1], R.L. Punamäki[1], M. Flykt[1], L. Unkila-Kallio[2], M. Tulppala[3], A. Tiitinen[2]
[1]*University of Tampere, School of Social Sciences and Humanities/Psychology, University of Tampere, Tampere, Finland*
[2]*Helsinki University Central Hospital and University of Helsinki, Department of Obstetrics and Gynaecology, Helsinki, Finland*
[3]*University of Helsinki, Department of Obstetrics and Gynaecology, Helsinki, Finland*

Study question: Do children born after assisted reproductive techniques (ART) differ from naturally conceived (NC) controls in the levels and diurnal patterns of cortisol at 9–10 years?

Summary answer: ART children showed lower levels of cortisol, particularly in the morning and late afternoon. Diurnal patterns, in contrast, were similar between ART and NC children.

What is known already: Balanced functioning of the HPA system is crucial for stress adaptation, vitality and health. A number of risk factors can lead into altered HPA axis development and cortisol dysregulation, the pre- and perinatal period being especially vulnerable. Even very early events during embryogenesis can affect the development of the HPA system, e.g., through subtle epigenetic changes. The dysregulation of HPA axis can be determined by either altered *levels* or *diurnal patterns* of cortisol. Although pregnancies after ART show increased obstetric and perinatal problems, we have no previous knowledge about HPA axis development and cortisol regulation among ART children.

Study design, size, duration: The prospective follow-up study compares salivary cortisol levels and their diurnal patterns between 9- and 10-year-old ART children ($n = 30$) and their matched pairs of NC children ($n = 30$). The pairs were matched for parental age and education level and child's gender. Statistical analyses further controlled for mother's parity, child's gestational age, birthweight and age at the time of the cortisol assessment.

Participants/materials, setting, methods: Children's cortisol patterns were measured from saliva samples through 5 within-one-day-assessments (awakening, 1 h after awakening, midday, late afternoon and evening). Cortisol level was analyzed using a sensitive method of liquid chromatography-tandem mass spectrometry (LC-MS/MS). Statistical methods included paired *t*-tests and linear mixed-effects modelling.

Main results and the role of chance: Compared to NC children, children born after ART showed lower level of cortisol in the morning right after awakening, ART group $M = 4.75$ µg/l, NC group $M = 6.32$ µg/l, $t(56) = -2.09$, $p < 0.05$, as well as in late afternoon, ART group $M = 1.23$ µg/l, NC group $M = 2.21$ µg/l, $t(56) = -2.48$, $p < 0.05$. In contrast, cortisol diurnal patterns, including awakening response and diurnal decline, were unaffected by assisted reproductive treatment.

Limitations, reasons for caution: Although day-to-day variation in cortisol secretion can be marked, we were unable to collect samples across several days. Our results thus need to be interpreted with caution. Several possible confounders were not included, for example mother-child or father-child relationship quality or children's cortisol levels before middle childhood.

Wider implications of the findings: The findings indicate the importance of considering child endocrine function and HPA system development in understanding the developmental outcomes among children born after ART.

Trial registration number: None.

P-579 Evolution in attitudes towards twin pregnancies in infertile patients. Results in surveys carried out in 2007 and 2015

J. Llacer[1], V. Cañavate[1], G. Gosalbez[1], R. Sanus[1], L. Peñaranda[1], R. Bernabeu[1]
[1]*Instituto Bernabeu, Reproductive Medicine, Alicante, Spain*

Study question: Is the attitude towards twin pregnancies changing in the last years especially in infertile patients receiving information about risks associated multiples pregnancies?

Summary answer: Twin pregnancies continue being a desirable situation for the majority of infertile patients despite receiving information about risks associated with multiple gestations.

What is known already: Multiple pregnancies are considered a serious complication of assisted reproduction technology therefore eSET must be the first option for most patients if not all. One of the biggest obstacles for the implementation of SET policies is the opposition of patients considering twin pregnancies as a desirable situation. Our group and other authors published surveys some years ago finding 75% patients considering twin pregnancies as a positive outcome after IVF. In recent years, efforts have been made to raise awareness about medical and social implications of multiples pregnancies; therefore, to assess changes in attitudes is crucial to design future strategies.

Study design, size, duration: All the women and their partners attending for the first time the reproductive medicine department at Instituto Bernabeu during the period of 4 months from July to December 2015 were offered to fill in a questionnaire. The patients and their partners were required to self-complete the questionnaire separately without consulting each other. To assess changes in attitudes, the questionnaire was identical to the first evaluation carried out in our institution in 2007.

Participants/materials, setting, methods: 275 patients filled the survey (185 women and 90 partners). The questionnaire consists of 15 items valuing the age, sex, level of education, work, previous children, time to conceive, multiple pregnancies in the family or circle of friends. Also we investigated whether they undergone fertility treatments previously. Respondents rated double and triple pregnancies as very negative, negative, indifferent, positive or very positive. The results were compared with an identical survey carried out in 2007.

Main results and the role of chance: 76.0% of respondents considered twin pregnancy as positive or very positive while only 8% saw it as negative or very negative. The results were similar to those obtained in 2007 when 77.9% rated twin pregnancy as positive or very positive compared with 4.9% rated as negative or very negative. Significant differences were observed in terms of the valuation as positive o very positive of triplet pregnancies from 76.0% in 2007 to 49.6% in 2015.

Men and women had similar ratings, 79.3 and 73.1% respectively evaluated twins as positive very positive outcome.

No relationship was found between age and attitude towards twins, average was 36.7 years in patients rating as positive or very positive and 37.0 years as negative or very negative

Patients with children had a more negative attitude to have twins, 54.8 considered it as positive or very positive compared to 79.6% in those without children. Respondents who had received previous IVF treatments and therefore had information about the risks of multiples pregnancies considered twins as more desirable outcome. 85.1% of they rated as a positive or very positive compared with 74.2% in patients without previous treatments.

Limitations, reasons for caution: At present, we receive patients with poorer prognosis (poor ovarian responders and recurrent implantation failure) than in 2007 and this could be a bias factor.

Wider implications of the findings: The strategy to inform patients about neonatal and maternal risks associated with twin pregnancies is useless for changing the attitudes towards twins at least in infertility patients.

Efforts must be done to explain general population and patients that eSET policy is able to improve the success rates per egg retrieval.

Trial registration number: Not a clinical trial

P-580 Calcium dobesilate versus cabergoline for prevention of ovarian hyper stimulation syndrome

A.S. Saad[1], K.A.A. Mohamed[2], S.A.A. Saad[2]
[1]*Hawaa Fertility Center, Obstetrics and Gynecology, Banha University, Benha, Egypt*
[2]*Banha University, Obstetrics and Gynecology, Banha, Qalyubiya, Egypt*

Study question: To compare the effect of oral Calcium dobesilate to oral cabergoline in the prevention of ovarian hyperstimulation syndrome (OHSS) in high-risk women underwent intracytoplasmic sperm injection (ICSI).
Summary answer: Ovarian hyperstimulation syndrome was significantly lower in dobesilate group than in cabergoline group. severe OHSS was more common in cabergoline group
What is known already: Ovarian Hyperstimulation Syndrome (OHSS) is one of the most serious complication of ovulation induction. The pathophysiology of OHSS is characterised by increased capillary permeability, leading to leakage of fluid from the vascular compartment, with third space fluid accumulation. one of the most accepted theory for this is an increase in vascular endothelial growth factor (VEGF).

Cabergoline has been studied as a potential drug for use in the prevention of OHSS due to its role in suppression of (VEGF). Calcium dobesilate is used in the treatment of diabetic retinopathy and chronic venous insufficiency and *in vivo* proved to inhibit VEGF
Study design, size, duration: This was a randomized single blind study in Benha university hospital with two hundred high-risk patients undegoing ICSI or IVF from April 2014 till December 2015 were randomly divided into two groups. The women with even numbers in Group I and Group II with odd numbers. Sample size calculation was

$$SS = \frac{Z^2 \times (p) \times (1 - p)}{C^2}$$

SS = Sample Size.
Z = Z-value.
P = Percentage of population affected.
C = Confidence interval.

Participants/materials, setting, methods: Two hundred high-risk patients undegoing ICSI or IVF characterized by presence of more than 20 follicles by ultrasound, E2 more than 3000 pg/ml or retrieval of more than 15 follicles were randomly divided into 2 groups. The women with even numbers (100) in Group I and were administered calcium dobesilate at day of HCG injection and for 2 weeks while Group II received Cabergoline at day of HCG injection and for eight days.
Main results and the role of chance: One hundred patients in each group completed the study.

Follow-up of the patients showed that OHSS was significantly lower in the calcium dobesilate group (12/100) than cases in cabergoline group (28/100) ($p = 0.005$) and that severe OHSS cases were significantly more common in the cabergoline group (13/100) than in the calcium dobesilate group (2/100) ($P < 0.003$).

All OHSS cases in both groups were early onset OHSS. The patients with mild and moderate OHSS from both the study groups were monitored on an out–patient basis until the resolution of signs and symptoms. All the severe cases in our study were grade 4 of Golan et al. criteria and treated as outpatient. Only one case in the cabergoline group was hospitalized with oliguria (urine output <400 cc per 24 h) and Haemoconcentration (hematocrit >45%).

Fertilization rates, the implantation, chemical and clinical pregnancy and multiple pregnancy rates as well as the number of miscarriages were similar in both groups.
Limitations, reasons for caution: 1- single blind, not double blind study.

2- study no. is a bit small.

3- No control, but this was for ethical reasons as we cannot leave these patients to face the hazards of OHSS.
Wider implications of the findings: Cabegoline showed some success for the prevention of OHSS in the literature with some papers agree and others disagree with its value but for the best of our knowledge this is the first study to try calcium dobesilate as a preventive drug for OHSS and to compare it with cabergoline
Trial registration number: NCT02271360

P-581 The incidence of elevated progesterone levels in modified natural cycle frozen thawed embryo transfer cycles and impact on outcomes

E. Groenewoud[1], B. Cohlen[2], N. Macklon[3]
[1]*Medical Centre Leeuwarden, Obstetrics and Gynaecology, Leeuwarden, Netherlands*
[2]*Isala Clinics, Fertility Centre, Zwolle, Netherlands*
[3]*Academic Unit of Human Development and Health, University of Southampton, Department of Obstetrics and Gynecology, South Hampton, UK*

Study question: What is the incidence of elevated late follicular phase progesterone levels in modified natural cycle frozen thawed embryo transfer (mNC-FET) and what is the effect on clinical pregnancy rates (CPR)?
Summary answer: A progesterone (*P*) level ≥5 nmol/l was observed in 37% of patients undergoing mNC-FET. An elevated progesterone level had no influence on pregnancy rates.
What is known already: Elevated late follicular phase progesterone levels have been associated with lower clinical and ongoing pregnancy rates in patients undergoing fresh embryo transfer after IVF. This has been ascribed to advancement of endometrial maturation resulting in embryo-endometrial asynchrony. It remains unclear to what extent elevated progesterone levels occur in the late follicular phase of mNC-FET and whether they result in a comparable negative effect on pregnancy rates.
Study design, size, duration: The cohort studied in this prospective study derived from the mNC-FET arm of an RCT comparing this means of endometrial preparation with artificial cycle FET (AC-FET). Between February 2009 and April 2014, 969 patients were included in this trial of which 495 were randomized to NC-FET. 271 of these patients were ultimately available for analyses.
Participants/materials, setting, methods: Patients from 17 IVF units were included this study. Ultrasonic monitoring of the dominant follicle was performed until the leading follicle reached a diameter of 16–20 mm. A blood sample was then drawn before administering a 5000 IU dose of human chorion gonadotrophin (hCG). Thawing and transfer was planned based on the moment of hCG injection. The blood samples were centrally analyzed after completion of the trial.
Main results and the role of chance: The ROC curve constructed showed no specific progesterone level above which CPRs were influenced negatively (area under the curve 0.55). 100 of the 271 patients included (36.9%) revealed an elevated serum *P* (≥5 nmol/l) on the day of hCG administration. These patients had a CPR similar to those without a raised *P* level (CPR 25% versus 26%, OR 1.1 95% CI 0.6–2.0). Ongoing pregnancy rate (OPR) did not significantly differ between these two groups (14% versus 15%, OR 1.1 95% CI 0.5–2.4). There was no significant difference in median progesterone level between pregnant and non-pregnant patients (5.1 nmol/l versus 5.0 nmol/l, $p = 0.9$). Logistic regression analyses identified embryo quality as the only independent predictor of clinical pregnancy. A combined LH surge and elevated progesterone in the presence of a dominant follicle on ultrasound (premature luteinisation) occurred in 71 patients (26.2%). There was evidence for a negative trend in CPR in patients with premature luteinisation, however this difference was not statistically significant (CPR 25.5% versus 16.9%, OR 0.6, 95% CI 0.3–1.2).
Limitations, reasons for caution: This study represents a nested subgroup analysis of one arm of an RCT that was designed to answer a different research question. The relatively low OPR limits power for analyzing this secondary endpoint.
Wider implications of the findings: Elevated progesterone levels were commonly observed in mNC-FET cycles but had no apparent impact on pregnancy rates. This suggests that putative causes and impact of raised late follicular phase *P* levels on mNC-FET outcomes differ from those in IVF.
Trial registration number: ANTARCTICA trial from which this cohort derived is registered (NTR number 1586).

P-582 Are criteria for the assessment of blastocyst quality clear enough and embryologists sufficiently trained for reproducibility of blastocyst scoring results?

M. Zafosnik[1], M. Taborin[1], M. Reljiğ, B. Kovağğ
[1]*Univerzitetni Klinicni Center Maribor, Gynecology and Reproduction, Maribor, Slovenia*

Study question: What is the level of reliability/agreement between and within embryologists in assessment of blastocyst quality?

Summary answer: Excellent reliability and agreement in the assessment of blastocyst expansion and overall score. Highest variability in the assessment of trophectoderm and inner cell mass.

What is known already: Numerous blastocyst scoring systems have been developed that take into account blastocoele expansion, morphology of the inner-cell-mass (ICM) and trophectoderm (TE). However, the characteristics of different grades of ICM and TE are generally poorly described. The ICM usually shows substantial inter- and intravariations in size, shape, cell number and cellular connections with TE that depend on blastocyst expansion rate. The assessment of TE is also difficult, especially when fragments or blastomeres are located in subzonal place or within blastocoel. The interobserver variability manifests not only the consistency in embryo assessment between embryologists but shows also the quality of evaluation criteria.

Study design, size, duration: Intra- and interobserver agreement analysis between embryologists of one IVF clinic. Our clinical practise is prolonged cultivation and blastocyst vitrification. Evaluation of blastocysts is based on morphological parameters using Gardner's system for assessing ICM, TE and degree of blastocoele expansion and our originally developed scoring system which takes into account blastocyst's implantation ability therefore blastocysts are ranked in eight classes (B1–B8) providing an overall score. This system considers the presence of excluded blastomeres and/or fragments.

Participants/materials, setting, methods: Five experienced embryologists took part in this study. Seventy randomly selected images of day-5 embryos of different morphology, from morula to hatching blastocyst, were presented to each embryologist twice for evaluation in the span of one week. Intraclass correlation coefficient (ICC) was used to calculate the intra- and interobserver agreement and was interpreted as perfect (>0.81), substantial (0.61–0.80), moderate (0.41–0.60), fair (0.21–0.40) and slight (<0.20) (Viera and Garrett, 2005).

Main results and the role of chance: The ICC analysis of interobserver variability showed perfect agreement (reliability of average measures) for the whole group of observers in the assessment of the blastocyst expansion ($ICC_{average}$ = 0.958, 95% CI = 0.940–0.972), morphology of the ICM ($ICC_{average}$ = 0.830, 95% CI = 0.758–0.886), TE (ICC = 0.827, 95% CI = 0.754–0.884) and in blastocyst scoring ($ICC_{average}$ = 0.927, 95% CI = 0.895–0.951). Unfortunately embryo scoring is performed by a single embryologist therefore single measures ICC represents more realistic situation. The reliability of single measures ICC was substantial in the assessment of expansion (ICC_{single}=0.820, 95% CI = 0.759–0.873) and in blastocyst scoring (ICC_{single} = 0.718, 95% CI = 0.631–0.796) and only moderate in the assessment of ICM (ICC_{single} = 0.495, 95% CI = 0.386–0.608) and TE (ICC_{single} = 0.489, 95% CI=0.380–0.603).

In the analysis of intraobserver variability the agreement in repeated measurements ($ICC_{average}$) and the reliability of single measurement (ICC_{single}) of each individual was calculated. There was perfect to substantial agreement for the assessment of blastocyst expansion ($ICC_{average}$ varied between 0.960 and 0.942; ICC_{single} varied between 0.891 and 0.923) and substantial to only moderate agreement for the assessment of other blastocyst quality parameters ($ICC_{average}$ varied between 0.960 and 0.942; ICC_{single} varied between 0.789 and 0.440). The lowest reliability and agreement (substantial to moderate) was noted in the assessment of ICM and TE.

Limitations, reasons for caution: Assessment of embryo morphology from images often results in different interpretations. Blastocyst scoring of ICM and TE is very subjective, reliable only in fully expanded blastocysts. Assessment under microscope or with time-lapse provides more information for monitoring of embryonic development which may improve agreement in embryo assessment.

Wider implications of the findings: Morphological assessment is still the most frequently used criteria for selecting embryos for transfer or cryopreservation. In order to optimize IVF/ICSI treatments it is important that embryos are assessed uniformly which implies an internal and external quality control as crucial elements of modern IVF laboratory.

Trial registration number: This is not a clinical trial.

P-583 Pre-treatment with oral contraceptive pill (OCP) in IVF antagonist cycles: may it affect reproductive outcomes? A retrospective study

M.R. Campitiello[1], M. Cattoli[1], C. Pacilio[1], C. Zacà[1], A. Borini[1]
[1]*Tecnobios Procreazione, Tecnobios Procreazione, Bologna, Italy*

Study question: Ovary and implantation outcomes in patients synchronized with OCP for a short or a long period during IVF antagonist cycles compared with patients that didn't receive the drug.

Summary answer: A statistically significant difference has been observed in the different groups in term of ovary outcomes, implantation, pregnancy, biochemical pregnancy and spontaneous abortion rates.

What is known already: Griesinger in his meta-analysis (2010) found ongoing pregnancy rate significantly lower in patients with OCP pre-treatment during IVF Antagonist GnRh protocol. Velasco, in a randomized controlled trial (2011), found no difference in live birth rate among patients with OCP in antagonist IVF cycles or with a long term protocol. In a recent review Velasco et al. (2015) describes with caution that OCP treatment might have a negative effect on outcome in GnRh antagonist IVF Cycles. On the contrary, Orvieto et al. (2014) believes that OCP pre-treatment have a positive role, especially during a stimulation protocol known as ultra-short flare GnRh-agonist/GnRh-antagonist.

Study design, size, duration: In our retrospective multicentric cohort study we analyzed 5885 GnRH antagonist IVF cycles performed in 4718 patients from January 2002 to July 2015. Three groups have been identified: Group A Group B and Group C, respectively of 187,1689,3049 patients. The average both FSH and HMG dosage administered was comparable in all groups (rFSH 2,195.7 ± 1,231.8 UI HMG 3,126.3 ± 1,968.2 UI) Endometrial tickness on day of embryo transfer was between 9.5 and 10.1 mm in all groups.

Participants/materials, setting, methods: All patients included are between 18 and 37 years old and BMI was ≤35 Kg/m2. Poor Responders was estimated in <2%. Group A and Group B were pre-treated with ethynilestradiol 0.03 mg+ gestoden 0.075 mg. Group A for a period ranging from 7 to 12 days immediately followed by the administration of Gonadotropin. Group B for a period ranging from 13 to 40 day, waiting for menses with gonadotropin.

Main results and the role of chance: Chi-square test among the proportions and ANOVA test for the comparisons among the average multiples, have been used. We found a significant difference (p = 0.002) between Group A vs. Group C and Group B and Group C for the number of follicles (p = 0.001), for MII oocytes and fertilized oocytes (p = 0.002). Implantation rate for Groups A, B and C was 15.8%, 16.9% and 20.0%, respectively. The correlation between the group of treatment has come out as significant (chi2 = 16.3569; p = 0.0003). The pregnancy rate found in Groups A, B and C was of 23.5%, 27.4%, 30.3% respectively. The correlation between the group of treatment has come out as significant (chi2 = 7.5761; p = 0.023). The biochemical pregnancy rate in Groups A, B, C was 11.8%, 8.1 and 6.8% respectively. A significant correlation to the group of treatment has been observed (chi2 = 7.8956; p = 0.019). Abortion rate in Group A was 5.4%, in Group B 6.7% and in Group C 6.2%. The differences observed in the abortion rate were not correlated to the group of treatment. Twinning were found with a similar frequency in the three groups (5.4%, 5.5% and 5.3%) with no statistical significant differences among the groups.

Limitations, reasons for caution: Our data shows a worsening of outcomes in patients pre-treated with OCP. We argue that caution must be exercised in drawing conclusions too quickly on whether or not OCP might have a negative effect. Although a large patient's number, it's necessary a prospective randomized trial to confirm our data.

Wider implications of the findings: We found a significant negative effect of OCP pre-treatment (Group A and Group C), disagreeing with Bellver et al. (2007) that doesn't show significative differences whether or not OCP pre-treatment. The real benefits of OCP c have to be clarified, together with the correct protocols (long or short) during IVF cycles.

Trial registration number: not a clinical trial

P-584 Placental anomalies in singleton pregnancies after assisted reproduction technology: a systematic review and meta-analysis

A. Buchanan[1], G. Chambers[2], E. Kolibianakis[3], J. Bosdou[3], C. Venetis[4]
[1]*University of New South Wales, Faculty of Medicine, Sydney, NSW, Australia*
[2]*University of New South Wales, National Perinatal Epidemiology and Statistics Unit, Sydney, NSW, Australia*
[3]*Medical School, Aristotle University of Thessaloniki, 1st Department of Obstetrics and Gynaecology, Thessaloniki, Greece*
[4]*University of New South Wales, School of Women's and Children's Health, Sydney, NSW, Australia*

Study question: Are singleton pregnancies after assisted reproduction technology (ART) associated with a higher risk of placental anomalies as compared to pregnancies after spontaneous conception (SC)?

Summary answer: Singleton pregnancies after ART are at an increased risk of placenta praevia and placental abruption as compared to spontaneously conceived singleton pregnancies.
What is known already: Placental anomalies (placenta praevia, placental abruption, morbidly adherent placenta and cord-insertion anomalies) in singleton pregnancies are not common but are associated with significant maternal and neonatal morbidity and mortality. It has been suggested that pregnancies after ART represent a high risk group where the incidence of these placenta anomalies is increased. Although, various epidemiological studies have been performed evaluating the obstetric outcomes after ART, a systematic review focused on evaluating the risk of placental anomalies in ART singleton pregnancies when compared with spontaneously conceived pregnancies, is currently lacking.
Study design, size, duration: This is a systematic review and meta-analysis of comparative studies. In November 2015, electronic searches were conducted on medical databases (MEDLNE, EMBASE, Cochrane, CENTRAL, Web of Science, Scorpus, ISI) for studies meeting predefined eligibility criteria (from 1978 to present). Data was extracted and methodological quality assessed independently by two reviewers. Studies to be included were appraised for risk of bias and suitability for meta-analysis. Subgroup analysis allowed for the identification of heterogeneity moderators.
Participants/materials, setting, methods: As eligible were considered observational studies examining the occurrence of placental anomalies in singleton pregnancies following ART compared to that of spontaneously conceived singleton pregnancies. Outcomes examined were the incidence of placenta praevia, placental abruption, placenta accreta/increta/percreta, as well as anatomical or cord insertion anomalies. Overall, *30* studies were included in the current meta-analysis, representing a sample of *5*8,6*98* ART pregnancies compared to a cohort of 3,9*2*8,3*01* spontaneously conceived pregnancies.
Main results and the role of chance: The incidence of placenta praevia in singleton pregnancies after ART was significantly increased as compared to pregnancies spontaneously conceived (OR: OR: 3.56, 95% CI: 2.80–4.52; $n = 25$ studies). This finding was confirmed by limiting the analysis to matched studies or studies providing estimates adjusted for various confounders ($n = 20$) confirmed this finding (OR: 2.90, 95% CI: 2.34–3.75).

Placental abruption also appeared to be significantly more frequent in singleton pregnancies after ART as compared to singleton pregnancies after spontaneous conception (OR: 1.91, 95% CI: 1.67–2.19; $n = 16$ studies). This finding was confirmed by limiting the analysis to matched studies or studies providing estimates adjusted for various confounders ($n = 11$) confirmed the original finding (OR: 1.74, 95% CI: 1.48–2.05).

Abnormal cord insertion was evaluated in only three studies, the statistical synthesis of which suggested a significantly increased incidence of cord insertion anomalies in singleton pregnancies after ART as compared to pregnancies after spontaneous conception (OR: 3.07, 95% CI: 1.59–5.95).

A single eligible study suggested the presence of increased risk for placenta accreta in singleton ART pregnancies as compared to the spontaneously conceived ones (OR: 2.67, 95% CI: 1.42–5.02).

No significant difference was detected in terms of abnormal placental shape between ART and SC singleton pregnancies (OR: 1.72, 95% CI: 0.19–15.28)
Limitations, reasons for caution: Limitations relevant to this meta-analysis may arise from terminology discrepancies on behalf of the included studies. Although, adjusted estimates were used, the presence of residual confounding factors cannot be excluded. This meta-analysis was not designed to distinguish between the effect of ART use and that of underlying infertility.
Wider implications of the findings: The widespread use of ART necessitates an appreciation of the maternal health outcome and risk stratification. This meta-analysis offers a comprehensive assessment of the placental-related obstetric risk for appropriate counseling of patients when undergoing ART.
Trial registration number: Not applicable

P-585 The birth weight of term singletons after frozen-thawed embryo transfer (FET) treatments is higher using hormonal substitution than natural cycle

C. Tomás[1], P. Humaidan[2], S. Pelkonen[3], A. Perheentupa[4], S. Nuojua-Huttunen[5], H. Tinkanen[6], H. Martikainen[3]
[1]*Ovumia Oy, Fertility Center, Tampere, Finland*
[2]*Skive Regional Hospital, The Fertility Clinic, Skive, Denmark*
[3]*University of Oulu, Department of Obstetrics and Gynecology, Oulu, Finland*
[4]*University of Turku, Department of Obstetrics and Gynecology, Turku, Finland*
[5]*Family Federation of Finland, Oulu IVF Clinic, Oulu, Finland*
[6]*University of Tampere, Department of Obstetrics and Gynecology, Tampere, Finland*

Study question: Is the protocol for preparation of the endometrium in frozen embryo transfer (FET) treatment related to the birth weight at term?
Summary answer: Singleton term newborns after FET hormonal substitution are independently and significantly heavier than children born after FET natural cycles
What is known already: FET treatments are increasingly important in fertility treatments. Studies suggest a higher live birth rate and heavier newborns after the transfer of frozen as compared to fresh embryos. This might be due to improved laboratorial conditions or less disturbed peri-implantation environment in frozen cycles. FET, in combination with GnRHa-trigger can overcome ovarian hyperstimulation syndrome, high estradiol or high progesterone levels seen in some fresh cycles. The gold standard protocols of FET are the hormonal substitution or the natural cycle protocols. Studies suggest that hormonal substitution may lead to a higher early pregnancy loss rate in comparison to natural cycle.
Study design, size, duration: We have retrospectively collect all frozen embryo transfers from 4 central hospitals and 2 private centers, that resulted in 2428 term singleton newborns, from 1997 to 2015. From those cycles, 1022 (42%) were performed in spontaneous cycle with progesterone support during the luteal phase, and 1406 (58%) in hormonally substituted cycles (E2 + *P*).
Participants/materials, setting, methods: We compared the birth weight of the newborns at term after FET cycles in natural cycles with the newborns after FET in substitution cycles. After uni-factorial analysis, we built up a multivariate logistic regression analysis to identify the factors that independently influenced the weight of the newborns
Main results and the role of chance: During the study period, the percentage of preterm births was similar in fresh (8.3%) and in frozen cycles (7.4%). The delivery of multiples, as well as deliveries of singletons born pre-term or post-term or from mothers with a BMI over 35, were excluded from further analysis.

The mean birth weight of singleton term children conceived after FET treatment using hormonal substitution was significantly higher ($p < 0.0001$) than that of children conceived after natural cycle FET (3675 ± 488 vs. 3563 ± 486 gr, respectively). This effect was noted both in male and female newborns. A multifactorial regression model analysis identified the protocol of treatment ($p < 0.0001$), the gender of the newborn ($p < 0.0001$), the gestational age ($p < 0.0001$) and the method of fertilization ($p < 0.016$) as independent factors for the birth weight. The highest mean birth weight occurred in boys born after FET treatments with hormonal substitution and fertilization with ICSI technique.
Limitations, reasons for caution: The study is retrospective and includes treatments from many IVF centers. However, the sample size is large. Other unknown factors, not identified in the logistic regression model, might influence the birth weight
Wider implications of the findings: The identification of various factors during FET treatment, which may influence the outcome of the newborns are of outmost importance. In this aspect the hormonal substitution protocol might have an important impact on epigenetic factors, peri-implantation, and early placentation, which influence the birth weight of the newborn
Trial registration number: None

P-586 Genome-wide DNA methylation evaluation of cord blood from assisted reproductive technology (ART) neonates

K. Louie[1], E. Chan Wong[1], S. Ma[1]
[1]*Child and Family Research Institute, Obstetrics and Gynaecology, Vancouver, BC, Canada*

Study question: To determine whether sperm injection and/or in-vitro culturing of embryos alters the DNA methylation in the cord blood of neonates.
Summary answer: The DNA methylation in the cord blood of ART neonates appears to be comparable to that of naturally conceived (NC) neonates.

What is known already: ART procedures such as sperm injection into oocytes during intracytoplasmic sperm injection (ICSI) and in-vitro culturing of embryos during in-vitro fertilization (IVF) have been suggested to alter the DNA methylation in the cord blood of neonates. However, previous studies have not included a proper control for the underlying infertility of the ART population. There is yet to be a comparative DNA methylation study including neonates born from intrauterine insemination (IUI), which is a treatment for sub-fertile couples and includes ovulation induction and sperm processing, but not in-vitro conditions.
Study design, size, duration: A control-treatment study including 15 ICSI, 17 IVF, 16 IUI, and 16 NC singleton neonates. Written consent and questionnaires were obtained from the parents prior to birth. Cord blood samples were collected at birth. This study was approved by the UBC research ethics board.
Participants/materials, setting, methods: DNA was extracted from cord blood and bisulfite converted. Samples applied to the Illumina GoldenGate Methylation Cancer Panel I for the evaluation of *1,5*05 CpG sites. Microarray results were analyzed in Illumina BeadStudio (3.1.3.0). Primers were designed to target regions incorporating candidate microarray CpGs using the PyroMark Assay Design 2.0. Pyrosequencing was used to analyze the DNA methylation of these regions using the PyroMark Q96 MD. Statistical analyses were conducted in *R* (3.2.3).
Main results and the role of chance: We previously showed that altered DNA methylation at CpG sites were found (via microarray) in the cord blood of IVF neonates when compared to both IUI and NC, but not ICSI neonates. The RARRES1 promoter was selected for DNA methylation verification via pyrosequencing due to high statistical significance and greatest absolute DNA methylation difference between IVF and IUI (+16.3% in IVF; $P < 0.001$). RARRES1 promoter DNA methylation alterations have been associated with cancer; however, no studies have looked at this promoter with regards to reproduction and development. A total of 6 CpG sites within the promoter, including cg12199224 which was on the microarray, were evaluated for DNA methylation in 5 ICSI, 9 IVF, 6 IUI, and 9 NC neonates. The mean DNA methylation over the region, as well as at individual CpG sites, was not significantly different between groups (ICSI = 5.1% ± 1.4%, IVF = 4.1% ± 1.8%, IUI = 4.0% ± 1.1%, NC = 5.0% ± 2.8%).
Limitations, reasons for caution: The study evaluated a limited number of CpG sites within the promoter region of the RARRES1 gene. In addition, not every case has yet been verified by pyrosequencing. A larger sample size and verification of other candidate CpGs/regions are further needed to confirm the previous microarray results.
Wider implications of the findings: Our preliminary findings suggest that IUI neonatal cord blood may not be significantly different in DNA methylation compared to those from ART. This may suggest that ART procedures such as sperm injection and/or in-vitro culturing may not be significantly altering the DNA methylation in neonates.
Trial registration number: N/A

P-587 DNA methylation and gene expression of imprinted genes is not associated with altered placental-fetal weight ratio in singleton births

S. Schafer[1], R.N. Vincent[1], K. Louie[1], L.D. Gooding[1], E.C. Wong[1], K. Martelli[1], J. Havelock[1], S. Ma[1]
[1]*University of British Columbia, Obstetrics and Gynecology, Vancouver, BC, Canada*

Study question: To determine whether pregnancies with higher placental-fetal weight ratio (PW:FW) have altered DNA methylation and/or gene expression at imprinted genes.
Summary answer: There were no differences in DNA methylation and gene expression in the cord blood or placental tissue between high PW:FW ratio and normal ratio pregnancies.
What is known already: Assisted reproductive technology (ART) pregnancies have been previously associated with altered DNA methylation and gene expression at imprinted genes. Furthermore, ART pregnancies have a higher incidence of high PW:FW ratio as compared to naturally conceived (NC) pregnancies. However, whether the subset of pregnancies with high PW:FW ratio have altered DNA methylation and gene expression at imprinted genes is not well studied.
Study design, size, duration: A control-treatment study using data collected between 2003 and 2015 on 375 singleton births (67 ICSI, 11 IUI, 63 IVF, 234 NC) from Vancouver. Births from pregnancies complicated by smoking, medications during pregnancy, gestational diabetes, hypertension, pre-eclampsia, placental previa, preterm, and intrauterine growth restriction were not included.
Participants/materials, setting, methods: Placenta and cord blood was obtained at birth from pregnancies who gave written consent. The PW:FW ratio were calculated from the placental weight over the birth weight. Cord blood and placental tissue were extracted for DNA and RNA. DNA methylation was evaluated by pyrosequencing at the imprinted genes KvDMR1, PEG10, PLAGL1, and LINE-1. Gene expression was studied by RT-qPCR at the imprinted genes CDKN1C, IGF2, KCNQ10T1, and PLAGL1.
Main results and the role of chance: We found a significantly increased PW:FW in IVF vs. NC ($p < 0.0001$) as well as ICSI vs. NC ($p < 0.005$). We also found a significantly increased placental weight in IVF vs. NC ($p < 0.0001$) and ICSI vs. NC ($p = 0.018$). We saw no significant difference in fetal weight in IVF vs. NC ($p = 0.700$) and ICSI vs. NC ($p = 0.872$). All these differences remained significant or very nearly significant regardless of the exclusion of preterm, IUGR, or SGA births. Among births that were at least two standard deviations greater than the mean PW:FW of NC births ($n = 19$), we found no significant differences in the expression of CDKN1C, IGF2, KCNQ10T1, and PLAGL1 mRNA compared to all other births. Similarly, DNA methylation in KVDMR1, LINE-1, PEG10, PLAGL1 was not found to be significantly different between groups.
Limitations, reasons for caution: The number of cases with higher PW:FW ratio was limited. Not all cases had complete clinical information for potential confounding factors. Furthermore, not all cases were included in the DNA methylation and gene expression analyses.
Wider implications of the findings: The altered DNA methylation and gene expression seen among ART births in previous studies may not be entirely responsible for the increased PW:FW. Alternatively, altered DNA methylation and gene expression among ART cohorts in previous studies may not be significantly influenced to the small subset of high PW:FW ratio pregnancies.
Trial registration number: N/A

POSTER VIEWING SESSION

REPRODUCTIVE (EPI)GENETICS

P-588 Genetic polymorphism in the vitamin D receptor gene and 25-hydroxyvitamin D serum levels in east Indian women with polycystic ovary syndrome

D. Sur[1]
[1]*MAGS Medical and Research Center, Obstetrics and Gynecology, Kolkata, India*

Study question: Whether the VDR gene polymorphisms are associated with susceptibility to PCOS.
Summary answer: The present findings suggest that the Apa-I, Fok-I polymorphism of the VDR gene is associated with PCOS and seems to modulate ovarian steroid secretion.
What is known already: Polycystic ovary syndrome (PCOS) is the most common metabolic abnormality such as changes in lipid profile, diabetes, hypertension and metabolic syndrome occurring in young women of reproductive age. Low vitamin D levels were found to be associated with the development of obesity and insulin resistance in women with PCOS. Variants on vitamin D receptor (VDR) gene have also been related to metabolic comorbidities in general population.
Study design, size, duration: A case-control study was done.125 women with PCOS were enrolled, along with 82 women without any evidence of PCOS as a control group; the women of both groups were aged 16–40 years.

Participants/materials, setting, methods: Women with PCOS and a control group, all aged 16–40 years, were enrolled. Genotyping of VDRFok-I (rs2228570), VDR Apa-I (rs7975232) as well as GC (rs2282679), DHCR7 (rs12785878) SNPs between groups were determined by using direct sequencing. Serum 25-hydroxyvitamin D [25(OH)] levels were measured by ELISA.
Main results and the role of chance: Mean serum 25(OH)D in the PCOS and control samples were 19.08 ± 7 and 23.27 ± 6.03 ($p = 0.048$) which were significantly lower in PCOS patients compared with controls. CC genotype of the VDR Apa-I SNP was same frequent in PCOS (25.6%) and controls (25.6%) (OR: 0.9995; 95% CI: 0.528 to 1.8921; $p = 0.9987$). The CC genotype was also significantly associated with lower E2 ($p = 0.031$) and androstenedione levels ($p = 0.026$). We observed a significant association of GC polymorphism with 25(OH)D levels. PCOS women carrying the GG genotype (in GC genes) had significantly higher risk for vitamin D deficiency than women carrying the TT genotype.
Limitations, reasons for caution: A limitation of the study is the small sample size; therefore, we have to be careful in making this conclusion.
Wider implications of the findings: Polymorphisms of the VDR gene might be associated with PCOS and biochemical markers related to PCOS.
Trial registration number: ECR/130;67/Inst/WB/2013

P-589 Comparison clinical outcome of next generation sequencing (NGS), aCGH and FISH on pre implantation genetic screening in frozen thaw embryo transfer cycle

S. Chanchamroen[1], K. Sawakwongpra[1], W. Suksaluk[1], S. Martkamchan[1], C. Jiramongkolrat[1], T. Ruttanajit[1], W. Quangkananurug[1]
[1]*Safe Fertility Center, Laboratory, Bangkok, Thailand*

Study question: To determine the efficiency of NGS for pre implantation genetic screening in FET cycle compare with aCGH and FISH from both younger and older patients.
Summary answer: Data show NGS results in high pregnancy rates. NGS and aCGH could be beneficial as the euploid selection and allowing single embryo-transfer without decreasing outcome.
What is known already: A variety of methodologies for 24 chromosome analysis have been develop and available for clinical use. Currently used PGS methods of aneuploidy screening such as aCGH have been reported to improve pregnancy rates. The recent advances in NGS have provided new methods for screening embryos. It has shown promise of improved clinical outcome. However, there is still limited information of NGS in clinical setting.
Study design, size, duration: This is retrospective study. 718 patients were enrolled in this study during the period of January to July 2015 and divided into two groups according to female age. One is younger group (<38 years) ($n = 607$: NGS = 299, aCGH = 152, FISH = 42, no PGS = 114) and second is older group (≥38 years) ($n = 111$: NGS = 34, aCGH = 42, FISH = 12, no PGS = 23). Euploid blastocysts were transferred based on the PGS results in FET cycle.
Participants/materials, setting, methods: A total of 4,790 blastocysts were biopsied and then performed FISH, aCGH and NGS according to their studied groups. The method involed whole genome amplification followed by NGS veriseq kit or 24 sure array-CGH kit. Copy number variation analysis was accomplished with BlueFuse Multi software. FISH method including of cell spread on slide, fixed, hybridization and washed according to instruction of multivision PGT for chromosome 13, 18, 21, X and Y probe (Vysis).
Main results and the role of chance: NGS can detect all type of chromosome abnormality including of single (24%), dual (11%), and complex (8%). Interestingly, the percentage of embryos which called mosaicism by NGS is significantly higher than aCGH (NGS = 3.68% vs. aCGH = 1.2%, $p < 0.001$). The euploid rate from older were lower than from younger female (NGS = 26.1 vs. 54.5%, aCGH = 35.3 vs. 59.3% and FISH = 41.4 vs. 52.8%, $p < 0.01$).

Clinical pregnancy rate from NGS is comparable with aCGH but higher than FISH and no PGS in both younger and older female (<38 years old group: NGS = 61.8%, aCGH = 57.1%, FISH = 52.4%, no PGS = 48.2% and ≥38 years old group: NGS = 60.5%, aCGH = 56.6%, FISH = 16.7%, no PGS = 10%). The average number of embryo per transfer from NGS and aCGH groups were significant decrease when compare with FISH and no PGS group in both younger and older female (younger group: NGS = 1.4, aCGH = 1.4, FISH = 1.6, no PGS = 2.1, $p < 0.0001$ and older group: NGS = 1.2, aCGH = 1.2, FISH = 1.8, no PGS = 2.0, $p < 0.0001$).

Additionally, eighty-eight cleavage biopsied embryos which resulted abnormal by FISH were re biopsied on blastocyst stage then performed aCGH or NGS. The percentages of euploid blastocyst after re biopsy are similar for both aCGH and NGS (43.24% vs. 43.14%).
Limitations, reasons for caution: This study show high pregnancy outcomes following transfer euploid blastocyst in frozen thaw cycles. Clinical effectiveness after transfer in fresh cycle should be further study.
Wider implications of the findings: This study report an application of NGS-based comprehensive aneuploidy screening on blastocyst stage in a clinical setting versus aCGH and FISH 5 probe. NGS methodology is representing a valuable alternative to the other comprehensive aneuploidy screening techniques currently available.
Trial registration number: -

P-590 Characterization of promoter of human SET gene

S. XU[1], J. LIU[2]
[1]*Mercer University, Mercer University School of Medicine, Savannah, GA, USA*
[2]*Nanjing Medical University, Obstetrics and Gynecology, Nanjing, China*

Study question: What is the promoter sequence and proximal minimal promoter region of SET? Which transcription factors (TFs) may regulate SET expression?
Summary answer: SET core promoter was located within the region −157/+47 relative to the transcription start site. TFs like ZFX, E2F and NRF-1 may regulate its activity.
What is known already: SET is a multifunctional protein involved in histone binding, nucleosome assembly, transcription control and cell apoptosis. Our previous studies showed SET was one of the over-expressed genes in ovaries of patients suffering from polycystic ovary syndrome (PCOS) when compared to normal ovaries using cDNA microarray technology. We also found that in theca cell, SET played a positive role in regulating ovarian androgen biosynthesis by enhancing the transcription of steroidogenic enzymes 3beta-hydroxysteroid dehydrogenase 2 (HSD3B2) and cytochrome P450 17 alpha hydroxylase/lyase (P450c17) and increase lyase activity of P450c17, which maybe lead to the hyperandrogenism in PCOS.
Study design, size, duration: We isolated a genomic clone of the human SET gene promoter containing 998 nucleotides of the 5' flanking region. The sequence was analyzed by blast and UCSC, and then cloned into pGL3-Basic vector to construct SET promoter reporters. Using a series of 5' deletion promoter plasmids in luciferase reporter assays, we identified the core region which is sufficient for full promoter activity. Applying Biology Information Technology, we can then predict the candidate TFs for SET.
Participants/materials, setting, methods: A nearly 1.2 kb 5'-flanking region of SET gene was amplified by polymerase chain reaction and digested with NheI and XhoI, then subcloned into promoter-less luciferase expression plasmid pGL3-Basic. So did the deletion clones. DNA sequence analysis confirmed these sequences. Firefly and Renilla luciferase activities were measured with the Dual-Luciferase Reporter Assay System after the transiently transfection of the reporter plasmids with various lengths. Jarspar and genomatix programs were used to predict TFs of SET.
Main results and the role of chance: HeLa cells and HEK293 cells have similar profiles of luciferase expression upon transfection. The promoter region extending from −996 to +137 showed activity and progressive deletion experiments showed region −157 to +137 having the strongest promoter activity. Moreover, the activity of +47/+137 construct was as low as the empty control plasmid, indicating that the essential regulatory element(s) necessary to sustain the basal transcriptional activity is located within sequences between −157 and +47. This region lacks typical TATA box but contains CCAAT box and a highly GC-rich content. Analyzing the region with the Jaspar and Genomatix websites, we found several DNA-binding sites have high scores in both programs, including E2F1, E2F3, E2F4, ZFX, SP1, and NRF-1 site. They are the candidate TFs which can regulate SET transcription expression. SET is a newly uncovered gene associated with hyperandrogenism in PCOS. Understanding the transcriptional regulation of SET may contribute to therapeutic strategies aimed at altering high androgen level in patients with PCOS and help them to resume normal ovulation.
Limitations, reasons for caution: As a gene associated with androgen synthesis, SET is prominently expressed in ovarian theca cells and oocyte. It's reasonable to conduct experiments in these cells. However, the cell lines of these cells

are unavailable. In the further study, we will culture theca cells to clarify the transcription regulation of SET.
Wider implications of the findings: SET is overexpressed in aggressive cells from malignant neoplasm, and contributes to cell survival. In gynecologic area, SET accumulates in ovarian cancer and breast cancer. Illustration the transcription regulation of SET may lead to the development of novel drugs with improved anti-cancer activity without immune suppression and other toxic effects.
Trial registration number: none

P-591 Karyomapping: a retrospective case series of clinical application of karyomapping for couples requiring preimplantation genetic diagnosis for single gene disorders and/or chromosomal rearrangements

J. Ben Nagi[1], K. Doye[2], D. Wells[3], H. Exeter[4], E. Drew[4], P. Serhal[1]
[1]*Centre for Reproductive and Genetic Health, Reproductive Medicine, London, UK*
[2]*Centre for Reproductive and Genetic Health, Genetic, London, UK*
[3]*Institute of Reproductive Sciences, Reproductive Sciences, London, UK*
[4]*Centre for Reproductive and Genetic Health, Embryology, London, UK*

Study question: Can karyomapping be applied in a clinical setting to couples requiring preimplantation genetic diagnosis (PGD) for single gene disorders and/or chromosomal rearrangements?.
Summary answer: Clinical application of karyomapping offers an efficient and robust method for PGD for single gene disorders and chromosomal rearrangements, with several advantages over conventional methods.
What is known already: PGD is an early form of prenatal diagnosis. Although generally successful, traditional PGD strategies based upon the polymerase chain reaction (PCR) are associated with several technical and logistical limitations. These include allele dropout, which impacts diagnostic accuracy, long work-up times required in order to tailor tests to individual patients, and failure to detect lethal aneuploidies. In contrast, karyomapping represents a more generic approach. The method utilises microarray technology to determine the genotype of >300,000 single nucleotide polymorphisms (SNP). The genetic status of individual embryos can be determined by analysis of linked SNP alleles inherited along with the mutant gene.
Study design, size, duration: This is a retrospective case series of PGD cycles from May 2014 to December 2015. Karyomapping was considered feasible if the DNA from a relative of known genetic status or from an affected foetus was available. Karyomapping was applicable in 90 couples during this period of time. 76/90 (84%) couples had PGD by karyomapping. The remaining 14 couples (16%) are awaiting treatment at the time of writing.
Participants/materials, setting, methods: Couples self-referred or were referred from regional genetic centres. Couples were counselled and standard IVF protocols were applied. Initially, couples had day-three embryo biopsy and transfer of a suitable blastocyst. This strategy was changed in May 2014 to blastocyst biopsy, vitrification and subsequent frozen embryo replacement. The karyomapping was carried out by Reprogenetics, UK, essentially as described by Natesan et al. (2014). Patients were advised to do urinary pregnancy test 16 days after embryo transfer.
Main results and the role of chance: 85/90 (95%) and 3/90 (3%) couples were referred for autosomal single gene disorder and X-linked disease, respectively. The remaining 2/90 (2%) were referred for chromosomal rearrangements. Additional, PCR or array comparative genomic hybridization (a-CGH) was carried out in order to increase diagnostic accuracy in 5/90 (6%) and 1/90 cases, respectively. A total of 84 transvaginal oocyte retrievals and 85 cycles of embryo biopsies were performed. One couple had blastocysts transferred from an IVF centre elsewhere. Day-3 embryo and blastocyst biopsies were carried out in 16/85 (19%, 95% CI 12–28) and 69/85 (81%, 95% CI 72–88) cycles, respectively. A total of 72 embryo transfers were performed. 60/72 (83%, 95% CI 73–90%) and 12/72 (17%, 95% CI 10–27) were frozen and fresh embryo transfers, respectively. From 63 embryo transfers with a known pregnancy outcome, 42/63 (67%, 95% CI 54–77) had a positive pregnancy test. The ongoing pregnancy rate is 37/63 (59%, 95% CI 46–70). 2/63 (3%, 95% CI 1–11) embryo transfers were biochemical pregnancies and 3/63 (5%, 95% CI 2–13) embryo transfers have resulted in early first trimester miscarriages. 21/63 (33%%, 95% CI 23–46) had a negative pregnancy test. In 9/72 (13%, 95% CI 7–22) embryo transfers, the outcome is pending.
Limitations, reasons for caution: This is the largest karyomapping dataset so far reported, but results are retrospective and non-randomized.
Wider implications of the findings: Karyomapping is reliable, accurate and efficient for couples requiring PGD for single gene disorders and/or chromosomal rearrangements. Its utilisation of a generic protocol dramatically accelerates test work-up compared to conventional PCR, helping to expedite the start of treatment. Additionally, it provides aneuploidy screening, minimising risks of miscarriage and implantation failure.
Trial registration number: N/A

P-592 Is the number of previous embryo transfer cancellations a predictor of next cycle outcome in preimplantation genetic screening (PGS) cycles?

F. Bronet Campos[1], C. Rubio[2], G. Pirastu[3], E. Martinez[4], A. Mercader[5], L. Rodrigo[2], M. Florensa[6], J.A. Garcia-Velasco[7]
[1]*IVI Madrid, IVF/PGD, Madrid, Spain*
[2]*Igenomix, Genetics, Valencia, Spain*
[3]*IVI Madrid, IVF, Madrid, Spain*
[4]*IVI Madrid, PGD, Madrid, Spain*
[5]*IVI Valencia, PGD, Valencia, Spain*
[6]*IVI Barcelona, IVF, Madrid, Spain*
[7]*IVI Madrid, Medical, Madrid, Spain*

Study question: Is the number of previous PGS cycles without euploid embryo correlated with the likelihood to find at least one euploid embryo in the next PGS?
Summary answer: There is an increase in the chances of having an embryo transfer in a second cycle if in the first there was an euploid embryo
What is known already: PGS has been used in an *In Vitro* Fertilization (IVF) to improve the implantation rate and to reduce the miscarriage rate for a long time. Recently the technology has allowed us to analyze the whole chromosome complement. There are many patients that repeat cycles without a limit. However, little is known about the effect of the previous cancellations of embryo transfers. We should ask ourselves when we should stop
Study design, size, duration: An observational, retrospective, multicenter study of the patients included in the cycles of PGS dated from January 2011 to June 2015 in IVI clinics. A total of 820 patients were included in this study, age ranging from 27 to 48 years. The inclusion criteria were: recurrent miscarriage (≥2 previous abortions), implantation failure (≥3 previous IVF failures), Advanced Maternal Age (≥38 years), male factor ($<5 \times 10^6$/ml)
Participants/materials, setting, methods: All patients underwent PGS and analysis was performed using Array-CGH. All the patients have performed more than one PGS cycle. Patients were divided in different groups taking into account if they had transfer or not in the previous cycles. In order to determine whether the lack of euploid embryo relates to the rate of embryo transfer in the next cycle, cycles with euploid embryos but without embryo transfer, because the embryos were arrested, were excluded
Main results and the role of chance: The likelihood of having embryo transfer in each cycle if the patient had not it in the previous one was: 2nd cycle: 37% (n = 663); 3rd cycle: 55% (n = 134); 4th cycle: 0% (n = 23). The embryo transfer rate in the first cycle was 48.1% We found significant differences in the second PGS cycle if the patient had an embryo transfer in the first one ($p < 0.0001$). On the contrary, we could not find any statistical difference in the third and fourth cycles according to previous cancellations
Limitations, reasons for caution: In this study all type of patients have been included in the analysis. It would be interesting to have a bigger size sample to separate them in different groups according to the maternal age
Wider implications of the findings: There is an increase in the likelihood of having an embryo transfer in a second PGS cycle if in the previous one there were euploid embryos. The chances to have an embryo transfer for patients with more than two previous cycles are not correlated with the number of previous cancellations
Trial registration number: none

P-593 Blastocystic mosaicism: correlation analysis of chromosomal composition in different trophectoderm biopsies and inner-cell mass identifying by next-generation sequencing (NGS)

T.H. Chuang[1], L. Meng-Ju[1], S.U. Chen[2], H.H. Lai[1]
[1]*Stork Ladies Clinic, Stork Fertility Center, Hsinchu, Taiwan*

[2]National Taiwan University Hospital and College of Medicine, Obstetrics and Gynecology, Taipei, Taiwan

Study question: Are euploid cells preferentially allocated near to inner-cell mass (ICM) or randomly distributed throughout the whole blastocyst? This could lead misdiagnosis in the accurate genetic screening of trophectoderm (TE) biopsy at a particular site.
Summary answer: The euploid/aneuploid cells were randomly distributed throughout the whole blastocyst, and thus the inconsistency rate between different TE biopsies to ICM were quantitatively equal.
What is known already: Trophectoderm biopsy is considered less harmful to the developing embryos, and removal of multicellular samples allows low-rate aneuploidy (a mixture of diploid and aneuploid cells between 20% to 50%) to be detected by using next-generation sequencing (NGS). However, the possibility of inconsistent ploidies between TE and ICM due to confined mosaicism (aneuploid cell lines only in a particular site) remains unclear.
Study design, size, duration: During January to December in 2015, biopsies at the six o'clock position to ICM (TE1), at the three o'clock position to ICM (TE2), and at the ICM in 33 donated blastocysts obtained from 13 randomly selected patients were analyzed on NGS platform prospectively. The inconsistency of three different biopsies in the recruited blastocysts were calculated.
Participants/materials, setting, methods: The mean age of included patients was 34.2 years, and 29 frozen-thawed blastocysts were completely diagnosed by NGS at the three different biopsy positions. The aneuploid percentage of each sample was analyzed by NGS at the finest resolution after comparing with the well-validated array comparative hybridization system: euploid (aneuploid percentage <20%), low-rate aneuploid (aneuploid percentage between 20% to 50%), aneuploid (aneuploid percentage >50%).
Main results and the role of chance: Neither ICM nor TE fractions displayed higher euploid ratio (TE1: 32.3%; TE2: 30.3%; ICM: 29.0%). Of the overall consistency in ploidies, no significant advantage was observed between any TE fractions to ICM (TE1 to ICM: 89.7% *vs.* TE2 to ICM: 90.3%); but of the aneuploid variation type, slightly increase of consistency was observed between TE2 to ICM (TE1 to ICM: 50.0% *vs.* TE2 to ICM: 60.0%). A total of 25 embryos was uniformly euploid or aneuploid in the all three biopsies (86.2%, 8 euploids and 17 aneuploids), and the mosaic blasotycts included: 1 low-rate aneuploid in the TE fractions and euploid in the ICM (3.4%); 1 euploid in the TE fractions and low-rate aneuploid in the ICM (3.4%); 1 euploid in the TE2 and low-rate aneuploid in both the TE1 and ICM (3.4%); 1 low-rate aneuploid in the TE1 and aneuploid in both the TE2 and ICM (3.4%). Therefore, the inconsistency rates of TE1 or TE2 to ICM caused by confined mosaicism were equally 10.3% (3/29).
Limitations, reasons for caution: Number of studied blastocysts can be increased.
Wider implications of the findings: The inconsistency rate of different TE biopsies to ICM identified by NGS system was obtained in this preliminary study, and it verified the randomly distribution of euploid cells in a blastocyst. The data provided the implication for further investigations of the aneuploidy and mosaicism mechanism in human embryo development.
Trial registration number: 201512096RIN, by the ethic committee of National Taiwan University Hospital

P-594 Application of next-generation sequencing technology for comprehensive aneuploidy screening of blastocysts in ART

N. Alexandrova[1], A. Ekimov[2], E. Shubina[2], T. Kodyleva[2], N. Makarova[3], L. Levkov[1], D. Korostin[4], D. Trofimov[4], E. Kulakova[1], S. Gennady[5]
[1]Research Centre for Obstetrics, Gynecology and Perinatology, Reproduction, Moscow, Russia
[2]Research Centre for Obstetrics, Gynecology and Perinatology, Molecular and Genetic Diagnostics, Moscow, Russia
[3]Research Centre for Obstetrics, Gynecology and Perinatology, IVF, Moscow, Russia
[4]Research Centre for Obstetrics, Gynecology and Perinatology, Molecular and Genetics Diagnostics, Moscow, Russia
[5]Research Centre for Obstetrics, Gynecology and Perinatology, Moscow, Russia

Study question: Can next-generation sequencing (NGS) techniques be used reliable tool for aneuploidy screening in patients undergoing IVF treatments?
Summary answer: Application of NGS in clinical preimplantation genetic screening (PGS) cycles demonstrates that this methodology is reliable to help to transfer of euploid embryos
What is known already: neuploidy is a leading cause of failure of assisted reproductive technologies programs (ART). Embryo selection with preimplantation genetic screening (PGS) improves efficiency of ART programs, increases frequency of implantation and decreases frequency of miscarriages. Currently, microarray comparative genomic hybridization (aCGH) is a commonly used method for the preimplantation screening. However, use of next-generation sequencing (NGS) is considered to be an alternative for PGS.
Study design, size, duration: Study: cross-sectional parallel evaluation, with both NGSand array-CGH techniques, of 38 blastocysts obtained from clinical PGS cycles.
Participants/materials, setting, methods: 38 patients undergoing PGS were enrolled in the study. All embryos were cultured to blastocyst stage; trophectoderm biopsy was performed on Day 5 of developmentor. The samples were analyzed using both comparative genomic hybridization and semiconductor high-throughput sequencing (Ion torrent). Whole genome amplification was carried out by PCR-based method for 28 samples and by MDA for 10 samples.
Main results and the role of chance: Comparative genomic hybridization showed that 25 samples (65.7%) had a normal karyotype, 13 samples (34.3%) had aneuploidies. In 37 samples, results of NGS were identical with aCGH, in one case the aCGH result was interpreted as 47, XXY while the NGS result was interpreted as 46, XY. This findings are due to the more strict criteria of data interpretation by aCGH in comparison with NGS. We need to elaborate the method of analysis of results of aCGH and NGS.
Limitations, reasons for caution: Further data and broad-based clinical application are required to better define the role of NGS in PGS.
Wider implications of the findings: NGS methodology may represent a valuable alternative to the other comprehensive aneuploidy screening techniques currently available. Although comparable results were obtained with both amplification methods, MDA amplification gives less noisy data. Further work is required to choose the most appropriate platform for PGS.
Trial registration number: ǰD-6043.2015.7

P-595 Accurately diagnose reciprocal translocation carrier in preimplantation human embryos by "MicroSeq" technology

L. Hu[1,2,3], D.H. Cheng[1,4], K.L. Luo[1,5], G. Fei[1,5], Y.Q. Tan[1,4], W.B. He[1,4], P.Y. Xie[3], K. Yang[6], T. Feng[6], G.X. Lu[1,3,5], G. Lin[1,3,5]

[5]Reproductive and Genetic Hospital of Citic-Xiangya, Assisted Reproductive Center, Changsha, China
[6]Peking Jabrehoo Med Tech., Bioinformatics, Beijing, China

Study question: Can balanced reciprocal translocation embryos be accurately diagnosed in preimplantation genetic diagnosis (PGD)?
Summary answer: Chromosome microdissection followed by next generation sequencing can accurately identify the breakpoint and help to distinguish normal and balanced translocation embryos in PGD cycle.
What is known already: Reciprocal translocations carriers usually suffer from spontaneous abortion due to abnormal meiosis during gametogenesis. Fluorescence *in situ* hybridization (FISH)-PGD and comprehensive chromosome screening have been used to identify unbalanced embryos and prevent recurrent spontaneous abortion. However, there is no clinical applicable technique to diagnose embryos with balanced reciprocal translocations and to enable patients to choose real normal embryos preferentially transferred. Several techniques such as array based comparative genomic hybridization, next generation sequencing had been applied to characterize the breakpoints of reciprocal translocations. However, to our knowledge no clinical trials have been performed to diagnose balanced reciprocal translocation embryos in PGD.

Study design, size, duration: This clinical diagnostic study included totally 8 couples with balanced reciprocal translocation in CITIC-XIANGYA from July 1, 2014 to December 31, 2015. Breakpoints and surrounding SNP haplotypes were characterized before oocyte retrieval. Results of balanced reciprocal translocation embryos were compared to prenatal diagnosis results to determine the accuracy.

Participants/materials, setting, methods: Eight patients with balanced translocation participated in the study after signing informed consent. We combined chromosome microdissection and NGS (MicroSeq) to identify the translocation breakpoints and their surrounding SNP haplotype. With the information of the breakpoint and SNP haplotype, specific primers were designed and used for analyzing DNA amplified samples of 37 blastocysts from the 8 couples. The PCR results were then compared with the PGD-CCS and prenatal diagnosis results of the analyzed blastocysts.

Main results and the role of chance: We characterized balanced translocated chromosomes in 8 patients by MicroSeq. The precise breakpoint could not be characterized in only one patient because the breakpoint is located in 22q11.21, which harbored a complicated palindrome structure. However, haplotype surrounding the breakpoints in 8 patients were successfully characterized. Interestingly, translocations in 6/7 patients with fully characterized balanced translocations cause gene disruption. We then analyzed 37 blastomeres by both PGD-CCS and breakpoint-specific PCR with the breakpoint and haplotype information. Among them, 26 blastomeres were characterized aneuploidy by PGD-CCS. As predicted by PGD-CCS, 2/26 embryos should have two translocated chromosomes, 23/26 embryos should have one translocated chromosome, and 1/26 should not have any translocated chromosome. Our breakpoint analysis result was consistent with PGD-CCS prediction. Furthermore, we characterized the 11/37 "normal" embryos diagnosed by breakpoint-specific PCR. 9/11 embryos had two breakpoints, which implicated they were embryos with balanced translocations (balanced embryos). No breakpoint could be detected in another 2 embryos, implicated that they were real normal embryos. 4/9 balanced embryos and 2/2 normal embryos were transferred. 4 patients got pregnant. By prenatal diagnosis, 3 babies were confirmed balanced translocation carriers and one was normal without balanced translocation, which consisted with our breakpoint analysis.

Limitations, reasons for caution: One limitation of the study is failure to confirm the PGD results in some embryos due to implantation failure and ethical reasons. MicroSeq could not accurately find the breakpoints in regions which harbored complicated palindrome structures. However, SNP haplotype around the breakpoint region help to diagnose balanced translocation embryos.

Wider implications of the findings: This study showed that the genetic influence of balanced translocations might be underestimated since a significant portion (85.7%) of chromosome translocations caused gene disruption in this study. Characterizing surrounding SNP haplotypes of the breakpoints by MicroSeq could help to diagnose embryos with Robosonian's balanced translocation in the future.

Trial registration number: NA.

P-596 Reduced mRNA levels and isoforms of the FMR1 gene in infertile women with low CGGnn <26 repeats

Q. Wang[1], V. Kushnir[1,2], S. Darmon[1], D. Barad[1,3], Y.G. Wu[1], L. Zhang[1], D. Albertini[1,4], N. Gleicher[1,5]

[1]Center for Human Reproduction, New York, NY, USA
[2]Wake Forest School of Medicine, Obstetrics and Gynecology, Winston-Salem, NC, USA
[3]Albert Einstein College of Medicine, Obstyetrics and Gynecology, Bronx, NY, USA
[4]University of Kansas Medical Center, Molecular and Integrative Physiology, Kansas City, KS, USA
[5]Rockefeller University, Laboratory of Stem Cell Biology and Molecular Embryology, New York, NY, USA

Study question: Do FMR1 mRNA levels and isoforms differ in infertile women between *low FMR1* $CGG_{n<26}$ and *non-low* $CGG_{n\geq26}$ repeats?

Summary answer: Containing a mixture of isoforms, *FMR1* message RNA levels, are significantly reduced in women with *low FMR1* $_{n<26}$ compared to those with *non-low FMR1*$_{n\geq26}$ repeats.

What is known already: The fragile X mental retardation 1 (*FMR1*) gene exists in various mutations, defined by CGG_n, which have been reported to be associated with distinct ovarian aging patterns and varying IVF outcomes. Most profoundly associated with early ovarian aging and negative reproductive outcomes appears to be the *low* $CGG_{n<26}$ mutation. Moreover, distinct alternative splicing and various FMR1 mRNAs/proteins of the gene have been reported.

Study design, size, duration: We prospectively studied luteinized granulosa cells obtained in IVF cycles during 2014/2015, and investigated whether amounts of *FMR1* mRNA and its isoforms differ in presence of different *FMR1* mutations. Mural granulosa cells were collected on day of retrieval.

Participants/materials, setting, methods: 62 IVF patients were studied. CGG_n is at our center routinely determined at initial presentation, utilizing a commercial assay. Definition as *low* mutation ($n = 25$) required at least one $CGG_{n<26}$ allele, while a *non-low* patient ($n = 37$) was defined by both alleles being $CGG_{n\geq26}$. Message RNAs were extracted and reverse transcribed to cDNA. Various FMR1 isoforms were examined by quantitative PCR using 5 sets of primers targeting middle and C-terminal regions of FMRP protein sequences.

Main results and the role of chance: All here examined 5 groups of FMR1 isoforms were found significantly differently expressed in mural granulosa cells of *low* and *non-low* groups, with all isoforms in the *low FMR1* group found significantly reduced ($P = 0.011$, $= 0.045$, $= 0.003$, $= 0.009$, $= 0.005$, respectively).

Limitations, reasons for caution: The sample size of this still ongoing study was too small to assess individual mutations within the *non-low* study group, such as *normal* (both alleles within $CGG_{n = 26–34}$) and homozygous high/high (both alleles at $CGG_{n>34}$).

Wider implications of the findings: Gene expression has been reported at all follicle maturation stages in rat. Difference in mRNA levels and isoform distribution of the *FMR1* gene may regulate the translation and cellular localization within follicles of FMRP, leading to dysfunction of FMRP proteins, affecting ovarian aging and outcomes differently with different *FMR1* mutations.

Trial registration number: N/A

P-597 Preimplantation genetic diagnosis (PGD) for translocation carriers using whole genome screening by microarray analysis at the blastocyst stage

C. Christodoulou[1], A. Dheedene[2], I. De Croo[1], B. Heindryckx[1], L. Deleye[3], F. Van Nieuwerburgh[3], D. Deforce[3], P. De Sutter[1], B. Menten[2], E. Van den Abbeel[1]

[1]Universitair Ziekenhuis Gent, Centre for Reproductive Medicine, Gent, Belgium
[2]Universitair Ziekenhuis Gent, Center for Medical Genetics, Gent, Belgium
[3]Gent University, Laboratory of Pharmaceutical Biotechnology, Gent, Belgium

Study question: What is the value of whole genome screening by array comparative genomic hybridization (CGH) for PGD in embryos of translocation carriers?

Summary answer: Array CGH for PGD of translocation carriers is a beneficial clinical application to identify viable euploid embryos for transfer.

What is known already: Translocation carriers usually have a normal phenotype, but through the generation of unbalanced gametes from impaired chromosome segregation they have an increased risk of having fertility problems, recurrent miscarriages or an abnormal chromosomal offspring. Recent embryological and genetic technical advances in the field of PGD have improved the means of selecting a balanced or unaffected embryo, suggesting a benefit to the pregnancy rates for couples with chromosome aberrations.

Study design, size, duration: This is a retrospective data analysis study contacted from October 2013 to December 2015. A total of 224 blastocysts originating from 50 PGD oocyte retrieval cycles were investigated. These cycles involved 34 couples with a mean maternal age of 32.5 years with one of both parents being a carrier of Robertsonian translocations ($n = 9$), of reciprocal translocations ($n = 21$), of inversions ($n = 2$), of an insertional translocation ($n = 1$) and of a double two-way exchange reciprocal translocation ($n = 1$).

Participants/materials, setting, methods: Trophectoderm biopsy and vitrification of embryos was performed on the 5th or 6th day of development. Whole genome amplification (WGA) was performed on all samples, and the amplified DNA from 207 blastocysts was analyzed with array CGH via the 24sure+microarrays (Bluegnome, Illumina). Embryos with normal chromosome content were warmed and transferred to the patients in natural, non-stimulated cycles.

Main results and the role of chance: We detected chromosome abnormalities in 133/207 embryos (64.2% of successfully amplified) while 74 showed

a normal microarray profile (35.7%). In 48 of the 133 abnormal embryos (36.1%), an unbalanced rearrangement originating from the parental translocation was identified. Interestingly, 34.6% of the abnormal embryos (46/133) harbored *de novo* chromosome aberrations that were not directly linked to the parental translocation in question. We also detected a combination of unbalanced – parental derived – rearrangements and *de novo* chromosome aberrations in 27/133 abnormal embryos (20.3%). More specifically, from a total of 223 chromosome abnormalities detected, we identified 78 aneuploidies and 23 structural abnormalities (a combined 45.3%), unrelated to the parental rearrangement. Due to technical limitations, results were not generated in 12/207 (5.8%) of the samples. The pregnancy rate per embryo transfer, corresponding to the detection of hCG at least 15 days after embryo replacement, was 43.9%. Our preliminary data are in favor of the implementation of comprehensive chromosome screening (CCS) on trophectoderm biopsies for PGD, enabling better embryo selection and possibly leading to a higher pregnancy rate.
Limitations, reasons for caution: Besides the detection of chromosomal aberrations due to the parental translocation, this approach revealed a high occurrence of aneuploidies and structural rearrangements unrelated to the parental translocation. It is a retrospective data analysis study with a small cohort size.
Wider implications of the findings: Use of array CGH for PGD on trophectoderm biopsy at the blastocyst stage is more convenient than fluorescent *in situ* hybridization (FISH) and leads to a more reliable estimate of the genomic content of the embryo compared to single or double cell biopsy at the cleavage stage.

[7]*University of Cambridge School of Clinical Medicine, Institute of Metabolic Science, Cambridge Biomedical Campus, MRC Epidemiology Unit, Cambridge, UK*

Study question: Can we identify the genetic basis of spontaneous dizygotic (DZ) twinning by establishing a Twinning consortium for genetic association studies?
Summary answer: We identified the first robust genetic variants for DZ twinning. These variants are significantly associated with a broad range of fertility traits in women.
What is known already: The tendency to conceive spontaneous DZ twins is a complex trait that aggregates in families, and there is evidence that it is at least, in part, genetically determined. Although the fundamental physiological mechanism for DZ twinning is the release and fertilization of multiple oocytes, for which both animal models and human data suggest multifactorial inheritance, the underlying molecular basis of the trait is not understood. So far, efforts to find genetic factors that contribute to DZ twinning in humans have not been successful.
Study design, size, duration: We performed the first genome-wide association study (GWAS) for being a mother of DZ twins in 1,980 mothers of spontaneous DZ twins and 12,953 controls from The Netherlands, US and Australian European ancestry cohorts. 9,073,348 SNPs (after imputation against the 1000G reference set) were tested. Findings were replicated in a large Icelandic cohort (3,597 mothers of twins and 297,348 controls) and tested for association across a broad range of fertility traits in women.
Participants/materials, setting, methods: All cases underwent screening to exclude mothers who received assisted reproductive techniques. Controls were screened to exclude pedigrees containing DZ twins. The mean maternal age at delivery was 29.3 (SD = 4.5) for the discovery cohorts and 30.3 (SD = 4.5) for the replication cohort.
Main results and the role of chance: Two single nucleotide polymorphisms (SNPs) were identified (rs11031006 near FSHB, $p = 1.54 \times 10^{-9}$, and rs17293443 in SMAD3, $p = 1.57 \times 10^{-8}$) and replicated ($p = 3 \times 10^{-3}$ and $p = 1.44 \times 10^{-4}$, respectively). Based on ~90,000 births in Iceland, the relative risk of a mother delivering twins increased by 18% for each copy of the rs11031006-G allele, and 9% for the rs17293443-C allele. A higher polygenic risk score (PRS, or cumulative genetic risk profiles from across the genome) for DZ twinning, calculated based on the results of the DZ twinning GWAS, was significantly associated with DZ twinning in Iceland ($p = 0.001$). A higher PRS was also associated with having children ($p = 0.01$), greater lifetime parity ($p = 0.03$) and earlier age at first child ($p = 0.02$). The rs11031006-G allele was associated with higher serum follicle-stimulating hormone (FSH) levels, earlier age at menarche, earlier age at first child, higher lifetime parity, lower polycystic ovary syndrome risk, and earlier age at menopause. Conversely, the rs17293443-C allele was associated with later age at last child.
Limitations, reasons for caution: NA.
Wider implications of the findings: This study extends our understanding of the control of natural multiple follicle growth and reproductive aging. This new knowledge will contribute to the development of novel ways to manipulate ovarian functioning, which is crucial for the treatment of infertility as well as for contraception.
Trial registration number: na

P-599 A comparison of transcriptomic profiles in endometrium during window of implantation between women with unexplained recurrent implantation failure and recurrent miscarriage

J. Huang[1], H. Qin[2], Y.H. Yang[1,3], X.Y. Chen[1], J.M. Zhang[1,3], S. Laird[4], C.C. Wang[1,5], T.F. Chan[2], T.C. Li[1]
[1]*The Chinese University of Hong Kong, Department of Obstetrics and Gynaecology, Hong Kong, China*
[2]*The Chinese University of Hong Kong, School of Life Sciences, Hong Kong, China*
[3]*Guilin Medical University, Reproductive Medicine Center of the Affiliated Hospital, Guilin, China*
[4]*Sheffield Hallam University, Biomedical Research Center, Sheffield, UK*
[5]*The Chineses University of Hong Kong, Li Ka Shing Institute of Health Sciences, Hong Kong, China*

Study question: Are there any differences in the endometrial transcriptome profiles in the window of implantation among women with unexplained recurrent implantation failure, recurrent miscarriage and normal fertile control?
Summary answer: There were significant differences in transcriptomic profiles between women with unexplained recurrent implantation failure (RIF) and recurrent miscarriage (RM).
What is known already: The endometrium becomes receptive to the embryo only in the mid-luteal phase of the menstrual cycle. Endometrial factors play an important role in implantation. Extensive studies have shown that women with recurrent miscarriage or recurrent implantation failure have altered expression of individual receptivity markers during the window of implantation.
Study design, size, duration: There were a total of 24 subjects recruited, 9 women with unexplained recurrent implantation failures (RIF), 11 women with recurrent miscarriage (RM) and 4 fertile subjects.
Participants/materials, setting, methods: Endometrium samples were collected exactly 7 days after luteal hormone surge (LH+7). The transcriptome was determined by RNA-Seq using 14 samples (5 RIF, 6 RM, and 3 controls). Differential gene expression validation was confirmed by quantitative PCR using all 24 samples.
Main results and the role of chance: Expression profiles of RIF and RM can be separated by principle component analysis. Genes contributed to the biological difference between RIF and RM was identified. Among all molecular pathways C3, CD55, C4A, C4BPA, CFD, and SERPING1 in complement cascade were highly expressed in RIF samples; while cell signaling seemed to be significantly activated in RM patients during WOI. The significant differences between RIF and RM suggested that the underlying mechanisms of unexplained recurrent implantation failure are different from unexplained recurrent miscarriage.
Limitations, reasons for caution: More functional studies are needed to validate the role of complement pathway in implantation.

Wider implications of the findings: RIF and RM may be the result of defective implantation at different stages of early pregnancy. Identification of the pathways involved in each process would enable the differential design of treatments for each patient group.
Trial registration number: None.

P-600 Influence of genetic polymorphisms associated with ovarian response on clinical outcomes within an oocyte donation program

M. Cruz[1], C. Santiago[2], D. Agudo[1], B. Navarro[3], A. Requena[4], F. Gómez-Gallego[2]
[1]*IVI Madrid, IVF Lab, Madrid, Spain*
[2]*Universidad Europea de Madrid, School of Doctoral Studies and Research, Madrid, Spain*
[3]*Universidad Europea de Madrid, Biomedical Basic Sciences, Madrid, Spain*
[4]*IVI Madrid, Gynecology, Madrid, Spain*

Study question: Does genetic polymorphisms affect ovarian response and clinical results in an oocyte donor program?
Summary answer: There is currently no evidence that genetic polymorphisms are associated with ovarian response to controlled ovarian stimulation in a population of fertile egg donors,
What is known already: Ovarian response to gonadotropins is characterized by a wider inter-individual variability, with low responders with few or no mature follicle, and high responder characterized by an increased risk of developing a syndrome of ovarian hyperstimulation.

In assisted reproductive treatments, the stimulation protocol for low/high ovarian response to exogenous FSH is individualized, although the response to intense stimulation with gonadotropins is difficult to predict. However, it has been suggested that one of the reasons for this variability of ovarian response to stimulation protocols lies in the genetic status of the patient
Study design, size, duration: 70 oocyte donors were subjected to ovarian stimulation protocol. After oocyte recovery, they were classified into three groups depending on the number of oocytes obtained: low response (≤6 oocytes), normal-response (7–15 oocytes) and high response (>15 oocytes). Then we identified genetic polymorphisms associated with FSH receptor gene, the β-LH subunit, CYP19A1, estrogen receptor, GDF-9 and BMP-15 for the purpose of describing a suitable genetic profile that helps predict most effective way ovarian response
Participants/materials, setting, methods: Subjects were assigned to receive daily doses of 150 UI rFSH; from day 6 of stimulation onwards, 0.25 mg GnRH antagonist were administered and a single dose of GnRH agonist (0.2 mg) was administered for triggering final oocyte maturation. Oocyte pick-up was programmed 36 h after inducing ovulation. Oral epithelial cells were taken using FTA cards; the further analysis of genetic polymorphisms was performed by PCR with Taqman probes on a device StepOne Plus
Main results and the role of chance: The distribution was 15.7% for low-responders, 37.1% for normal-responders and 47.1% for high-responders. The age was 23 to 33 (28.09 ± 3.08 years), 18 to 35 (26.54 ± 4.95 years), 18 to 32 years (24.52 ± 3.73 years) and the estradiol levels were 881.78 ± 1530.12 pg/ml, 2343.04 ± 1389.45 pg/ml 3249.06 ± 1538.95 pg/ml, respectively. The age in the low-response group was significantly older than in the high-responder group ($p = 0.031$). The estradiol levels were different in the low-response group vs. normal and high-responders ($p = 0.035$ and $p < 0.001$; respectively).

All the genotype frequencies were in the Hardy-Weinberg equilibrium.

Univariate analysis revealed that any polymorphism was associated with ovarian response: FSHR T307A (rs6165) ($p = 0.359$); FSHR N680S (rs6166) ($p = 0.343$); LHB W8R (rs1800447) ($p = 0.160$); ESR1 Pvu T/C (rs2234963) ($p = 0.234$); ESR1 Xba A/G (rs9340799) ($p = 0.369$); LHB I15T (rs34349826) ($p = 0.160$); CYP19A1 (TTTA)*n* (rs57921193) ($p = 0.094$); CYP19A1 (I/D) (rs11575899) ($p = 0.770$), GDF9 546G/A (rs10491279) ($p = 0.630$); BMP15 −9C/G (rs3810682) ($p = 0.566$). On the other hand, we have shown an association statistically significant for LHB with the number of follicles ($p = 0.036$; for both LHB polymorphisms). There was not significance with the number of oocytes.
Limitations, reasons for caution: This study has been performed in oocyte donors, which form a fairly homogeneous group in terms of age and ovarian response, so these results may not be extrapolated to other groups of women undergoing an assisted reproductive treatment.
Wider implications of the findings: Although data are accumulating with evidence suggesting that the ovarian response to controlled ovarian stimulation is mediated by genetic polymorphisms, these biomarkers are not determining factors in predicting ovarian response to the administration of exogenous gonadotropins when stimulating oocyte donors. However, more data are needed to draw firm conclusions
Trial registration number: None.

P-601 Chromosome abnormalities detected by array comparative genomic hybridization and next-generation sequencing: results on >38,000 embryos

E. Liu[1], T. Escudero[1], L. Ribustello[1], K. Bauckman[1], P. Colls[1], S. Munne[1]
[1]*Reprogenetics, PGS, Livingston, NJ, USA*

Study question: Are there significantly different chromosome abnormality rates, controlled by age, between PGS next-generation sequencing (NGS) using the VeriSeq assay and array comparative genomic hybridization (aCGH)?
Summary answer: NGS is a more accurate method of identifying euploid embryos across all age groups due to its ability to detect mosaicism in trophectoderm biopsies.
What is known already: SART success rates can be enhanced by implementing PGS as shown by recent randomized trials. The newest technique for PGS is next generation sequencing (NGS), which has the potential to provide additional information about the embryo beyond chromosomal aneuploidy (specifically polyploidy and mosaicism) and may offer higher accuracy for aneuploidy detection. NGS techniques should be valued over the current PGS gold-standard of array-CGH and offer increased precision and higher analytical depth to substitute aCGH.
Study design, size, duration: Sureplex whole genome amplification (WGA) products of 38,909 blastocyst biopsies were assessed. 24,507 biopsied samples comprising 4,981 cases for aCGH testing were received from 161 fertility centers between 01/01/2015 and 12/11/2015. 14,702 biopsied samples comprising 2,861 cases for NGS testing were received from 73 fertility centers between 01/28/2014 and 12/11/2015.
Participants/materials, setting, methods: SurePlex WGA products of biopsies were processed using Illumina 24 sure microarrays for aCGH or VeriSeq PGS assay with the MiSeq sequencing platform for NGS. Both results were interpreted through BlueFuse Multi analysis software and diagnosed as euploid or abnormal for aCGH or euploid, abnormal, or mosaic for NGS, and distributed in age groups following guidelines set by Society for Assisted Reproductive Technology (SART).
Main results and the role of chance: Results are shown in the below table. NGS yielded a lower proportion of euploid embryos available for transfer across all age groups tested. The ability of NGS testing to identify mosaicism, which aCGH is less able to do, accounts for a large proportion of this discrepancy.

Age Group	[a]CGH-# Euploid Embryos	[a]CGH-Total analysed	[a]CGH-% Euploid	NGS-# Euploid Embryos	NGS-Total Analysed	NGS-% Euploid	NGS-% Mosaic
Egg donors	2863	4416	64.83%	2095	3347	62.59%	11.35%
< 35	4461	7421	60.11%	1904	4091	46.54%	22.66%
35–37	2410	4561	52.84%	1081	2682	40.31%	19.02%
38–40	1751	4538	38.59%	808	2683	30.12%	13.38%
41–42	521	2252	23.13%	210	1239	16.95%	10.57%
>42	142	1019	13.94%	71	660	10.76%	9.70%

Limitations, reasons for caution: The results are an assessment of abnormalities detected in different age groups within a large study. It is not a direct comparison of the same embryos analysed by both methods which has already been published.
Wider implications of the findings: Mosaic blastocysts have lower potential of implantation, higher risk of miscarriage and more likely to result in babies with congenital abnormalities. NGS distinguishes better between mosaic and euploid embryos, thereby increasing the selection of embryos with higher implantation potential, avoiding misclassifying mosaics as euploid (false negative) or aneuploid (false positive).
Trial registration number: N/A.

P-602 Genetic screening analysis in infertility patients: a retrospective single center review

A. Peyser[1], T. Singer[1], C. Mullin[1], A. Hershlag[1]
[1]*Northwell Fertility, Hofstra Northwell School of Medicine, Manhasset, NY, USA*

Study question: The objective of this study was to examine the merit of pan-ethnic genetic screening of infertility patients at a single fertility center.
Summary answer: Wide genetic screening of infertility patients is justified by the frequent discovery of carrier status, and the small yet significant percentage of dual carrier state.
What is known already: Of over 25,000 genes identified, the average human is a carrier for 5–10 single gene mutations. Several panels have been developed to include a wider range of genes in order to further reduce the chance of having a child affected with even the rarest genetic conditions. Recent improvement in PGD (Pre-implantation genetic diagnosis), have led to greater precision in diagnosis of single gene mutations. This approach, of wide screening of patients who are candidates for fertility treatment, especially IVF, followed by exclusion of affected embryos through PGD, holds great promise in reducing the genetic load of the next generation.
Study design, size, duration: A retrospective cohort study of 4279 infertility patients who underwent the same genetic screening at our fertility center between June 2013 and July 2015.
Participants/materials, setting, methods: Serum samples from each patient were tested for a pan-ethnic panel of 102 genes (Counsyl®, San Francisco). This panel was selected based on incidence in the population as well as clinical significance.
Main results and the role of chance: 29% (1252/4279) of patients were found to be carriers of at least one autosomal recessive genetic mutation. The five most common mutations included: Hb beta chain-related Hemoglobinopathy (135/4279, 3.2%), Cystic Fibrosis (134/4279, 3.1%), Pseudocholinesterase Deficiency (103/4279, 2.4%), Spinal Muscular Atrophy (85/4279, 1.9%) and GJB2-related DFNB1 nonsyndromic hearing loss and deafness (74/4279, 1.7%). Out of all patients, 13% (585/4279) were found to be carriers of mutations that may cause physical symptoms. In 1.6% (15/948) of the couples, both male and female partners carried mutations for the same gene. All of the latter underwent pre-implantation genetic diagnosis (PGD).
Limitations, reasons for caution: Not applicable.
Wider implications of the findings: Genetic screening in fertility patients helps prevent the unexpected occurrence of a genetic disease in the offspring. The pan-ethnic panel abandons patients' often inaccurate reporting of their genetic heritage. In <2% of cases, both partners carried the same gene and used PGD to prevent their children from being affected.
Trial registration number: NA.

P-603 Short sperm telomere length is associated with patients who are overweight or obese: A possible mechanism for poor IVF treatment outcomes

Q. Yang[1], Z. Feifei[2], H. Linli[2], Z. Nan[2], B. Rui[2], Y. Guidong[2], S. Yingpu[2]
[1]*The First Affiliated Hospital of Zhengzhou University, Zhengzhou, China*
[2]*The First Affiliated Hospital of Zhengzhou University, Reproductive Center, Zhengzhou, China*

Study question: Whether sperm telomere length (STL) is related to the obesity? The impacts of men's body mass index (BMI) on STL, early embryo quality, clinical outcomes in couples undergoing IVF.
Summary answer: Short sperm telomere length is associated with patients who are overweight or obese.
What is known already: Our previous study showed that STL is positively associated early embryonic development. And other studies found that leukocyte telomere length (LTL) is shorter in obesity compared with normal weight people.
Study design, size, duration: 651 couples were recruited from August 2013 to August 2015, including 345 males with normal weight and 306 males with abnormal weight (normal group: 20–25 kg/m^2; abnormal group: >28 kg/m^2).
Participants/materials, setting, methods: Fertilization rate, embryo quality and pregnancy rate were compared between two groups. The average STL was determined in the genomic DNA by using a real-time PCR for each patient. A standardized protocol was used to perform a photometric nitro blue tetrazolium (NBT) assay to measure seminal ROS production. A sperm chromatin dispersion (SCD) kit was used to detect DNA fragmentation rate in the sperm according to the manufacturer's recommendations.
Main results and the role of chance: Couples with male's BMI over 28 kg/m^2 exhibited significant lower fertilization rate ($p = 0.002$), good-quality embryo rate ($p = 0.044$) and clinical pregnancy rate ($p = 0.038$) compared to their normal weight counterparts. In a multivariable logistic regression analysis adjusting for female age, female BMI, basic FSH level, male age, number of embryos transferred and sperm count, male BMI over 28 kg/m^2 was associated with lower clinical pregnancy rate (odds ratio 0.75 [95% CI: 0.61–0.88]; $p < 0.01$). The mean STL in the abnormal BMI group was also significantly shorter than that of normal weight group ($p < 0.001$). In addition, individuals with abnormal BMI had higher ROS (Reactive oxygen species) content ($p < 0.01$) and sperm DNA fragmentation rate ($p < 0.01$) when compared with normal BMI. And the mitochondrial activity was also lower in the normal BMI group than that of abnormal BMI group.
Limitations, reasons for caution: This study showed that short sperm telomere length is associated with patients who are overweight or obese. Additional studies are needed to confirm these observations.
Wider implications of the findings: STL has the potential to be used as a marker for the prediction of embryonic quality for the patients who are overweight or obese.
Trial registration number: none.

P-604 Polygenic profiles for predicting early menopause

T. Laisk[1], A. Salumets[1], R. Mägi[2]
[1]*University of Tartu, Women's Clinic, Tartu, Estonia*
[2]*University of Tartu, Estonian Genome Center, Tartu, Estonia*

Study question: Can we use polygenic risk scores to predict the risk for early menopause, before age 45?
Summary answer: Genetic risk profiles including approximately 20,000 markers have a good predictive value for assessing the risk of early menopause.
What is known already: Reproductive aging has an impact of female fertility and general health, and involves a considerable genetic component as evidenced by recent genome-wide association studies (GWAS). Currently, no genetic markers are used for predicting menopausal age.
Study design, size, duration: Retrospective cohort study.
Participants/materials, setting, methods: Polygenic risk scores were generated using the publicly available ReproGen consortium menopausal age GWAS meta-analysis summary statistics including data for 2.4 million markers and involving approximately 70,000 women. Correlation between risk scores and menopausal age was tested among 3,189 post-menopausal women (at least 45-year-old) in the Estonian Biobank. Receiver operating characteristic (ROC) curves were generated to evaluate the predictive value of genetic risk scores for discriminating women with early menopause.
Main results and the role of chance: A genetic risk profile including 19,683 markers was significantly correlated with age at natural menopause ($r^2 = 0.4$, $p = 4 \times 10^{-82}$). The same profile was a good predictor of early menopause (AUC = 0.70), outperforming the predictive value of smoking status (AUC = 0.55), which is one of the most important lifestyle factors affecting menopausal age. Combining genetic risk scores and smoking status improved model performance only slightly. Women among the top 10% of the genetic risk score had a relative risk of 2.80 for early menopause (the risk for early menopause of 14.0%), compared to the population average (5%), while women with the lowest 10% of scores had a relative risk of 0.30 (the risk for early menopause of 1.5%). When the extremes of the genetic risk score were compared, more than a 9-fold difference (14.0 vs 1.5%) in risk for early menopause was observed.
Limitations, reasons for caution: Genetic risk profiles need further testing in combination with hormonal and ultrasound markers currently used for assessing ovarian reserve and predicting menopause.
Wider implications of the findings: Polygenic profiles show considerable discriminative power for detecting women at risk of early menopause and age-related infertility, and therefore have the potential to increase the accuracy of ovarian reserve assessment, leading to more personalized counselling regarding family planning and patient management (like the use of assisted reproduction and oocyte cryobanking).
Trial registration number: NA.

P-605 Progesterone receptor gene is involved in recurrent implantation failure

L.D. Vagnini[1], C.G. Petersen[1,2], A. Renzi[1], G.R. Oliveira-Pelegrin[1], I.T. da Silva[3], R. Valieris[3], A.L. Mauri[1,2], A. Nicoletti[2], F. Dieamant[1,2], M. Cavagna[1,2,4], J.B.A. Oliveira[1,2], R.L. Baruffi[1,2], J.G. Franco Jr[1,2]
[1]*Paulista Centre for Diagnosis and Research, Research, Ribeirao Preto, Brazil*
[2]*Centre for Human Reproduction, Professor Franco Jr, Research, Ribeirao Preto, Brazil*
[3]*Laboratory of Bioinformatics and Computational Biology, AC Camargo Cancer Center, Research, Sao Paulo, Brazil*
[4]*Women's Health Reference Center, Perola Byington Hospital, Research, Sao Paulo, Brazil*

Study question: Could any polymorphic variant of human progesterone receptor (PGR) gene be used as molecular biomarker in recurrent implantation failure (RIF)?
Summary answer: Next-generation sequencing (NGS) of PGR gene has identified two polymorphic variants that could be involved in implantation failure.
What is known already: It is known that PGR mediates the action of progesterone hormone and both are critical for development and maintenance of the endometrium and consequently for implantation of embryos after in vitro fertilization (IVF). Since RIF is the most frequent cause of lack of pregnancy after IVF and some polymorphic variants of PGR have been implicated in this context, it is important an enhanced understanding of these variants and their roles within the uterine compartments.
Study design, size, duration: A cross-sectional study was conducted with blood samples of 48 women presenting recurrent implantation failure (RIF) subjected to IVF/ICSI protocols and 46 fertile women (control group). RIF group - inclusion criteria: ≥2 failed IVF/ICSI attempts/≥5 embryos transferred, age ≤ 39 years and normal karyotype; exclusion criteria: uterine defects, ultrasonographic evidence of hydrosalpinx, infections, endocrine problems, coagulation defects or thrombophilia and autoimmune defects. Control group - volunteers with at least 1 live birth, without treatment and no history of miscarriage.
Participants/materials, setting, methods: Genomic DNA was extracted from the peripheral blood of RIF and control groups. The coding regions (exons) and no translated variants in both 3'/5'UTRs of PGR gene were analyzed by NGS using TruSeq Custom Amplicon/MiSeq-Systems. Raw paired-end reads were aligned to human reference genome GRCh37 using BWAv0.7.12. Reads were re-aligned around indels and quality scores re-calibrated using GATK–(v3.5-0-g36282e4). GATK's UnifiedGenotyper was used as a variant caller to detect Single Nucleotide Variations (SNVs) on the full alignments.
Main results and the role of chance: Following the best practices of GATK for amplicon sequencing we found two prevalent variants in RIF group and their frequencies are shown in Table 1. The genotypic frequencies of these variants in women presenting RIF and in controls subject are shown in Table 2. A significant difference between RIF and control group ($p = 0.03$) was found by chi-square test.

Table 1. Variants frequencies

Gene	rs	allele	Control	Control	RIF	RIF
			n	Minor allele frequency	*n*	Minor allele frequency
PGR	rs1042838	C>A	8	0.092	15	0.173
PGR	rs11224563	C>T	8	0.094	15	0.176

Table 2. Genotypic frequencies (PGR gene)

	*RIF [*n*(%)]	Control [*n*(%)]	*p*-value
rs1042838			
C/C	32 (68.1)	38 (82.6)	0.03
C/A	15 (31.9)	6 (13.0)	
A/A	0 (0.0)	2 (4.4)	
rs11224563			
C/C	32 (68.1)	38 (82.6)	0.03
C/T	15 (31.9)	6 (13.0)	
T/T	0 (0.0)	2 (4.4)	

*01 sample in RIF group was not mapped.

Limitations, reasons for caution: More studies are necessary to confirm this data considering variations in different ethnic population.
Wider implications of the findings: Taking into account that PGR variants (rs1042838 and rs11224563) may be involved with recurrent implantation failure, the expansion of this research should be considered.
Trial registration number: Not applicable. The local ethics committee authorized this study.

P-606 Age effect on male gamete performance through apoptotic and DNA repair gene expression

T. Cozzubbo[1], N. Pereira[1], S. Cheung[1], A. Clement[1], Q.V. Neri[1], Z. Rosenwaks[1], G.D. Palermo[1]
[1]*Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, Reproductive Medicine, New York, NY, USA*

Study question: We question the effect of age on the sperm's ability to generate offspring by assessing DNA repair and apoptosis regulating genes.
Summary answer: Transcriptome profiling utilizing RNA-Seq in human spermatozoa reveals that age sensitive genes related to DNA repair and apoptosis is indicative of reproductive outcome.
What is known already: It has been known gametes produced by an aging male may suffer increased aneuploidy and compromised chromatin integrity. Standard semen parameters, although useful in the diagnosis, are not predictive of male fertility and are not very useful in cases of idiopathic infertility. Upon fertilization, the sperm provides a complete, highly structured, and epigenetically marked genome that plays a distinct role in embryonic development. Characterization of sperm RNAs by next generation sequencing through gene expression may be suited to better understand the effect of age on the ability of the male gamete to generate offspring.
Study design, size, duration: In a 12-month period, we assessed the effect of age on male gamete integrity and its ability to participate in embryo development. The analysis was carried out by measuring the expression of DNA repair ($n = 4$) and apoptotic modulating ($n = 3$) genes. RNA extraction from 26 semen specimens was carried out on men undergoing infertility screening, with 19 men in the study group and compared to 7 men acting as a control.
Participants/materials, setting, methods: An average of 25×10^6 human spermatozoa was used to isolate total RNA using a spin column commercial kit. The nucleic acid quality and spermatozoal RNA concentration was assessed. The RNA samples were then made into paired-end libraries. Pilot paired-end 76bp RNA-Sequencing (RNA-Seq) using an Illumina platform (NextSeq 500) was carried out and expanded to 60M reads. Expression values are calculated in Fragments Per Kilobase Of Exon Per Million Fragments Mapped (FPKM) and normalized read counts.
Main results and the role of chance: A total of 7 men with an average age of 26 ± 5 years presented with a sperm concentration of 27.3 ± 27, and motility of 46.6 ± 24, and morphology of 3.0 ± 2. Sperm RNA-Seq, and expressed as FPKM, was carried out and after differential analysis patients were plotted in function of male age. We found that a DNA repair gene cluster *(APLF*, *CYB5R4*, *ERCC4* and *TNRFSF21)* and an apoptotic modulating gene cluster (*MORC1*, *PIWIL1* and *ZFAND6*) had a higher expression in younger patients (47.2 ± 15 FPKM) that progressively declined with advancing male age (9.5 ± 13 FPKM) ($p = 0.02$). This evidenced a clear inverse correlation between gene expression (FPKM) and male age. Once the reproductive potential as the ability to achieve a pregnancy was assessed, it clearly evidenced that the loss of expression of these genes was accompanied by the inability to procreate. A conserved gene expression for the specific genes analyzed confirmed the reproductive capacity and indicated a threshold at 30 years of age.
Limitations, reasons for caution: This study is part of an ongoing investigation to profile men undergoing male infertility screening and must be confirmed in a larger cohort. Gene expression profiling of infertile men may serve as an assay to measure the reproductive potential of the male gamete.
Wider implications of the findings: Sperm RNA-Seq is a reliable and reproducible technique that may aid in the diagnosis of men undergoing infertility screening. DNA repair and apoptotic genes play a key role in body development and function. This notion may clarify the cause of infertility that cannot be predicted solely by standard semen analysis.
Trial registration number: N/A.

P-607 Practical benefits of re-examination of blastocysts using next-generation sequencing technology (NGS)

J. Liss[1,2,3], A. Bruszczynska[1], A. Wozniak[1], S. Pukszta[1], C. Cybulska[1], K. Lukaszuk[1,2,3,4]
[1]Invicta, Fertility and Reproductive Centre, Gdansk, Poland
[2]Invicta, Fertility and Reproductive Centre, Wroclaw, Poland
[3]Invicta, Fertility and Reproductive Centre, Warsaw, Poland
[4]Medical University, Department of Nursing, Gdansk, Poland

Study question: To evaluate the clinical value of re-examination of the test-failure blastocysts in preimplantation genetic diagnosis cycles.
Summary answer: Test-failure blastocysts that survived after warming, can be rebiopsied, vitrified and warmed, and have a high chance to be euploid and lead to live births.
What is known already: The test-failure rate of embryos in PGD/PGS cycles depends on diagnostic method and is approximately 5–8%. The low concentration of WGA product, dead trophectoderm (TE) cells from morphologically poor embryos, damage of nuclei after biopsy may affect the quality of results. Blastocysts after biopsy need to be frozen and transferred in the frozen cycle. The most reports are about biopsy and freezing the embryos at two different stage: cleavage-stage and blastocyst. The tolerance of blastocysts to undergo the second round of biopsy, vitrification and warming and their implantation potential has not been fully investigated.
Study design, size, duration: Retrospective study including the data analysis of 299 PGD/PGS cycles involving blastocysts stage embryos performed between November 2014 and September 2015 at INVICTA Fertility Centre, Poland. During that period a total of 1224 blastocysts were evaluated with the NGS protocol. Of those, 75 blastocysts in 52 cycles showed test-failure (6.5%).
Participants/materials, setting, methods: 75 test-failure blastocysts were re-examined. Of the 75 warmed embryos, 43 completely expanded after 2–6 h and 11 overnight. 21 blastocyst (28%) did not expand. All 54 expanded blastocysts were successfully rebiopsied and retested using NGS technology. The method involved whole genome amplification (WGA) before NGS protocol. Ion Torrent Suite Software and Invicta Bioinformatics Team Script were used for chromosome copy number variation analysis.
Main results and the role of chance: All 75 blastocysts were graded based on the trophectoderm quality (scored with TE grades A–C) before the first biopsy. The expansion rates after warming in TE grade A, B and C groups were 94.4%, 70% and 59.3% respectively. Among the 54 rebiopsied blastocysts, in the case of 9 (16.7%) embryos there was no product after WGA. 19 blastocysts had normal chromosomal status (35.2%), 26 blastocysts were abnormal (48.1%). The rates of normal chromosomal status in blastocysts with TE grade A, B, and C were 43.8%, 56.3% and 23.1% respectively and they did not differ significantly among the three groups. Normal blastocysts were transferred in 13 frozen single embryo transfer cycles. Of the 19 re-examined euploid blastocysts 17 survived (89.5%). Implantation rate in TE grade A, B and C was 57.1%, 25% and 0% respectively. Single clinical pregnancies were found in 6 cases (46.2%). Four healthy infants were born and one pregnancy is still ongoing. One miscarriage was noted at 11 weeks.
Limitations, reasons for caution: The study is limited by sample size. A higher sample size or a prospective randomized design could be used in future studies to corroborate the current findings.
Wider implications of the findings: The test-failure blastocysts still have a high percentage of normal chromosomal status. Blastocysts can survive two rounds of biopsies, vitrification and warming and may have a good implantation potential. Re-examining blastocysts that have failed the initial test, particularly those with high TE quality, may be clinically valuable in PGD/PGS cycles.
Trial registration number: not applicable.

P-608 Gene expression of apoptotic markers in cumulus and granulose cells is altered in young women with reduced ovarian reserve

L. Rancan[1], R. Nuñez-Calonge[2], S. Cortes[2], E. Vara[1], L. Ortega[2], P.M. Shahani[1], I. Garcia[1], P. Caballero[2], J. Fernandez-Tresguerres[1]
[1]Facultad de Medicina, Universidad Complutense, Bioquímica y Biología Molecular, Madrid, Spain
[2]Clinica Tambre, Reproduction Unit, Madrid, Spain

Study question: Is gene expression of apoptotic markers altered in cumulus (CC) and granulose cells (GC) from young women with reduced ovarian reserve compared with oocyte donors?
Summary answer: An imbalance of apoptosis in favor of proapoptotic markers was observed in CCs and GCs from low ovarian reserve young women compared with oocyte donors.
What is known already: CCs and GCs transcriptome has been studied to identify multiple genes that are differentially expressed in CC and GCs surrounding a good- versus a poor quality oocyte and several microarray studies have been performed in order to identify biomarkers associated with oocyte quality. However, to date, there is no consensus as to which genes are the most useful as biomarkers of oocyte competence and limited knowledge exists about changes in apoptotic markers in GC and CC associated with low ovarian reserve (LOR).
Study design, size, duration: This observational, prospective study compared the mRNA expression of 92 apoptotic markers in 185 oocyte-cumulus and 114 oocyte-granulose complexes retrieved from 3 healthy fertile oocyte donors <35 years old and 3 patients <35 years old who had a low response (≤5 oocytes retrieved) after gonadotropic stimulation from June to November 2015. Only donors with at least a previous cycle with pregnancy were included.
Participants/materials, setting, methods: All patients were stimulated with the same protocol (FSHr and triggering with GnRH analogues). GCs and CCs were collected from each patient and immediately fresh-frozen. mRNA was extracted using commercial kits and the mRNA expression of 92 apoptotic genes and 4 endogenous controls was measured by qRT-PCR using microarray plates. No parametric tests were used in order to identify any significant difference between the groups. Statistical significance was set at $p < 0.05$.
Main results and the role of chance: Sixteen mRNA were significantly different between donors and patients. NAIP, TBK1, BAD, BAX, CASP2, CASP3, CASP4 and CASP10 were significantly elevated in patients compared with donors. By the contrary, FAD, MCL1, RIPK1, TNFRS1A, BBCR3, BCL2, BIRC2, and BIRC3 were significantly reduced in patients compared with donors. Interestingly, the most marked effects were a decreased expression of BIRCs (downregulators of pro-apoptotic proteins) and an increased expression of the proapoptotic mediators BAX, BAD and caspases in the GCs of patients compared with donors. These effects were more marked in CGs than CCs. Our results suggest that low responder patients present an imbalance of apoptosis in favor of proapoptotic markers.
Limitations, reasons for caution: The main limitation of our study is the small number of replicates. The results observed in this studying using the array panels should be confirmed on a larger sample number.
Wider implications of the findings: These promising results improve the body of knowledge on low ovarian reserve pathogenesis, may aid our understanding of the physiology and regulation of apoptosis and could identify some potential microRNA biomarkers for this process. These findings could open up new therapeutic strategies for the treatment of low ovarian reserve.
Trial registration number: PI-646A.

P-609 Female carriers of reciprocal translocations tend to get adverse results in blastocyst quality and aneuploidy rate in PGD compared with male carriers

K.L. Luo[1], F. Gong[1], Y.Q. Tan[1], S.P. Zhang[1], G.X. Lu[1], G. Lin[1]
[1]Institute of Reproductive & Stem Cell Engineering, ART centre, Changsha, Hunan, China

Study question: To investigate the differences of mature oocytes number, fertilization rate, blastocyst formation rate, good blastocyst rate and aneuploidy rate in PGD between female and male carriers of reciprocal translocations.
Summary answer: Female reciprocal translocation carriers have adverse outcomes in good-quality blastocyst rate, euploidy rate and aneuploidy rate compared to male carriers.
What is known already: Present data demonstrate that there were little differences in PGD outcomes between female and male reciprocal translocation (rcp) carriers. But there are argues of limitations in sample size and in the method of aneuploidy detection by FISH.
Study design, size, duration: A retrospective study is performed to compare outcomes of PGD in female rcp carriers (n = 443) and male rcp carriers (n = 414) from 2012 to November 2015. Altogether 9173 mature oocytes were recovered and 2879 blastocysts were analyzed with Single Nucleotide Polymorphism (SNP) or Next Generation Sequencing (NGS).

Participants/materials, setting, methods: The study was performed at the Reproductive and Genetic Hospital of CITIC-Xiangya, China. Blastocysts were scored according to the standard Gardner blastocyst grading system and laser assisted trophectoderm biopsy was performed on day 5 or 6 post oocytes retrieval. Mann-Whitney-Wilcoxon (MWW) and chi-square test was used for statistical analysis.
Main results and the role of chance: Altogether 9173 mature oocytes (female rcp, $n = 4650$; male rcp, $n = 4523$) were recovered, 7807 blastocysts (female rcp, $n = 3968$; male rcp, $n = 3839$) were formed and 2879 blastocysts (female rcp, $n = 1480$; male rcp, n = 1399) were analyzed. There is no difference in age [29.5 (27, 32) vs 30 (27, 32), $p = 0.891$], number of mature oocytes [11 (7, 15) vs 12 (8, 16), $p = 0.151$], fertilization rate [85.3% (3968/4650) vs 84.9% (3839/4523), $p = 0.540$] and blastocyst formation rate [42.9% (1704/3968) vs 41.7% (1599/3839), $p = 0.248$] between female and male rcp carriers. But female rcp carriers shows an adverse result in good-quality blastocyst rate [36.2% (617/1704) vs 43% (688/1599), $p < 0.01$], euploid blastocyst rate [31% (459/1480) vs 35.2% (492/1399), $p = 0.018$], combined aneuploidy rate [26.3% (389/1480) vs 22.8% (319/1399), $p = 0.030$] compared to male rcp carriers.
Limitations, reasons for caution: The study is limited for its retrospective design. There also may exists bias caused by different operators.
Wider implications of the findings: The sample size and screening method of SNP and NGS gives us detailed informations on blastocyst formation, quality and aneuploidy rate which subsequently give us a better estimation of the chance for transferrable cycles. It'll be easier for the patients to make a decision on choosing or give-up on PGD.
Trial registration number: None.

P-610 Declined ovarian reserve is related to increased aneuploidy rate in the age group of 35–39

F. Gong[1], K.L. Luo[1], G. Lin[2], Y.Q. Tan[2], H. Guo[2], G.X. Lu[2]
[1]*Central South University, Institute of Reproduction and Stem Cell Engineering, Changsha, Hunan, China, ART centre, Changsha, China*
[2]*Reproductive & Genetic Hospital CITIC-Xiangya, ART Centre, Changsha, China*

Study question: To investigate aneuploidy rate between low responders (LR), normal responders (NR) and high responders (HR) in different age groups.
Summary answer: For women at the age of 35–39, aneuploidy rate increases as the recovered mature oocyte number decreases.
What is known already: Although abundant studies have shown that advanced maternal age will increase aneuploidy rate in human embryos, whether ovarian response is related to aneuploidy rate is still in debate.
Study design, size, duration: A retrospective study was performed on 1760 couples ($n = 278$ for age ≥ 40, $n = 390$ for age of 35–39, $n = 1092$ for age ≤ 34) who performed PGD from 2012 to November 2015. Aneuploidy rates not derived from maternal/paternal translocations were compared by different ovarian response (LR, mature oocyte number ≤ 5; NR, mature oocyte number = 6–13; HR, mature oocyte number ≥ 14).
Participants/materials, setting, methods: The study was completed at the Reproductive and Genetic Hospital of CITIC-Xiangya, China. Laser assisted trophectoderm biopsy was performed on day 5 or 6 post oocytes retrieval. Comprehensive chromosome screening was performed with single-nucleotide polymorphisms or next generation sequencing. Aneuploidy rates were compared with chi-square test.
Main results and the role of chance: For women over 40, aneuploidy rate between the LR, NR, HR group are not different [(75% (63/84), 78.2% (104/133) and 72.58% (45/62), $p = 0.672$)]. For women of 35–39, aneuploidy rate is statistically different between the LR, NR, HR group.[47.92% (69/144), 37.47% (178/475), 34.13% (86/252), $p = 0.022$]. For women younger than 35, aneuploidy rate between the LR, NR, HR group are also not different [25.23% (54/214), 23.63% (434/1837), 25.96% (447/1722), $p = 0.270$].
Limitations, reasons for caution: The study is limited for its retrospective design.
Wider implications of the findings: At the specific age group of 35–39, a decreased ovarian response may indicate an increase aneuploidy rate. This information will be useful for patients' decision-making in whether choose PGS or routine IVF/ICSI.
Trial registration number: None.

P-611 Cumulative oocyte vitrification improves Preimplantational Genetic Screening (PGS) clinical results in low-responder patients

P. Buendia Segura[1], A. Cobo[2], C. Rubio[3], A. Mercader[1], A. Delgado[1], L. Escrich[1], D. Beltran[1], E. Bosch[4], J. Remohi[5]
[1]*IVI Valencia, PGD-IVF Lab, Valencia, Spain*
[2]*IVI Valencia, Cryopreservation, Valencia, Spain*
[3]*Igenomix, PGD, Valencia, Spain*
[4]*IVI Valencia, Clinical Director, Valencia, Spain*
[5]*IVI Valencia, Director, Valencia, Spain*

Study question: PGS result could be influenced by the low number of oocytes obtained in low-responder patients.
Summary answer: Accumulation of vitrified oocytes equates the clinical results in low-responder PGS patients when the number of collected oocytes approaches the one in normo-responder PGS patients.
What is known already: Oocyte vitrification does not increase the incidence of chromosomal abnormalities when we analyzed in a PGS cycle embryos from fresh and vitrified oocytes from the same patient.
Study design, size, duration: This retrospective observational study included 368 PGS cycles from normo-responder patients in which the origin of the oocytes of all embryos analyzed were fresh and 45 PGS cycles from low-responders patients where the origin of all analyzed embryos derived from vitrified oocytes from two or more cycles of ovarian stimulation from our PGD program (from January 2011 to December 2014).
Participants/materials, setting, methods: 377 patients were included in this study, 344 with fresh oocytes and 43 with vitrified oocytes. Oocytes were vitrified by Cryotop® method. Biopsies were performed on day 3 in Ca^{2+} and Mg^{2+} free medium (G-PGD, Vitrolife) using laser technology (OCTAX). For 24-chromosome aneuploidy screening, array-CGH was employed. Euploid embryos were transferred on day 5, supernumerary embryos were vitrified either on day 5 or day 6. Statistical comparisons were performed using a Fisher´s exact test ($p < 0.05$).
Main results and the role of chance: Mean female age was 38.9 years [IC95%: 38.6–39.3] in the fresh oocyte group and 40.9 years [IC95%: 40.1–41.7] in the vitrified group. Mean MII initials/stimulation cycle was statistically significant: 9.4[IC95%: 8.9–9.9] fresh vs 4.4 [IC95%: 6–5.2] vitrified. Mean stimulation cycles/PGS cycles was 2.2[IC95%: 1.4–2.5] in the vitrified group. No differences were found in mean MII initials/PGS cycle: 9.4 [IC95%: 8.9–9.9] fresh and 10.0 [IC95%: 8.7–11.5] vitrified, neither mean MII inyected/PGS cycle: 9.4[IC95%: 8.9–9.9] fresh and 8.8[IC95%: 7.3–10.3] vitrified. Oocyte survival rate was 88.2% [IC95%: 85.2–91.2]. Biopsied embryos/fertilized oocytes rate and D5 blastocyst rate/biopsied embryos were significantly lower in vitrified group (75.6% [IC95%: 74.3–77.3] fresh vs 69.1% [IC95%: 63.8–73.9] and 67.5% [IC95%: 65.4–69.6] fresh vs 58.1% [IC95%: 51.3–64.9] vitrified, respectively). No statistically significant differences in fertilization rate. Informativity of chromosome analysis was 98.6%. Aneuploidy rate and types of chromosomal abnormalities were similar, without statistical differences between fresh or vitrified oocytes. There was no statistical differences in efficiency rate in terms of normal D5 blastocyst/MII microinyected: 10.0% [IC95%: 9.0–11.0] vs 7.1% [IC95%: 4.6–9.6]. Ongoing pregnancy rate/transfer and ongoing implantation rate were similar in both groups (47.5%[IC95%: 40.6–54.4] fresh vs 52.6%[IC95%: 30.2–75.1] vitrified and 42.6%[IC95%: 36.5–48.1] fresh vs 42.3%[IC95%: 23.1–61.3] vitrified, respectively).
Limitations, reasons for caution: One limitation of the study is the lower number of cases included in the second group. Another limitation is population differences in terms of age and infertility aetiology, but despite these differences and the poor prognosis expected in the low responder group, the results are encouraging.
Wider implications of the findings: Accumulation of vitrified oocytes before the actual PGS cycle is a possible strategy that might increase patient's chances for a healthy pregnancy, matching the results of patients of low responder to normo-responders. Increasing the oocytes cohort contributes to significantly lower the dropout rate and the embryo transfer cancellation.
Trial registration number: None.

P-612 Aneuploidy vs Age: A study chromosome by chromosome

T. Escudero[1], L. Ribustello[1], E. Liu[1], S. Munne[2]
[1]*Reprogenetics, aCGH Team, Livingston, NJ, USA*
[2]*Reprogenetics, President, Livingston, NJ, USA*

Study question: Aneuploidy increases with maternal age, but are there specific chromosomes that are more prone to aneuploidy than others?
Summary answer: Aneuploidy for chromosomes 13, 15, 16, 19, 21, and 22 is extremely correlated by age, but for chromosome 1 and 3 is independent of age.
What is known already: The association between maternal age and aneuploidy has been established since the 1990s (Sherman et al., 1994; Phillips et al., 1995; Munne et al., 1995). Early FISH studies established correlation between aneuploidy and age for chromosomes X, 16, and 21 (Hassold et al., 1993; Munne et al., 1995) and other chromosomes (Bahçe et al, 1999). Success rates of in vitro fertilization have been enhanced by implementing routine comprehensive chromosome screening (CCS) as shown by recent randomized trials. These techniques, mainly aCGH and NGS, are able to analyze all 24 chromosomes expanding the reach of the few chromosomes FISH could ever analyze.
Study design, size, duration: Retrospective study of 56,328 embryos at blastocyst stage from 11,272 cycles from 156 centers across the USA from January 2014 to August 2015.
Participants/materials, setting, methods: 48048 embryos were processed by aCGH (85.3%), and 8280 were processed by NGS (15.7%). Embryos were distributed in age groups according to the START guidelines.
Main results and the role of chance: The aneuploidy information of every chromosome in every age group was noted. The correlation between the age and the aneuploidy was calculated by the Pearson's correlation coefficient, and the *p* value for Pearson was calculated to ascertain if this correlation was significant and to what degree (Table I). Although the majority of the chromosomes showed correlation with age (except for chromosomes 1 and 3), some of the chromosomes showed a higher degree of correlation than others (13, 15, 16, 19, 21, and 22). The EGD group is quite homogeneous in regards to aneuploidy, each chromosome has more or less the same rate of aneuploidy. But as the maternal age of the groups increases, the aneuploidy rate for some chromosomes increases faster than other.

Chromosome	Correlation (R)	Pearson value	Extremely significant (0.01)
13	0.9278	0.0076	yes
15	0.9288	0.0074	yes
16	0.9815	0.0005	yes
19	0.9390	0.0055	yes
21	0.9567	0.0028	yes
22	0.9809	0.0005	yes

Limitations, reasons for caution: The comparison between both CCR techniques will be discussed during the presentation. Embryo survival at blastocyst stage may bias the preponderance of the aneuploidy of some.
Wider implications of the findings: There is a relation between size of the chromosome and aneuploidy. The chromosomes with smaller size have an increased aneuploidy rate. Additionally the egg donor group (EGD) has a more homogeneous aneuploidy rate among all the chromosomes. These two facts may point out that female meiotic errors affect smaller chromosomes.
Trial registration number: N/A.

P-613 Trophectoderm biopsy and transfer in a subsequent frozen thaw embryo replacement cycle in preimplantation genetic diagnosis cycles

K. Doye[1], J. Ben Nagi[1], H. Exeter[1], E. Drew[1], K. Loutradi[1], P. Serhal[1]
[1]Centre for Reproductive and Genetic Health, PGD, London, UK

Study question: What is the pregnancy outcome of trophectoderm biopsy and transfer in a subsequent frozen embryo replacement (FER) cycle in couples undergoing preimplantation genetic diagnosis (PGD)?
Summary answer: In PGD cycles, trophectoderm biopsy and transfer in FER cycles offers advantageous pregnancy outcomes compared with cleavage stage biopsy.
What is known already: Traditionally, embryo biopsies for PGD cycles have been performed at cleavage stage, with fresh transfer of a suitable blastocyst. ESHRE PGD Consortium collection I-XII data showed 92% and 0.7% were cleavage and blastocyst stage, respectively. Blastocyst biopsy compared with cleavage stage biopsy has been reported to have a higher rate of genotyping, less amplification failure, less allele drop out and fewer embryos to biopsy. It is also associated with higher implantation and pregnancy rates than cleavage stage biopsy. Furthermore, FER can prevent late onset ovarian hyperstimulation syndrome (OHSS), is associated with improved perinatal outcomes and a higher ongoing pregnancy rate.
Study design, size, duration: This is a retrospective case series of PGD cycles performed from July 2014 to December 2015. 85 couples had biopsy at blastocyst stage and vitrification. 66/85 couples had a suitable embryo to transfer. Of the remaining 19 couples, 12 are awaiting FER at the time of writing, whilst 7 couples had blastocysts which were not suitable for transfer.
Participants/materials, setting, methods: Couples were either referred from a regional genetic centre, or self-referred. Couples were counselled and standard IVF protocols were applied. Embryos were cultured to blastocyst and biopsied as described by Gardner, 2007. The cells were sent to the reference laboratory for genotyping. Standard procedures for thaw of embryos were performed and blastocysts were transferred in a subsequent medicated FER cycle. Patients carried out their urinary pregnancy test 16 days later.
Main results and the role of chance: 85 cycles of trophectoderm biopsy and vitrification were performed. 72/85 (85%) were for single gene disorders and 13/85 (15%) for chromosomal rearrangements. A total of 398 blastocysts were biopsied. 182/398 (48%) blastocysts were suitable for transfer. One blastocyst required repeat thaw and biopsy, due to initial amplification failure, which resulted in a suitable embryo to transfer. None of the blastocysts failed to survive the thaw process on the day of FER. All couples had elective single embryo transfer.

Of 54 PGD cycles for single gene disorder with known pregnancy outcome, 42 (78%) FER cycles resulted in a positive pregnancy test (95% CI 65–87). The ongoing pregnancy rate is 38/54 (70%) (95% CI 57–81). 2/54 (4%) FER cycles were biochemical pregnancies (95% CI 1–13) and 2/54 (4%) resulted in first trimester miscarriage (95% CI 1–13). 12/54 (22%) FER cycles had a negative pregnancy test (95% CI 13–35).

Of 12 PGD cycles for chromosomal rearrangements with known pregnancy outcome, 9 (75%) FER cycles resulted in a positive pregnancy test (95% CI 47–91). The ongoing pregnancy rate is 7/12 (58%) (95% CI 32–81). 2/12 (17%) such cycles resulted in first trimester miscarriage (95% CI 5–45).
Limitations, reasons for caution: This is the largest number of pregnancy outcomes so far reported from a trophectoderm biopsy, vitrification and FER dataset for single gene disorders and chromosomal rearrangements. However, results are retrospective and non-randomized.
Wider implications of the findings: Trophectoderm biopsy, vitrification and FER can be successfully applied to PGD cycles for single gene disorders and chromosomal rearrangements. This approach increases the rate of genotyping and moreover, implantation and pregnancy rates exceed those following cleavage stage biopsy.
Trial registration number: 0.

P-614 Number of blastocysts biopsied as a predictive indicator for obtaining at least one normal/balanced embryo with single nucleotide polymorphism microarray in translocation cases

Y. Wang[1], Y. Xu[1], C. Ding[1], J. Wang[1], Y. Zeng[1], W. Zhou[1], R. Li[1], C. Zhou[1]
[1]1st Affiliated Hospital of Sun Yat-Sen University, Key Laboratory of Reproductive Medicine of Guangdong Province, Reproductive Center of Obstetrics and Gynecology, Guangzhou, China

Study question: How many number of blastocysts to be biopsied is optimum, in order to predict at least one normal/balanced blastocyst after SNP-PGD for translocation carriers?
Summary answer: 3 and 4 accumulated blastocysts were predicted for Robertsonian and reciprocal translocation carriers younger than 37 with basal FSH level under 10.2 IU/L respectively.
What is known already: For a RT carrier, depending on segregation patterns in meiotic divisions, only 1/3 normal and 1/3 balanced karyotype gametes are alternate and further, can produce normal or RT karyotype embryos. As for a

rcp carrier, the alternate gametes are merely account for 1/9. Blastocyst-stage biopsy rather than cleavage-stage biopsy is now generally recommended in the advantage of lower mosaic rates and less biopsy-related damages. WGA-based SNP microarrays for PGD have the capability to screen concurrent 24 chromosomes in addition to testing for the specific unbalanced chromosome complement expected arising out of the parental translocation.

Study design, size, duration: Blinded retrospective study from July 2013 to December 2014, including 51 RT couples who underwent 55 cycles of PGD and 131 rcp pairs who underwent 181 cycles.

Participants/materials, setting, methods: Couples recruited were for the indication of only one partner carried translocation. Trophectoderm biopsy on day 5 or 6 followed by WGA-based SNP microarrays was performed in a Hospital-based IVF center. Main outcome measures were balanced/normal embryo rate (transferrable rate) and clinical pregnancy rate.

Main results and the role of chance: Reliable SNP-PGD results were obtained for 355 out of 379 (93.7%) biopsied blastocysts in Robertsonian group and 986 out of 1053 (93.6%) in Reciprocal group. The average numbers of biopsied embryos per patient and normal/balanced embryos per patient, the mean balanced/normal embryo rate per patient and the rate's 95% confidence interval (CI) were 7.4, 3.1, 40.7%, 34.6%—46.9%, respectively, in Robertsonian translocation carriers, and 8.0, 2.1, 27.3%, 23.9%—30.7%, respectively, in reciprocal translocation carriers. In adjusted linear regression model, the only three significant factors affecting the number of genetically transferrable embryos were the number of biopsied embryos (coefficient: 0.489, $p = 0.001$), basal FSH level (coefficient: 0.216, $p = 0.023$) and maternal age (coefficient: 0.060, $p = 0.042$). ROC analysis was then performed in a subgroup including female under age 37 and basal FSH level below 10.2 IU/L. Using ROC, a cut-off level of 2.5 for the number of biopsied embryos when Robertsonian translocation carriers intended to obtain at least one balanced/normal embryos (sensitivity = 86.8%, specificity = 66.7%, AUC = 0.912), and a 3.5 cut-off level for reciprocal translocation carriers (sensitivity = 90.4%, specificity = 73.3%, AUC = 0.877) were established. A 44.2% and 42.6% clinical pregnancy rate per ET in RT group and in rcp group was respectively achieved ($p = 0.836$).

Limitations, reasons for caution: Distinguishing a balanced embryo from a normal one was still inevitable. A specific abnormal product would not be scored if small copy number variants or polymorphisms were under 5MB cut-off value due to limited detection rate of SNP array.

Wider implications of the findings: The number of transferrable embryos could be roughly predicted. Besides, for carriers who need a series of stimulation cycles to accumulate embryos, recommendation about when to suspend COH for biopsy could be given. As for carriers with high OHSS risk, the initial does of Gn could be compromised.

Trial registration number: This study was approved by the Ethics Committees of both affiliated hospitals of Sun Yat-sen University. Written consent was obtained from each participant.

P-615 Female chromosomal structural abnormalities do not influence the ovarian response in controlled ovarian stimulation

Z. Shunji[1], L. Keli[2], G. Fei[2], L. Ge[2]
[1]*Reproductive & Genetic Hospital of CITIC-Xiangya, Reproductive Department, Changsha, Hunan, China*
[2]*Reproductive & Genetic Hospital of CITIC-Xiangya, Institute of Reproductive and Stem Cell Engineering, Central South University, Reproductive Department, Changsha, Hunan, China*

Study question: To determine whether patients of chromosomal structural abnormalities have an impact on ovarian response to controlled ovarian stimulation (COS) in preimplantation genetic diagnosis (PGD) patients.

Summary answer: This largest cohort of chromosomal structural abnormalities patients treated with PGD showed that ovarian response to COS was not impaired.

What is known already: In female translocation carriers, balanced X:autosomal translocations are described as being associated with gonadal dysfunction and premature ovarian failure. Some cases of balanced autosomal Roberstonian and reciprocal translocations associated with premature ovarian failure have been reported Few studies concluded that impaired ovarian function resulted in female translocation carriers. Only one study in 2005 concluded that there was a higher proportion of low responders in female translocation carriers Dechanet et al. report the largest study in 2011 which suggest that female chromosomal structural abnormalities did not influence the results of COS in PGD.

Study design, size, duration: A retrospective analysis was performed in a single IVF center. All couples for chromosomal structural abnormalities include Roberstonian translocations, reciprocal translocations and chromosomal inversion, presenting to PGD in either partner from 2013 through 2015. A total of 1075 cycles in 892 women were completed. Stimulation and embryology outcomes were compared between two groups: 559 cycles in 457 women with chromosomal structural abnormalities compared to 516 cycles in 435 women whose male partner had a chromosomal structural abnormalities.

Participants/materials, setting, methods: Average female age, day 3 Follicle stimulating hormone (FSH), antral follicle count (AFC), Anti-Müllerian hormone (AMH) were similar in both groups. Statistical analysis was performed comparing stimulation protocols, oocyet retrival and other cycle parameters.

Main results and the role of chance: 559 cycles of PGD from 457 female chromosomal structural abnormalities were compared to 516 cycles from 435 patients whose male partner had a chromosomal structural abnormalities. No difference was observed for patients characteristics: age (29 years and 28 years, $p = 0.281$), FSH (6.13IU/L vs 6.0 IU/L, $p = 0.40$), AMH (3.9 ng/mL vs 4.83 ng/mL, $p = 0.134$) and AFC (16 vs 17, $p = 0.408$). Concerning COS parameters, no difference was found for the duration of stimulation (11 days vs 11 days, $p = 0.052$), total dose of rFSH (1987.5IU vs 1886.25 IU, $p = 0.08$). No difference was shown for the number of retrieved oocytes (12 vs 13, $p = 0.307$). The cancellation rate for no embryos for transfer after SNP-array was different (13.4% vs 8.5%, $p = 0.01$).

Limitations, reasons for caution: Previous studies have shown a high dose of FSH may be associated with high chromosomal aneuploidy. We need further randomized controlled study to prove whether the cancellation rate for no euploid embryos after SNP-array was different is caused by the increased women age or the mild increased dosage of gonadotropin.

Wider implications of the findings: Our study showed that ovarian response of female chromosomal structural abnormalities was not impaired. Using a standard dose of stimulus allowed an adequate ovarian response.

Trial registration number: none.

P-616 Investigation of the relationship between telomere length and pregnancy outcome

K. Sawakwongpra[1], S. Payungporn[2], S. Chanchamroen[3], T. Ruttanajit[3], W. Quangkananurag[4], T. Tencomnao[1]
[1]*Chulalongkorn University, Allied Health Sciences, Bangkok, Thailand*
[2]*Chulalongkorn University, Medicine, Bangkok, Thailand*
[3]*Safe Fertility and PGD Center, Embryo laboratory, Bangkok, Thailand*
[4]*Safe Fertility and PGD Centre, Medicine, Bangkok, Thailand*

Study question: Is telomere length in human blastocysts potentially used as a predictive marker for pregnancy outcome?

Summary answer: Telomere length in human blastocysts is associated with the pregnancy outcome.

What is known already: Telomeres are the end of eukaryotic chromosome which participate in protecting the chromosome from degradation and maintain chromosome stability. Recent studies have shown that telomeres length is associated with embryo aneuploidy and development. Telomere length in blastocyst stage is longer than cleavage stage. The telomere length in oocyte was investigated, a shorter length was found in non-pregnancy woman as compare to pregnancy woman. Little is known regarding the correlation between telomere length in human blastocysts and pregnancy outcome.

Study design, size, duration: This study was retrospective by including our patients who were subjected to preimplantation genetic screening during January – June 2015. Chromosome screening by next-generation sequencing and bioinformatics analysis for telomere length were performed. Fifty-two blastocysts were biopsied either day 5 or 6. All embryos were transferred and clinical outcome were monitored. Data were collected from only single embryo transferred (SET) cases. Outcome of pregnancy and non-pregnancy cases were compared.

Participants/materials, setting, methods: Telomere lengths of biopsied blastocysts were assessed using next-generation sequencing with bioinformatics analysis to evaluate telomere length in all arms of chromosome (45 regions) of pregnant and non-pregnant groups.

Main results and the role of chance: A significant correlation between telomere length and pregnancy outcome was found in many chromosome arms including 1p, 11p, 11q, 12p, 17p, 20p ($p < 0.05$). Interestingly, the majority of blastocysts of successful pregnancy (35/45) result showed longer telomere length compared to unsuccessful pregnancy (10/45).
Limitations, reasons for caution: We detected telomere length only. Other factors such as chromosome regions other than telomere, etc. may interfere with this study.
Wider implications of the findings: In this study, we performed next-generation sequencing with bioinformatics analysis for determination of telomere length in order to improve the effectiveness of embryo selection.
Trial registration number: Research Involving Human Research Participant, Health Science Group, Chulalongkorn University (RECCU), Thailand (COA 162/2015).

P-617 Dynamics of Eukaryotic Translation Initiation Factor 4 and p70S6K signaling during human primordial-to-primary oocyte transition

E.H. Ernst[1], M.L. Grøndahl[2], S. Grund[3], L. Sunde[4], C. Yding Andersen[5], P. Villesen[3], K. Lykke-Hartmann[1]
[1]*Department of Biomedicine, Reproductive Genetics, Aarhus C, Denmark*

[3]*Science, Aarhus University, Bioinformatics Research Centre, Aarhus C, Denmark*
[4]*Clinical Institute, Aarhus University, Department of Clinical Genetics, Aarhus C, Denmark*
[5]*Copenhagen University Hospital, Rigshospitalet, Laboratory of Reproductive Biology, Copenhagen, Denmark*

Study question: What are the transcriptional dynamics of the Eukaryotic Translation Initiation Factor 4 (eIF4) and p70S6 Kinase signaling during human oocyte activation?
Summary answer: Several members of the eIF4 and p70S6K signaling pathway were significantly ($p < 0.05$) up-regulated during human primordial-to-primary transition, including the mTOR pathway effector *EIF4E*.
What is known already: Correct molecular governance of the human primordial-to-primary oocyte transition is a prerequisite for maintaining a sufficient oocyte stock to last a reproductive lifespan as well as ovulating fertilizable competent eggs. Among others, the PI3K/AKT-, and mTOR signaling pathways regulates primordial oocyte dormancy-, and activation, working both independently, and in parallel. Downstream effectors of these pathways are p70S6 Kinase, involved in cell growth, and The Eukaryotic Translation Initiation Factor 4 with members; eIF4A-, B, E, and γ, interacting as a complex that recruits mRNA to ribosomes initiating translation. Knowledge on eIF4, and p70S6K signaling in the primordial-to-primary transition is spares.
Study design, size, duration: We performed transcriptome analysis of pure pools of isolated human primordial ($n = 436$), and primary ($n = 182$) oocytes, respectively, from three normo-ovulatory patients in their late 20s via Next Generation Sequencing. Following quality control, and normalization, transcripts significantly ($p < 0.05$) highly expressed (Fragments Per Kilobase Of Exon Per Million Fragments Mapped - FPKM value) and with significant ($p < 0.05$) concordance in FPKM level between the three patients were subjected to enrichment analysis.
Participants/materials, setting, methods: Pure pools of primordial, and primary oocytes from three normo-ovulatory patients were isolated using Laser Capture Microdissection. Following transcriptome sequencing on the Illumina HiSeq platform, significantly ($p < 0.05$) highly expressed genes in primordial, and primary oocytes, respectively, and significantly ($p < 0.05$) differentially expressed genes between the two oocyte stages were subjected to enrichment analysis using Ingenuity® Pathway Analysis (IPA). For this study, we analyzed protein-coding transcripts only.
Main results and the role of chance: In the primordial oocyte, 38 highly expressed genes were assigned "Regulation of eIF4 and p70S6K signaling" which was significant ($p = 3.62E-16$). These included the *eIF4EBP2,* a transcript coding for a member of the EIF4E binding family of proteins that negatively regulate the EIF4E complex, and thus translation. Also, *EIF4G* was significantly highly enriched in primordial oocytes. EIF4G associates with EIF4E to form the functional translation complex EIF4F, however, *EIF4E* was *not* highly expressed in primordial oocytes. In the primary oocyte, 44 highly expressed genes were assigned "Regulation of eIF4 and p70S6K signaling" which was significant ($p = 4.76E-22$). These included *EIF4E*, *EIF4G, EIF4H*, *PAIP1*, and *PIK3CB*. No members of the EIF4E binding family were highly expressed in primary oocytes. When looking at genes differentially expressed in oocyte from the two stages, genes significantly up-regulated from primordial-, to primary oocytes were, among others, *EIF4E* and *PIK3CB*. Transcripts significant down-regulated from primordial- to primary included *EIF3D*, coding for a member of a complex that binds to the 40S ribosome and helps maintain the 40S and 60S ribosomal subunits dissociated and thus inactive in translation.
Limitations, reasons for caution: Tissue from a limited number of patients were included. This limitation was met by isolating large quantities of pure oocytes from each stage, sequencing each stage from each patient separately, and only including transcripts with low variance between three patients as well as high FPKM quantity in the enrichment analysis.
Wider implications of the findings: These results indicate a far more translational active primary oocyte as compared to the primordial oocyte and that "Regulation of eIF4 and p70S6K signaling" seems to have a central role in regulating translation of stored mRNA during the primordial-to-primary oocyte transition.
Trial registration number: Not a clinical trial.

P-618 Sperm non-coding RNA profiling as an indicator of reproductive potential

R. Elias[1], T. Cozzubbo[1], N. Pereira[1], S. Cheung[1], Q.V. Neri[1], Z. Rosenwaks[1], G.D. Palermo[1]
[1]*Weill Cornell Medicine, Reproductive Medicine, New York, NY, USA*

Study question: We question if sperm non-coding RNA have an influential role in profiling the infertile male partner and predict his ability to achieve a viable pregnancy.
Summary answer: Non-coding RNA (ncRNA) contributed by the spermatozoon at the time of fertilization are paramount regulatory molecules that can affect embryo developmental competence.
What is known already: Standard semen analysis has many shortcomings when providing information on the performance of spermatozoa when used for assisted reproductive technologies (ART). In men with idiopathic infertility, supplementary tests may be pivotal to gain insight on the paternal contribution to the zygotic genome. NcRNAs are functional RNA molecules that are transcribed from DNA but not translated into proteins. RNA profiling of the spermatozoon unveils a large variety of ncRNA that are now believed to play a very important role in regulating spermatogenesis, fertilization, embryo development and transgenerational epigenetic inheritance.
Study design, size, duration: In a 12-month period, we assessed the RNA profile of men undergoing infertility screening with specific focus on ncRNA. The analysis was performed by measuring the abundance of small non-coding (sncRNA) and long non-coding RNA (lncRNA) and comparing to semen characteristics and ART outcome. RNA extraction from 26 semen specimens was carried out on men undergoing infertility screening, with 19 men in the study group and that were compared to 7 fertile.
Participants/materials, setting, methods: An average of 25×10^6 human spermatozoa was used to isolate total RNA using a spin column commercial kit. The nucleic acid quality and spermatozoal RNA concentration was assessed. The RNA samples were then made into paired-end libraries. Pilot paired-end 76bp RNA-Sequencing (RNA-Seq) using an Illumina platform (NextSeq 500) was carried out and expanded to 60M reads. Expression values were calculated in Fragments Per Kilobase Of Exon Per Million Fragments Mapped (FPKM) and normalized read counts.
Main results and the role of chance: Of the 26 men screened, 8 were selected for sperm RNA-Seq with an average age of 26 ± 5 years presenting with a sperm concentration of 27.3 ± 27, and motility of 46.6 ± 24, and morphology of 3.0 ± 2. From the 23,261 genes assessed, statistical analysis evidenced 28 (0.12%) lncRNAs that were differently expressed ($p < 0.0001$) between the cohort of men all capable to naturally conceive ($n = 3$, control cohort) and men unable to sustain a pregnancy ($n = 5$, study cohort), even after intracytoplasmic sperm injection (ICSI) treatment. Over 90% of these identified genes were overexpressed in the infertile group when compared to the control. All 28 differentially expressed RNAs were classified as long intergenic non-coding RNA (lincRNA). Additionally, a set of genes ($n = 16$) had complete lack of expression

in the cohort of men that were unable to conceive. In relation to their function, 11/16 (68.8%) genes are considered a) to guide chemical modification of other RNAs, b) are associated with methylation, or c) affect both stability and translation of messenger RNA (mRNA).
Limitations, reasons for caution: This study investigates the regulatory role of ncRNA on embryo developmental competence and needs to be confirmed in a larger cohort. The exact regulatory function and localization within the spermatozoon, together with the resulting role in the embryonic genome need to be further investigated.
Wider implications of the findings: Profiling men seeking infertility treatment via RNA-Seq to supplement standard semen analysis may aid in the diagnosis and management of these couples. Screening men for an epigenetic imbalance of sncRNA and lncRNA provides crucial information on the etiology of idiopathic infertility and overall reproductive capacity of the infertile male.
Trial registration number: N/A.

P-619 Alteration of epigenetic profile in cumulus cells of polycystic ovary syndrome patients

E. Hosseini[1], M. Shahhoseini[2], F. Mehraein[1], R. Favaedi[2], S. Aghajanpour[3], P. Afsharian[2], L. Karimian[4], M. Ashrafi[3], R. Aflatoonian[3]
[1]*Department of Anatomy, School of Medicine, Iran University of Medical Sciences, Tehran, Iran*

[4]*Department of Endocrinology and Female Infertility, Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Iran*
[5]*Department of Embryology, Reproductive Biomedicine Research Center, Royan Institute for Reproductive Biomedicine, ACECR, Tehran, Iran*

Study question: This study aimed to evaluate global histone methylation and acetylation levels of cumulus cells in infertile patients with polycystic ovary syndrome (PCOS).
Summary answer: Differential methylation and acetylation levels of lysine 9 of histone3 (H3K9me2 and H3K9ac) in cumulus cells was observed in PCOS patients compared to non-PCOS women.
What is known already: PCOS is the most common endocrine disorder in infertile women. Differential genetic and epigenetic pathways of several genes in various tissue and cell types have been identified as important in etiopathogenesis of PCOS. Previous studies showed that changes in genes expression of CCs which surround oocyte are associated with pathogenesis of PCOS. Of essential genes for ovarian functions and folliculogenesis is CYP19A1 (aromatase coding gene) and its involvement in the pathogenesis of PCOS has been studied. However, comprehensive epigenetic studies in cumulus cells especially for aromatase aberrant gene expression in such disorder have been lacking till date.
Study design, size, duration: Case–control study was conducted on 24 patients (12 infertile PCOS patients and 12 patients with tubal factors of infertility or egg donor) aged 18–36 year old, who underwent ovarian stimulation with GnRH antagonist for Intracytoplasmic Sperm Injection (ICSI) between November 2014 to April 2015. Informed consents were obtained from the participants. Cumulus oocyte complexes (COC) were obtained from follicles during ovarian puncture. Shortly before ICSI, CCs were stripped from the COC with hyaluronidase.
Participants/materials, setting, methods: In order to identify global occupancy level of histone modifications marks (H3K9me2/H3K9ac) to chromatin fractions of CCs, chromatin from samples was extracted and Nucleosome-ELISA was performed using H3K9 acetylation/methylation antibodies. Also, RNA extraction and cDNA synthesis were performed. Expression of CYP19A1 gene was examined by qRT-PCR. DNA incorporation of MeCP2 (as a marker of DNA methylation) and histone modifications marks in PII, PI.3 and PI.4 promoters of CYP19A1 gene were examined by ChIP-Real time-PCR assay.
Main results and the role of chance: Data demonstrated significant increase in global occupancy levels of H3K9 acetylation mark and also significant decrease of H3K9 methylation mark to regulatory regions of chromatin in cumulus cells of PCOS patients vs control group. Also, relative expression of CYP19A1 gene was significantly higher in CCs from PCOS patients compared with the control group. In CCs of PCOS patients, incorporation of histone H3K9ac mark in PII, PI.3 and PI.4 promoter regions of CYP19A1 were significantly higher than those of control group ($p < 0.05$). Furthermore, a significant hypomethylation at H3K9 of promoter PII was observed in PCOS patients ($p = 0.0001$), whereas no significant difference of H3K9 methylation level was detected in PI.3 and PI.4 promoters between patients and control groups. Furthermore, PII and PI.3 promoters in CCs of PCOS patients were significantly DNA hypomethylated in compare to controls ($p = 0.003$ and $p = 0.001$, respectively).
Limitations, reasons for caution: Further studies are necessary to evaluate the role of transcription factors and to elucidate the precise mechanisms involve in aromatase gene expression in PCOS patient.
Wider implications of the findings: Epigenetic alterations could change the genes expression in CCs, which may play a key role in the abnormal folliculogenesis and ovarian function in PCOS. Mechanism of changes in aromatase gene expression, parallel to epigenetic alterations may help to further understand the ovarian hyperstimulation syndrome (OHSS) and its management in these patients.
Trial registration number: N/A.

P-620 Male age is not related with high rates of spermatozoa and embryo aneuploidy

B. Lledo[1], J.A. Ortiz[2], R. Morales[2], A. Fabregat[2], E. Garcia-Hernandez[2], A. Rodriguez-Arnedo[3], J. Llacer[4], R. Bernabeu[4]
[1]*Instituto Bernabeu, Alicante, Spain*
[2]*Instituto Bernabeu, Molecular Biology, Alicante, Spain*
[3]*Instituto Bernabeu, Reproductive Biology, Alicante, Spain*
[4]*Instituto Bernabeu, Reproductive Medicine, Alicante, Spain*

Study question: Is male age related with high aneuploidies in sperm and embryos?
Summary answer: Increased paternal age is not associated with sperm and embryos aneuploidies, therefore aging men do not have increased risk of producing chromosomally abnormal offspring.
What is known already: The frequency of IVF embryo aneuploidies is estimated to be high and its occurrence is related to maternal and paternal factors. The main factor is female age, however paternal factor could play an important role, mainly in patients with abnormal seminal parameters and chromosomal segregation. Nevertheless, the effect of male aging in aneuploidies remains controversial. Since the introduction of new PGS techniques more data have been added to elucidate the male age factor effect on aneuploidies. Moreover, to the best of our knowledge nothing is known about the effect of male aging and aneuploidies using PGSv2.0 in egg-donor cycles.
Study design, size, duration: We performed a retrospective observational study (from January 2013 to December 2015). To show the relationship between male age and sperm aneuploidies, 428 sperm FISH analysis were included in the study. We analysed 155 blastocysts from 51 oocyte-donor cycles in which the partner had a normal sperm FISH in order to evaluate the effect of male age in embryo aneuploidies avoiding the confounding effect of female factor and the abnormal FISH in the embryo aneuploidy.
Participants/materials, setting, methods: Sperm FISH (7 chromosomes analysed) was performed to patients who attended Instituto Bernabeu with a previous clinical history of repetitive miscarriage, implantation failure or severe male factor. Moreover, we included couples attended Instituto Bernabeu for oocyte donation where PGS was performed for previous miscarriage or implantation failure. For PGSv2.0 trophectoderm genome was amplified and aCGH performed using Agilent SurePrintG3 8 × 60K. The association between variables and male age was evaluated by logistic regression and chi-square (SPSSv20.0).
Main results and the role of chance: The seminal parameters and sperm FISH from 428 patients (from 20 to 53 years old) were evaluated. 31% of the analysed patients had an abnormal sperm FISH. No significant difference was reported according to male age and semen parameters according to WHO 2010 criteria ($p = 0.273$). Moreover, no differences in the results of the basic semen parameters and abnormal sperm FISH ($p = 0.626$) were reported. Finally, no differences were reported for male age and abnormal FISH ($p = 0.166$), however patients older than 50 y showed a tendency to higher sperm aneuploidies (50.0% vs 30.5%, $p = 0.081$). To show the effect on embryo aneuploidy we analysed 155 blastocyst from 51 oocytes from donor cycles where the male partner had a normal sperm FISH. The embryo aneuploidy rate was 26%. In these cycles no significant difference was reported between embryo aneuploidy and seminal parameters ($p = 0.83$). When the data was analysed according to sperm morphology and motility, astenozoospermia (46.2%) and teratozoospermia

(44%) showed higher aneuploidies rates than normozoospermia (24.6%) without statistical significance ($p = 0.14$). According to male age no differences were reported in embryo aneuploidy rate ($p = 0.787$) in oocyte donors where the partner had normal FISH.

Limitations, reasons for caution: The study is limited by its retrospective nature. A higher sample size or a prospective randomized design should be used in future studies to corroborate the current findings. In addition, research into the contribution of non-genomic paternal factor in the offspring of older male is needed.

Wider implications of the findings: This investigation reveals that, in cycles controlled for female age and partner with normal sperm FISH, increased paternal age is not associated with embryo aneuploidy. Moreover, this finding has been showed in sperm FISH studies.

Trial registration number: No trial.

P-621 Non-Invasive Prenatal Testing uptake and results among IVF patients in Ontario, Canada: preliminary results

A. Lanes[1,2], S. Doughan[1], E. Graves[1], A. Sprague[1,3], T. Huang[1], M. Johnson[1], A. Leader[4,5,6], B. Potter[2], N. Okun[7], M. Walker[1,5,6,8]
[1]*Children's Hospital of Eastern Ontario, BORN Ontario, Ottawa, ON, Canada*
[2]*University of Ottawa, School of Epidemiology, Public Health and Preventive Medicine, Ottawa, ON, Canada*
[3]*Children's Hospital of Eastern Ontario, Research Institute, Ottawa, ON, Canada*
[4]*Ottawa Fertility Centre, Ottawa Fertility Centre, Ottawa, ON, Canada*
[5]*University of Ottawa, Department of Obstetrics and Gynecology, Ottawa, ON, Canada*
[6]*The Ottawa Hospital, Research Institute, Ottawa, ON, Canada*
[7]*Mount Sinai Hospital, Obstetrics & Gynaecology, Toronto, ON, Canada*
[8]*The Ottawa Hospital, Department of Obstetrics, Gynecology, and Newborn Care, Ottawa, ON, Canada*

Study question: To assess the uptake and results of Non-Invasive Prenatal Testing (NIPT) among patients who conceived through the use of in vitro fertilization (IVF).

Summary answer: This study found that the uptake of NIPT in Ontario, Canada among women who conceived with IVF and/or frozen embryo transfer (FET) was 6.17%.

What is known already: NIPT analyzes cell-free fetal DNA in the plasma of pregnant women to detect fetal trisomies. In 2008, two groups used massively parallel sequencing to identify the over-representation of chromosome 21 in the maternal plasma of pregnancies affected with Down syndrome. Clinical validation trials showed high sensitivity and specificity for detecting common fetal chromosome disorders; subsequently this test became available in Ontario to women who met the risk criteria or on a self-pay basis. Previous studies among IVF conceptions showed that first and second trimester serum markers are different; therefore NIPT may be more appropriate for screening women who used IVF.

Study design, size, duration: This retrospective cohort study included 9,238 IVF and FET treatment cycles conducted in 2013 and 5,147 NIPT screens performed in 2013 and 2014. A proprietary probabilistic linking algorithm developed to link multiple data sources was used to link the NIPT records to the birth records in the Better Outcomes Registry & Network (BORN) Ontario database. This linking algorithm incorporated demographics, health card number, chart number, birthdate, estimated date-of-birth and LMPs.

Participants/materials, setting, methods: The analysis was conducted with data from BORN Ontario and the Canadian Assisted Reproductive Technologies Register (CARTR) Plus. BORN Ontario captures all births within the province of Ontario and CARTR Plus contains all fertility treatment cycles in Canada. This study assessed all IVF and FET cycles in Ontario, Canada that were performed from January 1 through December 31, 2013.

Main results and the role of chance: Among patients who used IVF or FET to conceive, there were 156 ongoing clinical pregnancies that had NIPT to screen for aneuploidies. In comparison, there were 4,988 pregnancies screened with NIPT who conceived spontaneously. NIPT uptake was 6.17% among patients who used IVF to conceive. The majority of women who had IVF and NIPT were between 35 and 39 years of age (55.4%), while the remainder were <35 years (25.2%) and ≥40 years (19.5%). These preliminary results found no high risk cases of Trisomy 18, XO, XXX or XXY among the IVF cohort and less than 6 high risk cases of Trisomy 21 and Trisomy 13 were identified. In comparison, the spontaneous conception group had a similar proportion of high risk Trisomy 21 cases, but a smaller proportion of Trisomy 13 high risk cases. Additionally, there were 109 cases identified as IVF conceptions on the NIPT record that did not link to an IVF record in CARTR Plus, which is considered as the gold standard for Canadian fertility data.

Limitations, reasons for caution: This was a preliminary analysis. This study contains the majority of NIPT records; however there are three additional labs conducting NIPT screening that have not been included yet, as their data were not available at the time of the study.

Wider implications of the findings: Once data for all Ontario-based NIPT screening has been analyzed we will be able to conclude whether NIPT identifies a greater association between IVF and the risk of aneuploidies compared to the risk for women who conceive spontaneously.

Trial registration number: N/A.

P-622 Intercycle variation in embryo aneuploidy rates

J.A. Ortiz[1], B. Lledó[1], R. Morales[1], A. Turienzo[1], J. Ten[2], A. Bernabeu[3], J. Llácer[3], R. Bernabeu[3]
[1]*Instituto Bernabeu, Biología Molecular y Genética, Alicante, Spain*
[2]*Instituto Bernabeu, Biología de la Reproducción, Alicante, Spain*
[3]*Instituto Bernabeu, Medicina de la Reproducción, Alicante, Spain*

Study question: Should we expect similar aneuploidy rates among different cycles in the same couple?

Summary answer: The embryo aneuploidy rate from the first CCS cycle is unable to predict the embryo aneuploidy rate in the next CCS of the same couple.

What is known already: The development of CCS has offered valuable insight into the chromosomal status of embryos. Embryo chromosomal aneuploidy is the most common cause of unsuccessful pregnancy after IVF. CCS applied as a therapeutic tool could improve implantation and live birth rates. Embryo aneuploidies occurrence is related to maternal and paternal factors. Some predictive factors upon embryo aneuploidy rate such as female age have been identified. Nevertheless, the recurrence of aneuploidy with repeated attempts and the predictive value of subsequent outcome remains unclear. Moreover, to the best of our knowledge nothing is known about this topic using PGSv2.0.

Study design, size, duration: We performed a retrospective observational study between January 2014 and December 2015 in Instituto Bernabeu, Alicante, Spain. The study includes the data analysis of 222 trophectoderm biopsies from blastocysts with conclusive CCS results obtained from 76 CCS cycles performed by 38 couples. Couples were categorized into two groups according to aneuploidy rate: below 33%, good prognosis; over 33%, bad prognosis.

Participants/materials, setting, methods: PGS was performed to couples who attended with a previous clinical history of recurrent miscarriage, repeat implantation failure or severe male factor. For PGSv2.0 trophectoderm genome was amplified and aCGH performed using Agilent SurePrintG3 8 × 60 K. The results from the two consecutive cycles performed by the same couple were compared in pairs for each couple. The association between variables was evaluated by Wilcoxon test for paired samples (SPSSv20.0).

Main results and the role of chance: Results from CCS were obtained in 97.5% of the biopsied embryos (5/222). To summarize, in the first and second CCS cycles the average maternal age (35.4 vs 35.5), the number of retrieved oocytes (13.21 vs 15.18), the number of the mature oocytes (11.39 vs 12.21) and the average of biopsied embryo (2.97 vs 2.87) showed no significant differences between cycles ($p > 0.05$). However, when we compared the embryo aneuploidy rate between the first CCS cycle and the second CCS cycle from the same couple, significant differences were reported ($p = 0.011$). According to the categorized (good and poor prognosis) groups, where 33% of embryo aneuploidy rate was used as cut-off, positive and negative predictive values of the first CCS cycle predicting the second CCS cycle were calculated. The positive predictive value was 61% and the negative predictive value was 57%. The sensitivity and specificity of the first CCS cycle predicting the second was 86.3% and 25% respectively.

Limitations, reasons for caution: A higher sample size should be used in future studies to corroborate the current findings. Different categories according to the number of biopsied embryos in each cycle could help us to clarify this finding.

Wider implications of the findings: Our data shows that patients with high embryo aneuploidy rate in the first CCS are highly likely to have a different rate in their second cycle. These data should help patients and clinicians after an unsuccessful CCS to make a decision whether to continue with their own or donated gametes.
Trial registration number:

P-623 Decreased number of mature oocytes in BRCA1 mutation carriers in IVF/PGD.

Study question: Do healthy *BRCA1/2* carriers produce fewer mature oocytes after ovarian hyperstimulation for IVF with preimplantation genetic diagnosis (PGD), when compared to a PGD control group?
Summary answer: Ovarian response, expressed as the number of mature oocytes, was reduced in *BRCA1* carriers, but not in *BRCA2* carriers.
What is known already: The *BRCA* genes are involved in DNA double stranded break repair. It was hypothesized that an accumulation of DNA damage, resulting from an impaired *BRCA* function, would not only lead to a higher risk of ovarian cancer, but might also affect ovarian reserve. Several studies have assessed ovarian reserve in *BRCA1/2* carriers using different endpoints (e.g., anti-Müllerian hormone, age of natural menopause). Conflicting results have been published, also in two studies reporting on ovarian response to hyperstimulation for IVF (/PGD). Besides, the latter studies were of relatively small size and the majority of *BRCA* carriers included were cancer patients undergoing fertility preservation.
Study design, size, duration: A retrospective, multicenter cohort study was performed with data of PGD treatments performed from January 2006 until September 2015. With 50 *BRCA1/2* carriers available, we obtained a power of 80% (α 0.05) to detect a difference of the previously described magnitude (i.e., 3.4 oocytes) when including 200 controls.
Participants/materials, setting, methods: Healthy female *BRCA1/2* carriers, without a history of breast cancer and/or chemotherapy, who underwent PGD were included in the exposed group. Controls underwent PGD for other PCR-PGD indications, unsuspected for a possible diminished ovarian reserve status. Only the first cycle performed in a long GnRH suppressive agonist protocol with at least 150 IU follicle stimulating hormone (FSH) was included for each couple.
Main results and the role of chance: Of 50 exposed couples, 38 were stimulated in a long agonist protocol with at least 150 IU FSH during their first cycle. This was the case for 154 out of 200 control couples. The mean number of mature oocytes was 6.6 ± 3.3 in *BRCA1* carriers, 7.4 ± 3.3 in *BRCA2* carriers, and 8.9 ± 4.7 in controls. Multiple linear regression analysis with the number of mature oocytes as dependent variable and adjustment for center, age, BMI, type of gonadotropin used and the total dose of gonadotropins administered, revealed a significantly lower yield in *BRCA1* mutation carriers as compared to controls (p = 0.01), but not in *BRCA2* mutation carriers as compared to controls (p = 0.50).
Limitations, reasons for caution: The exclusion of couples who were treated in another IVF protocol or with less than 150 IU FSH, may have introduced selection bias. Furthermore, we were unable to control for potential confounding lifestyle factors (e.g., smoking).
Wider implications of the findings: Our findings may illustrate an influence of the *BRCA1* gene on ovarian reserve. Prospective studies are needed to provide final proof for the role of the *BRCA* genes in ovarian reserve conditions.
Trial registration number: Not applicable.

P-624 Investigating genetic associations with endocrine hormone levels in women undergoing fertility treatment

N. Kumar[1], S. Bristow[2], R. Shraga[3], S. Yarnall[2]
[1]*Recombine, New York, NY, USA*
[2]*Recombine, Product, New York, NY, USA*
[3]*Recombine, Bioinformatics, New York, NY, USA*

Study question: Are single nucleotide polymorphisms (SNPs) associated with baseline serum hormone levels and endocrine signaling pathways in women?
Summary answer: We found that a SNP in the FSHR gene is associated with both AMH and day 2/3 FSH levels.
What is known already: The hypothalamic-pituitary-ovarian (HPO) axis and AMH hormone action are both important signaling pathways that promote oocyte growth and maturation. Disruptions to this signaling pathway can lead to subfertility, infertility, or other infertility indications. Research groups have shown that endocrine levels in women are affected by genetic influences. For example, SNPs within FSHR have been linked to FSH levels, which have been postulated to affect ovarian response in assisted reproductive technology (ART) treatments.
Study design, size, duration: We employed a retrospective cohort study design to identify significant associations between endocrine hormone levels and endocrine hormone SNPs. A total of 189 female study subjects were included in the study. Each participant consented to research in a de-identified manner. Patients were enrolled in the study between May 2014 and November 2015.
Participants/materials, setting, methods: The following exclusion criteria was used: PCOS diagnosis, FSH >11 mIU/mL, LH >30 mIU/mL, and progesterone >3 ng/mL. AMH levels and day 2/3 serum FSH, LH, and progesterone levels were collected by chart review. Genetic polymorphisms within FSHR, FSHB, and AMH were measured using Illumina's Infinium HD Genotyping assay. Welch's t-test was used to test 58 associations between hormone levels and SNPs. A p-value of $p < 0.05$ was considered significant.
Main results and the role of chance: Of the 58 comparisons between endocrine hormone levels and related SNPs, we observed two significant associations. First, we found that FSH levels were higher in individuals carrying the wildtype genotype than in individuals identified as heterozygous or homozygous mutant for the FSHR p.S680N SNP (p = 0.0396). This finding validates previous research demonstrating that FSH levels are impacted by the FSHR gene. Second, we found that AMH levels were lower in individuals carrying the wildtype or heterozygous genotype than in individuals identified as homozygous mutant for the FSHR p.S680N SNP (p = 0.040). To our knowledge, this association has not been shown previously. However, one study focused on a PCOS patient population (a group of participants excluded from this study) showed no association between AMH levels and FSHR SNPs. These findings reinforce the genetic influences on HPO signaling. The other comparisons between hormone levels and SNPs were not found to be significant.
Limitations, reasons for caution: A larger sample size may identify other significant associations this study did not observe. Additionally, the pool of study participants were not controlled for based on ethnicity or age, both of which may act as confounding factors.
Wider implications of the findings: HPO signaling is highly interconnected; multiple SNPs inherited together may influence signaling efficiency in more complex ways than previously thought. Larger studies designed to investigate multifactorial influences on endocrine signaling will lead to a deeper understanding of the clinical implications.
Trial registration number: NA.

P-625 Investigating X chromosome structure during mouse pre-implantation development

N. Ranisavljevic[1], K. Ancelin[1], T. Piolot[1], C. Patrat[1], E. Heard[1]
[1]*Institut Curie, Mammalian Developmental Epigenetics Group, UMR3215, Paris Cedex 05, France*

Study question: The aim is to analyse the structural organisation of the X chromosome in pre-implantation embryos at the single cell level.
Summary answer: DNA FISH analysis of sub-megabase scale regions reveals major transitions in structural organisation of the mouse X between the 2 and 8-cell stages of development.
What is known already: Using Chromosome Conformation Capture and super-resolution microscopy approaches to examine the X-inactivation centre, our lab previously uncovered the existence of discrete topologically associating domains (TADs) each spanning several hundred kilobases, that display preferential interactions *in cis* (Nora et al., 2012). TADs are conserved across cell types, as well as between human and mouse, and appear to represent functional units that partition the genome. However, when and where TADs are established during development, or whether they are simply inherited from the gametes, remains unknown.
Study design, size, duration: Not applicable. Experiments have been performed in our lab in between May and November 2015.
Participants/materials, setting, methods: Wild type mouse female (C57BL/6J background) induced by hormonal treatment are used to produce preimplantation embryos (2 and 8-cell stage). These embryos were used for 3D DNA FISH using two-color probes spanning several hundred kilobases within a TAD or spanning two TADs, and imaged with super-resolution Structured Illumination Microscopy (SIM). Images were treated using ImageJ software homemade macro describing the Pearson correlation coefficient in both channels. Results were processed with Origin software for statistical analysis.
Main results and the role of chance: A locus encompassing two TADs on the X chromosome was found to display a similar structural organisation in 8-cell stage embryos as previously described in mESCs (9 embryos examined, 41 signals examined and $p = 1.9.10^{-9}$, two samples *t*-test). However, at an anterior developmental stage (2-cell), a very different organisation is observed (59 embryos examined, 214 signals examined and $p = 1.8 \times 10^{-3}$, two samples *t*-test). This suggests that TAD organisation may occur sometime between the 2- and 8-cell stages. This implies that genome reorganisation may occur following zygotic genome activation rather than being inherited from the gametes, although this requires further investigation. We are now examining different regions of the genome, on the X chromosome and autosomes.
Limitations, reasons for caution: Information obtained with 3D DNA FISH is limited to small regions of the genome, and too sparse for description of chromosomal organisation transitions. Chromosome Conformation Capture technique applied to single cells (Nagano et al; Nature 2013) is currently adapted in the lab to obtain chromosome-wide information for early mouse embryos.
Wider implications of the findings: It will be important to expand our findings to other mammalian species. Human embryos obtained through IVF procedure and given up for research will be used to repeat similar DNA FISH analyses.
Trial registration number: N/A.

P-626 Oocyte vitrification is a valid strategy to accumulate gametes for preimplantation genetic diagnosis for aneuploidy using next generation sequencing

S. Chamayou[1], M. Sicali[1], C. Alecci[1], C. Ragolia[1], D. Lombardo[1], G. Storaci[1], S. Romano[1], A. Liprino[1], A. Cardea[1], A. Guglielmino[1]
[1]Unità di Medicina della Riproduzione, U.M.R. Soc. Coop A.r.l., Laboratory director, Sant'Agata Li Battiati, Italy

Study question: What is the relevance of aneuploidy in blastocyst from vitrified/warmed oocytes compared to fresh-oocytes from the same patients? How many surplus euploid embryos are obtained?
Summary answer: the percentage of aneuploidy in blastocyst produced from vitrified and fresh oocytes is similar. Oocyte vitrification increases the number of euploid viable blastocyst to transfer.
What is known already: Next Generation Sequencing is a valid technology for comprehensive chromosomal screening. Oocyte vitrification gives similar fertilization and pregnancy rates than fresh oocytes.
Study design, size, duration: The diagnosis of aneuploidies was performed from trophectoderm cells of blastocysts produced from fresh and vitrified/warmed oocytes on 51 infertile couples.
Participants/materials, setting, methods: 51 patients underwent a first ovarian stimulation to accumulate oocytes and a second to microinject with partner sperm together with the previously accumulated and warmed oocytes. Few trophectoderm cells were removed on day 5–6 blastocysts produced from the two sources of oocytes. Whole genome amplification was performed on few trophectoderm cells. Sample libraries were prepared Ion plus fragment library kit. Enriched barcoded-samples libraries were sequenced on next generation sequencer. Biopsied blastocyst were vitrified.
Main results and the role of chance: 101 blastocysts from fresh and 100 blastocysts from vitrified/warmed oocytes were produced. 100% of the samples were amplified after whole genome amplification. Chromosomal analyses were completed for all samples. 43 blastocyst from vitrified oocytes and 35 from fresh oocytes from sibling patients (42.6% versus 35.0%, $p > 0.05$) were euploid. Implantation rates of warmed and transfer of euploid blastocyst were similar from the two sources of oocytes (8/15 from vitrified oocytes and 18/31 from fresh oocytes). PGS results were confirmed after prenatal diagnosis.
Limitations, reasons for caution: The number (51) of infertile patients treated for PGS from vitrified and fresh oocytes remains limited. As described in the scientific literature, there can be discordance between chromosomal status of inner cell mass and biopsied trophectoderm cells. In NGS analysis, the percentage of aneuploidy should be measurable.
Wider implications of the findings: Preimplantation Genetic Diagnosis for aneuploidy on day 5 can lead to a limited number of euploid embryos to transfer or transfer cancellation. Oocyte vitrification and accumulation increases the chance to transfer an euploid blastocyst. This strategy can be applied to poor prognosis patients.
Trial registration number: no trial registration number.

P-627 Endometrial receptivity array (ERA) and the use of personalized embryo transfer (pET) in cases undergoing comprehensive chromosomal screening (CCS) for implantation failure (IF)

N. Findikli[1], F.K. Boynukalin[2], E. Yagmur[2], M. Kavrut[2], G. Karlikaya[2], M. Gultomruk[3], M. Bahceci[2]
[1]Bahceci Fulya IVF Centre, Embryology Laboratory, Istanbul, Turkey
[2]Bahceci Fulya IVF Centre, Infertility Clinic, Istanbul, Turkey
[3]Bahceci Fulya IVF Centre, R&D Department, Istanbul, Turkey

Study question: This study aims to analyze the relative efficiency of endometrial receptivity assessment, personalized embryo transfer and CCS in improving the cycle outcome in IF cases.
Summary answer: The results show that pET can be positively associated to the cycle outcome, which can be maximized by inclusion of CCS in older patients.
What is known already: Recent studies indicate that, there exists an increased percentage of displacement regarding the endometrial window of implantation (WOI) in patients experiencing recurrent implantation failures. However, the relative contribution of WOI displacement with respect to the number of previous treatment failures, the age of the female as well as the corrective contribution of pET together with the availability of euploid blastocyst transfer in IF have not yet been assessed in the literature.
Study design, size, duration: This prospective cohort study was performed in Bahçeci Fulya IVF Centre and includes 132 frozen embryo transfer (ET) cycles of 195 patients whose WOI have been assessed by ERA between November 2013 – November 2015.
Participants/materials, setting, methods: All female patients included in the study were devoid of any known endometrium-related pathologies. An endometrial biopsy was taken from the uterus fundus by the help of a pipelle either on day LH+7 in a natural cycle or on day P+5 in an HRT cycle. The distribution of ERA results and the impact of pET strategy in our study population (number of previous trials, presence of advanced maternal age etc.) has been retrospectively analyzed.
Main results and the role of chance: Overall, in 28.7% of the cases, ERA test displayed non-receptive endometrium. Subgroup analysis according to previous number of trials, presence of previous early miscarriages as well as female age showed no significant differences ($p > 0.05$) among the groups, but a similar proportion of WOI displacement was stably present in all subgroups studied. Performing pET in these patients sufficiently ameliorated the pregnancy and implantation rates. In 69 cycles, a FET has been performed according to ERA results-only and in 63 cycles, frozen embryo replacements were performed in combination with ERA results and euploid blastocyst(s) after CCS. In frozen ET cycles where females were >38 years, the use of ERA and CCS together have been found to be maximize the clinical outcome as compared to ERA-only cycles ($p < 0.02$).

Limitations, reasons for caution: This study includes a large series of cases in which a possible contribution of endometrial receptivity assessment has been evaluated retrospectively. Well–designed ITT analyses and large prospective randomized studies are needed to better evaluate the most optimal use of such assessment approaches in the near future.
Wider implications of the findings: Our results can show that, in cases with IFs, application of ERA test and subsequent pET in younger females can improve the pregnancy rates by approximately 20%. In older females (≥38 years), pET can only be beneficial when combined by frozen ET using euploid embryos after CCS.
Trial registration number: None.

P-628 An ESHRE PGD Consortium multicentre retrospective cohort study investigating the clinical utility of PGD with human leukocyte antigen (HLA)-matching and factors influencing a positive outcome

Study question: Has PGD-HLA been successful relative to diagnostic and clinical efficiency? Which parameters (assisted-reproduction (ART), embryology, genetic diagnosis) influence likelihood of donor-live-born baby/babies and transplantation?
Summary answer: Genetic probability remains a major limitation to overall success; further data analysis should highlight any influence from other variables in ART, embryology and genetic diagnosis.
What is known already: The first clinical cases for PGD-HLA were reported in 2001. It is now a well-established procedure, with an increasing number of cycles performed every year. However, PGD-HLA is still offered by relatively few PGD centers, including only 15% of the PGD Consortium members (based on annual data collections). The currently available data is fragmented and most reports on PGD-HLA application are limited in number and scope. Published systematic details on methodology, diagnostic results, overall ART success and haematopoietic stem cell transplantation (HSCT) outcomes are limited, precluding an evaluation of the true clinical utility of PGD-HLA cycles.
Study design, size, duration: Retrospective multi-centre cohort study aimed at investigating aspects of PGD-HLA cycles (performed 2001–2015) influencing positive outcomes: birth of genetically suitable donor-baby(ies) and HSCT. In April 2014, 30 PGD centres (Consortium members and non-members) with published/known PGD-HLA activity were invited to participate. Between February-September 2015, 14 centres submitted their data, through a custom-designed secure database, with login access (unique/centre). Data parameters covered all aspects of PGD-HLA cycles (ART, embryology and genetic diagnosis), donor-babies born and HSCT.
Participants/materials, setting, methods: From 716 cycles submitted by 14 centres (performed 2001–2015), data quality evaluation excluded 12 cycles, leaving 704, from 364 couples. The online database, based on Redcap, a free, secure, web-based data-capture application, was customized by CLEO (Collaborative Center for Clinical Epidemiology and Outcomes Research), Athens. Continuous variables are presented using mean, standard deviation, median and interquartile range, and categorical variables using absolute and relative frequencies. Data management and statistical analysis used STATA SE v.11.
Main results and the role of chance: Data included >700 HLA-PGD cycles performed between August 2001 and September 2015. Mean maternal age was 33 years. Most cases (81%) involved HLA-typing with concurrent exclusion of a single monogenic disease (58% with beta-thalassemia). In 92.5% couples, both partners were fertile, with average 1.93 HLA-PGD cycles/couple. Overall, 9751 oocytes were retrieved (13.89/cycle) and 5552 embryos analyzed (7.88/cycle). Most cycles involved fresh oocytes (94.87%) and day-3 embryo biopsy (85%). In 97% of cycles the genotyping method involved PCR only. 56.6% of couples achieved an embryo transfer (ET). Of 4392 embryos diagnosed (79% of analyzed), 644 were genetically suitable (16.2% of those analysed for HLA alone, ≈10% of those analysed for HLA with exclusion of monogenic disease). 598 embryos were transferred in 382 cycles, leading to 163 HCG-positive pregnancies (pregnancy rate/ET 42.67%, pregnancy rate/initiated cycle 24.3%). Until September 2015, 127 babies had been born, with 30 pregnancies ongoing. HSCT was performed in 55 cases (7.8% cycles initiated), of which 67% involved combined umbilical cord-blood and bone marrow transplantation from the HLA-identical sibling donor; 76.1% of transplants reported no complications. Technical aspects of HLA-PGD protocols, diagnostic findings, variable practice between centres, and other parameters potentially associated with a positive outcome will be discussed.
Limitations, reasons for caution: The findings of the study may be limited as not all PGD centres with PGD-HLA experience participated. Furthermore the study is based on retrospective data collection, from centres with variable practices and strategies for ART, embryology and genetic diagnosis.
Wider implications of the findings: This is the first multicentre study evaluating clinical utility of PGD-HLA, indicating variations in practice and outcomes throughout 15 years and between centres. Complete data analysis should highlight those parameters important for positive outcomes, approaches for further optimization, and provide health-practitioners and patients important information prior to initiating a cycle.
Trial registration number: Not a registered trial, but partly funded by ESHRE to customize the Redcap database and support data analysis by Drs. Georgia Kourlaba and Eleni Kourkouni, CLEO. The study also wishes to acknowledge Athens University Research Institute for the Prevention and Treatment of Genetic and Malignant Diseases of Childhood, Athens, Greece, for supporting PGD in the Department of Medical Genetics, University of Athens.

P-629 AMH and AMHR2 genes sequence variations in poor responders patients and controls – a pilot study

A. Leitao Marques[1], C. Ribeiro[2], T. Azevedo[2], T. Almeida-Santos[1], M. Grazina[2]
[1]*Centro Hospitalar e Universitário de Coimbra, Serviço de Medicina da Reprodução, Coimbra, Portugal*
[2]*University of Coimbra, Center for Neuroscience and Cell Biology, Biochemical Genetics Laboratory, Coimbra, Portugal*

Study question: Could genetic variations of *AMH* and *AMHR2* predispose infertile women to poor ovarian response?
Summary answer: Sequence variations in *AMH* gene and its signaling pathway (*AMHR2*) can influence AMH function and may be important to regulate ovarian reserve.
What is known already: The rate of follicular atresia is not equal for all women and genetic factors have been implicated in 5–15% of cases primary ovarian insufficiency. Ovarian reserve dictates the response to controlled ovarian stimulation and, to some extent, the pregnancy rate after IVF. Multiple studies have shown that variants of the *AMH* and *AMHR2* genes are associated with reproductive patterns of women, namely follicular phase E2 levels, unexplained infertility and age at natural menopause, suggesting a role of the AMH signaling pathway in the regulation of ovarian reserve.
Study design, size, duration: Cross-sectional pilot study where the entire coding sequence and the intron-exon junctions of the genes *AMH* and *AMHR2* were analysed in 34 infertile women with poor ovarian response. The variations found were then analysed in silico and then in 75 fertile (parous) controls.
Participants/materials, setting, methods: We recruited 34 infertile poor responder patients, as strictly defined by the Bologna criteria, and 75 controls at Centro Hospitalar e Universitário de Coimbra, Portugal (CHUC) and an

informed consent was obtained. The entire coding sequence and the intron-exon junctions of the genes *AMH* and *AMHR2* were analysed by Sanger sequencing in the study group and screened in the controls. An *in silico* analysis was performed using PyMol®.
Main results and the role of chance: A total of 20 different sequence variations were found: 14 in *AMH* and 6 in *AMHR2* gene, 3 of which were novel, further submitted to *in silico* analysis. This analysis reveals that 4 heterozygous alterations in *AMH* gene have a predictable functional impact. A preliminary screening showed that the alterations p.Asp288Gln and p.Gln185Glu are absent in 75 controls. Prediction by PyMol® analysis reveals that the mutated proteins have a significantly different structure when compared with the normal protein.
Limitations, reasons for caution: Reduced sample size, since it is a genetic study limited to a Portuguese population sample.
Wider implications of the findings: This study reveals new insights into the pathogenesis of ovarian insufficiency. There are no similar studies performed in European patients and our results agree with previous studies showing that variants of the *AMH* and *AMHR2* genes are associated with reproductive patterns, unexplained infertility and age at natural menopause.
Trial registration number: 041-CE-2013.

P-630 Validation of the de-novo segmental (>16 megabase) loss detected by next generation sequencing in 24 blastocysts from preimplantation genetics diagnosis

Z. shuang[1,2], C. Dehua[1,2,3], X. Pingyuan[1,3,4], O. Qi[1,3,4], H. Liang[1,2,3,4], X. Bo[3,4], L. Guangxiu[1,2,3,4], L. Ge[1,2,3,4]
[1]*Institute of Reproductive & Stem Cell Engineering, Central South University, Reproduction, Changsha, Hunan, China*
[2]*Key Laboratory of Stem Cells and Reproductive Engineering, Ministry of Health, reproduction, Changsha, Hunan, China*
[3]*Reproductive and Genetic Hospital of Citic-Xiangya, Reproduction, Changsha, Hunan, China*
[4]*China and National Engineering and Research Center of Human Stem Cell, Reproduction, Changsha, Hunan, China*

Study question: Whether the de-novo segmental abnormality above 16 megabase (Mb) detected in next generation sequencing–preimplantation genetics diagnosis (NGS-PGD) is authentic?
Summary answer: De novo segmental abnormalities above 16 Mb occurred in blastocysts and could be detected by NGS, but some existed as mosaicism in TE and ICM.
What is known already: Recently, NGS become a routine technique to be applied in PGD that can screen the whole chromosomal set and detect de-novo segmental abnormality. De novo chromosomal abnormalities had been validated to be accurate in many publications but the anthenticity of the de-novo segmental abnormalities, especially for those abnormalities above 16 Mb that usually would be reported have not been validated.
Study design, size, duration: The study was set in an IVF center at the Reproductive and Genetic Hospital of CITIC-Xiangya. Retrospective studied of 1759 embryos from Robertsonian or reciprocal translocation or inversion carriers that analysed by NGS-PGD between April 2013 and December 2015. Meanwhile using FISH to validate the de-novo segmental loss (>16 Mb) in 24 non-transferred blastocysts donated for research.
Participants/materials, setting, methods: Twenty-four blastocysts with the de-novo segmental loss (range from 16 Mb to 147.7 Mb) were thawed, all the blastocyst were then cut into half with either trophectoderm (TE) part and inner cell mass (ICM) part. All materials were separately fixed and analyzed by FISH using a combination of probes (locus-specific identifiers, centromeric and subtelomeric), specially designed to properly validate the de-novo segmental abnormalities. The FISH results were compared with those of NGS-PGD.
Main results and the role of chance: The frequency of the de-novo segmental abnormalities in embryos which applied NGS-PGD were 13.5% (238/1759), and there were 98 embryos exhibited only the de-novo segmental abnormalities. The de-novo segmental gain or loss discovered by NGS were occurred on all chromosomes, mainly on the chromosome 3, 8, 11, 12, 18 and X. For the 24 blastocysts, 23 (95.8%) blastocysts were successfully thawed and reliable FISH results were obtained; the remaining one had no result because of the degradation after thawing. After FISH analysed, 20 (86.9%) of 23 de-novo segmental loss detected by NGS were confirmed. The FISH analysis did not detect the de-novo segmental loss in three blastocysts, in which all cells analyzed were normal. Among the 20 blastocysts, 9 blastocysts had the de-novo segmental abnormalities in both TE and ICM, 11 blastocysts are mosaic with both de-novo segmental loss and normal signals. However, the mosaicism were only detected in the TE, and the corresponding ICM had normal signals in 2 blastocysts.
Limitations, reasons for caution: The sample size in the validation study is small and could not had consolidate conclusion on the results observed above. Further study with a larger sample size and a set up for both gain and loss may be helpful.
Wider implications of the findings: The preliminary study indicated that de-novo segmental abnormalities exist in human blastocyst from in vitro fertilization and may account partially for the implantation failure.
Trial registration number: Not application.

P-631 The proportion of aneuploidies is associated with the clinical outcome in patients with repetitive implantation failure undergoing pre-implantation genetic screening by aCGH

C. Tabanelli[1], A.P. Ferraretti[1], E. Feliciani[1], M.C. Magli[1], A. Pomante[1], L. Gianaroli[1]
[1]*S.I.S.M.E.R. S.r.l., Reproductive Medicine Unit, Bologna, Italy*

Study question: Repetitive implantation failures (RIF) may have different origins: is pre-implantation genetic screening (PGS) able to identify genetic cause from other causes?
Summary answer: PGS is able to identify the main cause of previous failures (genetic or other factors) when considering the proportion of aneuploidies.
What is known already: The repetitive implantation failure of good-quality embryos can have multiple causes but no diagnostic tests are available to identify the etiology. Therefore, the therapeutic strategies proposed can produce controversial results and are not able to identify the etiology. Oocytes/embryos defects are considered one of the potential cause of RIF and PGS is offered to these patients since years. Data from retrospective and prospective studies shows that, overall, RIF patients have more chromosomal abnormalities compared to control groups. However, the usefulness of PGS in terms of clinical outcome is still controversial, since other factors can be involved.
Study design, size, duration: Retrospective analysis of 60 RIF couples (failure of ≥3 transfers with good-quality embryos, female age ≤ 40 yrs, normal ovarian reserve, normal karyotype, normal uterine cavity) undergoing PGS by aCGH between April 2012 and April 2014. A severe male factor was present in 13 couples. The control group consists in a cohort of 77 RIF couples having the same criteria but not undergoing PGS.
Participants/materials, setting, methods: According to the policy adopted during the study period, couples without a severe male factor underwent polar bodies biopsies and aCGH analysis if zygote developed normally to 6–8 cells (47 couples, group A); couples with a severe male factor underwent PGS on blastomere (13 couples, group B). For the analysis of outcomes (LBR/patient), group A was divided depending on the proportion of aneuploidies: <50% and >50%.
Main results and the role of chance: No differences resulted between control and PGS cycles in the number of eggs (8.1 ± 4.5 vs 8.7 ± .4.0) and in the fertilization rate (78%vs 76%). The mean female age was 37.5 in PGS and 36.4 in control. In controls, the LBR was 26% Overall, in the PGS group, the incidence of aneuploidies was 69% (205/295) and the LBR was 20%. In group A PGS cycles (no severe male factor): 25 patients (53%) had a proportion of aneuploidies <50%. This group had a high probability to be transferred but the LBR (20%) was not improved by the transfer of embryos selected by PGS; other factors may be involved. 22 patients (47%) had a proportion of aneuploidies >50%. Those patients had a high risk to be not transferred (9/13), but when at least one embryos was available for transfer, the LBR (46%) resulted improved by PGS, suggesting that the main cause of the previous failure was a genetic factor. In group B PGS, the incidence of aneuploidies was 75%, 5 patients were transferred but even the transfer of euploid embryos was not able to improve the outcome (LBR 20%) suggesting complex abnormalities in embryos.
Limitations, reasons for caution: The study is a retrospective analysis and the number of cases is limited. However, the published studies on RIF and PGS do not usually include a significant higher number of cases and no studies analyzed the data depending on the proportion of aneuploidies.

Wider implications of the findings: RIF is a big challenge since its multiple causes and because no diagnostic tests are available to identify the main factor. Therapies are empirical and produce controversial results. Our preliminary data suggest that the proportion of aneuploidies by PGS can have a diagnostic role in identifying the RIF etiology.
Trial registration number: Not applicable.

P-632 A novel preimplantation genetic diagnosis strategy for Duchenne muscular dystrophy based on targeted next-generation sequencing and linkage analysis

J. Du[1], X. Hu[1], T. Feng[2], L. Xing[2], J. Dai[1], W. He[1], X. Liu[2], K. Luo[1], F. Gong[1], W. LI[1], G. Lu[1], G. Lin[1]
[1]*Reproductive & Genetic Hospital of CITIC-Xiangya, Genetic Centre, Changsha, Hunan, China*
[2]*Peking Jabrehoo Med Tech. Ltd., Peking, China*

Study question: To establish a rapid and broadly applicable strategy of PGD for DMD carriers based on target sequencing and linkage analysis.
Summary answer: Targeted next-generation sequencing (NGS) combined with SNP linkage analysis is a efficient strategy than previous methods and being applicable to 99% of DMD carriers.
What is known already: DMD is the most common fatal genetic disorder diagnosed in childhood, with an incidence of 1/3500 in live male births. The gene is about 2.3 Mb and has 79 exons. Multiple mutations were found, including large deletions (60%), large duplications (10%) and point mutations (30%). The traditional PGD approaches take up to three months to complete the pre-experiment. Although karyomapping is a faster PGD technology and suit for a wide range of conditions, it is not suit for DMD due to inadequate SNPs. Now we are still lack of a high efficiency and easy to clinical extension approach for DMD-PGD.
Study design, size, duration: Targeted NGS workflow based on an AmpliSeq panel was designed for sequencing 480 SNPs and coding region of DMD gene on Ion PGM™ Sequencer. Total 99 female carriers with DMD heterogeneous mutation were recruited for testing the application range. Of them 3 patients were carried out 3 PGD cycles to verify the efficacy of the novel DMD-PGD scheme. The work was carried out from January 2014 to December 2015.
Participants/materials, setting, methods: The study was set at the Reproductive and Genetic Hospital of CITIC-Xiangya, China. The designed AmpliSeq panel includes the coding region of DMD gene and 480 SNPs selected from 1 Mb upstream to 1 Mb downstream of the gene. Ninety-nine females carrying heterogeneous DMD gene mutation, including 51 large deletions, 15 large duplications and 32 point mutations, were recruited to determine the efficacy of the panel. Among them 3 carriers underwent PGD and 14 embryos were tested.
Main results and the role of chance: Among the 99 female DMD carriers, 98 had at least 3 informative SNPs in the upstream and downstream of the mutation loci of the gene, respectively. The successful rate of haplotype construction was 99% (98/99). The point mutations were detected in all 32 carriers and the efficacy rate was 100%. Of the 14 embryos from 3 PGD cycles for 3 families, 1 was normal male embryo, 4 were normal female embryos, 5 were female carrier embryos and 4 were in affected embryos. Among them, 2 families were transferred 2 normal female embryos and 1 female carrier embryos, respectively. The PGD results were confirmed by the following prenatal diagnosis.
Limitations, reasons for caution: This strategy can not directly detect the large deletions and duplications of DMD gene. In addition, 1 case (1%) had less than 3 informative SNPs within 1 Mb upstream and 1 Mb downstream of the mutation loci of the gene, which might decrease the accuracy of the results.
Wider implications of the findings: We establish a new DMD-PGD strategy based on targeted NGS and linkage analysis. Ninety–nine percent of female carriers were successfully constructed haplotype. The new scheme is rapid, accurate, low cost and easy to clinic extension.
Trial registration number: Not applicable.

P-633 Next generation sequencing (NGS) metrics following DOP-PCR whole genome amplification (WGA) of single and multi-cell samples for PGS

M.J. Jasper[1], T. Hardy[3], M. Pinese[2], M. McCabe[2], W. Ledger[3], M. Fraser[1]
[1]*Reproductive Health Science Ltd, Thebarton, SA, Australia*
[2]*Kinghorn Centre for Clinical Genomics, Garvan Institute of Medical Research, Darlinghurst, NSW, Australia*
[3]*School of Women's & Children's Health, University of New South Wales, University of New South Wales, Randwick, NSW, Australia*

Study question: Evaluate single cell and limited DNA template sample NGS metrics following WGA and sequencing on alternate capacity sequencers.
Summary answer: The amount of sequencing data available for interrogation is highly dependent on the number of samples multiplexed in a library, read length and platform configuration.
What is known already: When limited source material for genome wide evaluation is available, WGA is often used to generate sufficient DNA for downstream analysis. Limited WGA technologies are commercially available, and WGA using the EmbryoCellect™ kit (Reproductive Health Science Ltd) protocol utilizes a proprietary degenerate oligonucleotide primed PCR (RHS-DOP-PCR). When used in conjunction with the kit array, screens low template samples for aneuploid status. Aneuploidy screening using NGS technology is becoming increasingly popular in the IVF setting. The total aligned genomic and mitochondrial DNA sequence data generated from an NGS run is potentially sufficient for subsequent sample screening for other genetic anomalies.
Study design, size, duration: The aim of this study was to determine NGS run and aligned read data metrics from a range of NGS platforms as models for PGS utilizing the DOP-PCR based WGA of single cell and multi-cell aliquots as described (EmbryoCellect™ kit). Additionally, fluorescently labelled test and reference WGA DNA was hybridized to the EmbryoCellect™ kit microarray, consisting of repeat-depleted chromosome-specific probes. The dye ratio was determined and compared to the known karyotype of the sample.
Participants/materials, setting, methods: Single cell and 5-cell aliquots sorted from euploid and aneuploid cell lines (Coriell Institute) were subjected to WGA using EmbryoCellect™ kit protocol. Nextera libraries were prepared from WGA and unamplified gDNA samples and subsequently sequenced (paired-end) on either a MiSeq (n = 48; read length 300 bp), NextSeq (n = 23; 150 bp) or X-10 (150 bp) platform according to standard protocol (Illumina). The sequencing data was bioinformatically aligned to hg19. Sequencing run and aligned data metrics were tabulated for comparison.
Main results and the role of chance: On completion of the sequencing runs, approximately 4.5 fold more reads were generated using the NextSeq compared to MiSeq platform (mean; 1.3 million reads versus 5.8 million reads per sample were mapped to hg19). The sequencing of single cells and 5-cell aliquots on the X-10 yielded 110,000–120,000 Mb in comparison to 126 000 Mb from sequencing of the unamplified gDNA sample or approximately 400 million reads per sample. The average single cell Q30 scores were >89% for the Miseq run and >82% for the NextSeq NGS run. The average X-10 Q30 scores for single cells, 5-cell aliquots and gDNA were 83%, 81% and 87% respectively.
Limitations, reasons for caution: This data has been generated from limited NGS runs, and therefore increasing the number of sequencing runs is necessary to increase the number of samples per sequencing parameter/condition.
Wider implications of the findings: While specific gene sequence and mitochondrial DNA is present in single cell NGS data, breadth and depth of coverage to acquire a level of resolution suitable for PGD will be a key indicator for PGS + PGD success.
Trial registration number: –.

P-634 Development of a universal method for the preimplantation diagnosis of β-thalassemia and sickle-cell anaemia using a novel next-generation sequencing approach: a new paradigm for PGD

N. Kubikova[1,2], J. Sarasa[1,3], D. Wells[1,2]
[1]*Reprogenetics UK, Institute of Reproductive Sciences, Oxford, UK*
[2]*University of Oxford, The Nuffield Department of Obstetrics & Gynaecology, Oxford, UK*
[3]*IVF Spain, Alicante, Spain*

Study question: To develop a novel, low-cost PGD protocol applicable to all couples undergoing PGD for β-thalassemia and sickle-cell anaemia.
Summary answer: The study successfully harnessed the power of next-generation sequencing (NGS) technology, delivering a PGD protocol for diagnosis of any *HBB* gene mutations in preimplantation embryos.
What is known already: Worldwide, the most common inherited disorders are those caused by mutation of the beta-globin gene (*HBB*), responsible for beta-thalassemia and sickle cell anaemia. There are various challenges in providing

PGD for these conditions. Traditional PGD protocols involve the time-consuming process of designing customized tests for each mutation. This is problematic in the case of *HBB* as there is a wide diversity of mutations. Not only does the need to develop customized tests substantially delay treatment, but the work entailed greatly increases the cost of PGD. This is problematic considering the high prevalence of *HBB* mutations in many resource poor countries.

Study design, size, duration: A large multiplex PCR protocol was designed, allowing simultaneous amplification of multiple overlapping DNA fragments encompassing the entire *HBB* gene sequence. Additionally, 22 linked polymorphisms (SNPs) flanking the *HBB* gene were amplified in additional PCR fragments. The resulting DNA was subjected to NGS to reveal the genotype/mutation status.

Participants/materials, setting, methods: The protocol was validated in samples from 4 families carrying different β-thalassemia mutations. The method was also applied to whole-genome amplified (WGA) DNA from 24 embryos derived from couples carrying various mutations in the *HBB* gene (thalassemia and sickle cell). In total, 12 mutations were assessed and the results obtained using the new methodology were compared to those obtained from conventional PGD methods for diagnosis of single gene disorders.

Main results and the role of chance: The new NGS-based protocol accurately detected the mutations in the DNA samples tested, confirming all patient genotypes. Seventeen single nucleotide polymorphisms (SNPs) in close proximity to the *HBB* locus (all within 1 Mb) were also successfully sequenced. Five further SNPs were identified within the *HBB* gene locus (i.e., intragenic) in the patient samples. Of the 22 SNPs analysed, each was informative for at least one family. On average, the families tested had 10 informative SNP loci. This allowed the inheritance of haplotypes associated with mutant genes to be tracked with high precision, providing a supplementary means of diagnosis, additional to direct mutation detection. The combination of direct mutation detection and analysis of multiple informative polymorphisms provides a redundant diagnostic, highly resistant to misdiagnoses due to problems such as allele dropout. Concerning the WGA DNA derived from embryo biopsy specimens, the protocol was able to correctly diagnose all 24 associated embryos. When compared to the results obtained from conventional PGD or karyomapping the new test displayed 100% concordance. Importantly, no patient-specific test design or optimization was needed. As far as we are aware, this is the first report of an NGS-based method for PGD of a monogenic disorder.

Limitations, reasons for caution: As part of the clinical validation of this newly-designed protocol for diagnosis of β-thalassemia and sickle-cell anaemia in preimplantation embryos, analysis on additional embryos with a wider variety of mutations should be undertaken. This will permit a more robust and comprehensive evaluation of the sensitivity and specificity of the method.

Wider implications of the findings: For disorders characterized by large numbers of different mutations, NGS-based PGD protocols, such as that described here, provide a simple generic approach, which is substantially less time-consuming and more cost-effective than conventional PGD methods. Lower costs should improve patient access to PGD, especially in less affluent parts of the world.

Trial registration number: N/A.

P-635 Clinical outcome of SET transfer of euploid embryos by Next Generation Sequencing with and without MitoGrade (mitochondrial DNA selection)

K. Ravichandran[1], C. Mccaffrey[2], J. Grifo[2], A. Morales[3], M. Perloe[4], S. Munne[1], D. Wells[5], E. Fragouli[5]

[4]*Georgia Reproductive Specialists, Medical Director, Atlanta, GA, USA*
[5]*Reprogenetics UK, Institute of Reproductive Sciences, Oxford, UK*

Study question: What is the overall value of mitochondrial DNA (mtDNA) assessment in a clinical setting, and how can it help improve IVF outcomes?

Summary answer: Retrospective analysis demonstrates that mtDNA quantification has a high negative predictive value and can be used as an independent biomarker in determining embryo viability.

What is known already: Chromosomal abnormalities are a major cause of implantation failure. Recently our group has validated the relationship between mtDNA quantification and IVF outcomes in a non-selection study. In particular we have been able to establish a threshold above which the probability of implantation is greatly reduced. While further randomized testing is being conducted, we took this opportunity to retrospectively analyze the overall value of the established mtDNA threshold in previously completed clinical cases.

Study design, size, duration: Retrospective study in which mtDNA was assessed in a total of 572 euploid blastocysts obtained from 328 couples (average maternal age 34.95 ± 0.27 years) undergoing preimplantation genetic screening (PGS). Outcome data was collected from 6 different IVF centers for routine follow up. Implantation outcomes were then utilized to determine the validity of the established threshold.

Participants/materials, setting, methods: DNA from blastocyst biopsy samples was amplified (Sureplex, Illumina, USA) and then subjected to aneuploidy analysis using next generation sequencing (NGS, Veriseq protocol, Illumina, USA). Only those embryos classified as chromosomally normal had their mtDNA levels assessed using MitoGrade (Reprogenetics). mtDNA levels were then compared to the pregnancy outcomes to confirm implantation predictions. All embryos were single embryo transfers (SET).

Main results and the role of chance: Nearly 14% (80/572) of all blastocysts analyzed contained mtDNA levels above the established threshold and were predicted to have lower chances of implantation. To date, 246 euploid embryos were replaced in SET with a pregnancy rate of 62.3% (153/246). Retrospective assessment of mtDNA levels revealed 216 embryos to contain normal mtDNA levels. Therefore the pregnancy rate post mtDNA quantification was 71% (153/216) in the normal level mtDNA group. Furthermore of the 30 embryos with elevated mtDNA levels, only one led to a successful pregnancy. Therefore the negative predictive value of mtDNA quantification was 96.7% (29/30). This highly significant ($p < 0.001$) difference between implanting and non-implanting embryos validates the clinical applicability of mtDNA quantification.

More importantly, the mtDNA threshold retained its validity across six different IVF centers and was unaffected by maternal age.

Limitations, reasons for caution: The study was retrospective and the number of cycles was not enough to show a difference between no selection (62% pregnancy rate) and selection against MitoGrade elevated embryos (71% pregnancy rate). It was however large enough to show a significant difference in implantation rates between elevated and normal MitoGrade embryos.

Wider implications of the findings: This study demonstrates the validity of MitoGrade as an independent variable in predicting embryonic implantation potential of euploid embryos. Further research involving the biological significance of mtDNA levels and implantation rates would be invaluable.

Trial registration number: N/A.

P-636 XRCC1 polymorphism Arg399Gln is associated with male infertility

A. Garcia[1], M. de la Casa[2], J. Gosalvez[1], R. Roy[1]
[1]*University Autonoma of Madrid, Biology Faculty, Department of Biology, Genetics Area, Madrid, Spain*
[2]*Ginefiv Assisted Reproduction Center, Laboratory of Andrology, Madrid, Spain*

Study question: Is XRCC1 polymorphism Arg399Gln associated with male infertility?

Summary answer: The Gln variant of the XRCC1 polymorphism Arg399Gln is associated with a decrease in the risk of male infertility.

What is known already: XRCC1 is a critical enzyme in the BER DNA repair system. Its expression in testis in higher than in any other tissue; it appears to have an important role in repairing DNA damages during spermatogenesis. XRCC1 polymorphism Arg399Gln is located in the PARP (poly-ADP ribose polymerase) binding domain.

Study design, size, duration: Case-control study with 120 seminal samples from infertile patients and 79 from donors with probed fertility.

Participants/materials, setting, methods: All samples where genotyped using the PCR-RFLP system. The primers used in the PCR where F 5′-TTGTGCTTTCTCTGTGTCCA-3′ and R 5-TCCTCCAGCCTTTTCTGATA-3′ and the selected restriction enzyme was the MspI.

Main results and the role of chance: The allele frequencies where 0.66 (Arg) and 0.34 (Gln) in the patients group and 0.56 (Arg) and 0.44 (Gln) in the controls group. The genotype frequencies were 0.488 (Arg/Arg), 0.344 (Arg/Gln) and 0.172 (Gln/Gln) in the patients group and 0.278 (Arg/Arg), 0.557 (Arg/

Gln) and 0.165 (Gln/Gln) in the donors group. We observed significant differences in the allelic frequencies distributions between patients and donors (p = 0.006). We also observed that the patients group allele frequencies did not adjust to a Hardy-Weinberg equilibrium (p = 0.0087), appearing less heterozygous than expected. We hypothesize that the Gln variant may be a more active enzyme.
Limitations, reasons for caution: Our population only includes Spanish population.
Wider implications of the findings: There is no consensus among the literature regarding the effect of this particular polymorphism over fertility. Our findings may help to clarify this situation.
Trial registration number: Not a clinical trial.

P-637 Clinical application of sequencing-based preimplantation genetic diagnosis

F. Chen[1], X. Chenming[2], C. Songchang[2], Z. Junyu[2], W. Li[2], G. Ya[1], Z. Wei[3], L. Ping[1], J. Hui[1], H. Hefeng[2]
[1]*BGI-Shenzhen, Science and Technology, Shenzhen, China*
[2]*International Peace Maternity and Child Health Hospital, IVF Center, Shanghai, China*
[3]*BGI Genomics, Products development, Shenzhen, China*

Study question: current techniques are restricted to a few specific diseases and preliminary experiments in the lab always take long time to confirm the linkage SNP or STR for each family case.
Summary answer: We believe the sequencing-based preimplantation genetic diagnosis would served as a more effective, useful and routine techniques in the lab-level medical centers.
What is known already: Since the first case of sex determination in embryos with sex-linked diseases in 1990s, advanced technologies for preimplantation genetic diagnosis (PGD), such as PCR-based molecular techniques, Sanger sequencing, short tandem repeats (STR) linkage analysis and SNP mapping, has been quickly developed and optimized for accurate detection for monogenetic diseases, for example, α and β thalassemia.
Study design, size, duration: 34 monogenetic diseases with relatively high prevalence was involved in this study, including autosomal recessive/dominant and X-linked diseases. Families who have clear medical history and want to have a healthy baby through preimplantation genetic diagnosis in a IVF center, were reviewed and recruited for the study.
Participants/materials, setting, methods: Here we recruited seven families affected by monogenetic diseases from April to November 2015 in our hospitals, including one case of Hemophagocyic Histiocytosis, one case of Osteogenesis imperfect, three cases of polycystic kidney, one case of Spinal Muscular Atrophy and one case of Wilson's Disease. We combine the quick detection of causative mutations in 34 monogenetic diseases at one time for the victims and PGD for embryos with a haplotype-based approach.
Main results and the role of chance: We combine the quick detection of causative mutations in 34 monogenetic diseases at one time for the victims and PGD for embryos with a haplotype-based approach. we successfully phased the local haplotype across the interest gene or chromosome for each embryo and helped to select healthy embryos for implantation. The PGD results were concordant with prenatal diagnosis by conventional techniques in amniotic fluids, showing 100% accuracy. We believe the sequencing-based preimplantation genetic diagnosis would be faster and cheaper in the near future and served as a more effective, useful and routine techniques in the lab-level medical centers.
Limitations, reasons for caution: We believe more comprehensive evaluation across different hospitals as well as more monogenetic diseases should be performed in the future, to get a better understanding the technology, a lower cost in practice, a faster turnaround time and easier accessible training system for general clinicians in this field.
Wider implications of the findings: We believe the sequencing-based preimplantation genetic diagnosis faster and cheaper and served as a more effective, useful and routine techniques in the lab-level medical centers in the near future.
Trial registration number: No.

P-638 Relationship between mitochondrial DNA quantity assessed by next generation sequencing (NGS) in blastocyst stage embryos and their implantation

S. Pukszta[1], J. Liss[1], C. Cybulska[1], J. Zabielska[1,2], K. Lukaszuk[1,2]
[1]*Invicta Sp. z o.o., Reproduction and Fertility Centre, Gdansk, Poland*
[2]*Medical University of Gdansk, Department of Obstetrics and Gynecological Nursing, Gdansk, Poland*

Study question: The aim of our work was to indirectly estimate if mitochondrial DNA relative amount from 5th day biopsy procedure differs between embryos implanted and those that failed to implant.
Summary answer: Implanted embryos exhibited significantly higher amounts of mitochondrial DNA indicating mtDNA as a possible new biomarker for embryo prioritisation.
What is known already: Application of the preimplantation genetic screening (PGS) in reproductive medicine seems to be one of the most important improvement in treatment of human reproductive problems. Considering the current state of technological progress and available already perfected, validated methods, next generation sequencing (NGS) appears to be the most flexible. Among the available methods Next generation sequencing gives us additional diagnostic possibilities enabling us to obtain data from sequencing of mitochondrial DNA (mtDNA) while testing genomic DNA.
Study design, size, duration: One hundred and four patients treated with intracytoplasmic sperm injection (ICSI) at our IVF centre between August 2013 and March 2015 who decided to undergo PGD on 24 chromosomes on blastocysts with frozen embryo transfer were included in the investigation. Retrospective analysis was finally performed on 281 trophectoderm samples obtained from 5 day embryos.
Participants/materials, setting, methods: Trophectoderm cells were biopsied from embryos at the blastocyst stage and subjected to preimplantation genetic screening (PGS) by next generation sequencing (NGS). Obtained information regarding mtDNA copy number amount was compared between euploid and aneuploid as well between implanted and non-implanted. Successful implantation was defined by presence of gestational sac at 5 weeks and 3 days ±2 days after embryo transfer by transvaginal ultrasound.
Main results and the role of chance: Relative amount of mtDNA was lower in euploid than in aneuploid embryos [0.91 (0.6–1.7) 1.1 (0.7–2.1) p = 0.05] what is consistent with previous reports. Surprisingly, significantly higher rate of mtDNA was found for the implanted embryos [1.53 (1–2.2) vs 0.72 (0.5–1.3) in non-implanted, p = 0.005]. This greater mtDNA amount in implanted embryos may indicate a higher energetical potential and therefore likely better adaptive capabilities of the implanted embryos.
Limitations, reasons for caution: Our research does not categorically confirm the ratios of mtDNA to gDNA due to the whole genome amplification (WGA) procedure performed prior to NGS. WGA may result in altered proportions of readings of gDNA and mtDNA.
Wider implications of the findings: If these findings are confirmed by large multi-center studies, validated and repeatable results would enable introduction of the above described results into clinical practice.
Trial registration number: Not applicable.

P-639 Identifying housekeeping genes that are stably expressed in the endometrium of both fertile women and those with recurrent implantation failure and recurrent miscarriages

F. Cagampang[1], L. Stocker[2], Y. Cheong[2]
[1]*Institute of Developmental Sciences, Faculty of Medicine, Southampton, UK*
[2]*Princess Anne Hospital, Complete Fertility Centre, Southampton, UK*

Study question: Are there a set of House Keeping Genes (HKGs) that are stably expressed in the endometrium of fertile women and those with recurrent implantation failure and recurrent miscarriages?
Summary answer: Previously untested genes are more stable than those identified in the literature. We recommend three new HKGs for gene normalisation in endometrial tissues.
What is known already: The most commonly used HKG have been shown to vary across samples/tissues (Andersen et al., 2004; Vandesompele et al., 2002). Despite this, validation of the presumed stability of HKG in tissues such as the

endometrium is often not made (Colette et al., 2009; Matsuzaki, et al., 2006). There is no consensus on which HKGs are stably expressed in endometrial tissue but they vary with different pathologies (Sadek et al., 2012). This current failure may be because often the most commonly cited and used HKG are applied to disease states and pathologies in which they have not be tested nor verified.

Study design, size, duration: A case control gene expression study (August 2012 to December 2013, *n* =45) was performed in order to identify HKG that express inherent levels of stability across different patient endometrial tissues. Using data from >30,000 microarray experiments, pair-wise variation with the sequential addition of each HKG indicated the genes that could be used, with the normalisation factor as the geometric mean of the most stable gene.

Participants/materials, setting, methods: Women between 25–45 years were recruited and baseline demographics/fertility characteristics were collected. Women were included if they suffered recurrent miscarriage (RM) or recurrent implantation failure (RIF) or were fertile controls. Endometrial biopsies were taken by suction curette and total RNA extraction, cDNA synthesis and PCR was performed on all samples using a total of 18 HKG. The genes were arranged in terms of stability and normalisation was determined.

Main results and the role of chance: The present study using 18 HKGs found that genes not previously tested in endometrial samples are more stable than those previously identified as most stable in our patient groups. To establish the number of reference genes used to make this geometric mean, the 'V score' was utilised (this indicates how the normalisation factor changes when another gene is included in its calculation; and a 'V score' of 0.15 or below indicated that the additional gene had no significant contribution to the newly calculated normalisation factor). We recommend using PRDM4 (PR domain 4), UBE2D2 (Ubiquitin-Conjugating Enzyme E2D 2) and ENOX2 (Ecto-NOX Disulfide-Thiol Exchanger 2) as reference HKG for normalisation of endometrial tissues taken from patients with RM and RIF, as these appear to be the most stably expressed HKG regardless of endometrial pathology. While the genes we identified are applicable to studies of apparently normal endometrium, the investigation of a wider range of reference HKG may be more appropriate in order to identify the best candidates for studies of a given endometrial pathology.

Limitations, reasons for caution: Our results may be confounded by a small sample size; a larger scale study in this specific subgroup of women is further needed to confirm our findings.

Wider implications of the findings: The commonly used reference HKGs are not as stable as previously reported and the expression of HKG within the endometrium is affected by reproductive pathology. This information should be applied when using normalisation genes. Cellular functions of commonly used HKGs may have a role in these conditions.

Trial registration number: Regional ethics committee number 12/SC/0568.

P-640 A powerful tagging single nucleotide polymorphism method in terms of next-generation sequencing that combines preimplantation genetic diagnosis, informativity testing and aneuploidy screening

V. Penacho[1], S. González-Reig[2], L.A. Alcaraz[3], D. Amoros[4], N. Castejón[5]
[1]*Bioarray, R&D Manager, Elche, Spain*
[2]*Bioarray, PGS/PGD Manager, Elche, Spain*
[3]*Bioarray, Founding Partner & Technical Manager, Elche, Spain*
[4]*Bioarray, Bioinformatics Manager, Elche, Spain*
[5]*Bioarray, PhD Student in Bioinformatics, Elche, Spain*

Study question: Is our new NGS strategy that identifies point mutations by confirmatory tagging-SNP method reliable to determine mutation-free embryos avoiding the allele-drop-out (ADO) in PGD cycles?

Summary answer: We've developed and implemented a high-throughput tag-SNP genotyping combined with Ion-AmpliSeq™ sequencing (Thermo-Fisher Scientific) for the PGD of point mutations to ensure a sufficient informativity.

What is known already: PGD represents a reproductive option for couples at genetic risk of having a child with a specific monogenic disorder. PGD refers to genetic profiling of embryos prior to implantation and involves the use of assisted reproductive technology combined with in vitro fertilization (IVF) techniques. Only those disease-free embryos are transferred to the uterus with the aim of generating healthy offspring. Nowadays, PGD coupled with informativity testing on Short-Tandem Repeats (STRs) markers become mandatory before IVF. Analysis of SNPs linked to gene regions involved by mutation with NGS technology enables an all-in-one informativity testing, PGS and PGD shortly after embryo biopsy.

Study design, size, duration: This study comprises seven couples performing IVF cycles with PGS/PGD (November 2015–January 2016), where one or both members carried a point mutation. Two females were diagnosed as carriers of PKD1 gene mutations (c.1261C>T; c.1810C>T). One female carried one RET mutation: IVS9 (-1)bis(-2)delAG. One female carried mutation c.670delC on L1CAM. A couple carried two LAMB3 mutations (c.1903C>T in the female and c.810delC in the male). Other couple carried two UNC13D mutations (female: c.2346-2349del; male: c.1389+1G>A)

Participants/materials, setting, methods: Parental blood samples were required for informativity testing. LD Tag-SNP tool (NIEHS, US) provided linkage disequilibrium for SNPs selected within each gene. This tool prepared DNA sequences for primer design considering SNP information in 200,000 bp flanking region on both sides. Targeted next generation sequencing was performed using Ion-AmpliSeq™ 200 bp-primer pools and Ion PGM™ platform**.** After oocyte insemination and day-5 biopsy, DNA whole genome amplification was followed by PGS/PGD/informativity testing in all embryos.

Main results and the role of chance: A panel of around 130 different SNP markers has been studied during this set-up phase, to ensure a sufficient informativity in all cases. Database for all SNPs with European population genotype data was found in dbSNP. Around 15% of tag-SNP studied was fully informative in order to identify linked-point mutations carried by partners of couples studied. Along the PGS/PGD processes performed to date, no amplification failures in genomic regions involved by mutations, neither false positives nor negatives were detected. The overall ADO rate was no greater than 3%. The risk of double recombination between informative flanking markers was estimated in less than 0.05%. Regarding to one of the couples in which the female was diagnosed as PKD1 mutation carrier: c.1261C>T p.(Arg421Cys), 12 embryos resulted after one IVF cycle. NGS Ion PGM™ System along with Ion-ReproSeq™ workflow (Thermo-Fisher Scientific) determined that 4 were euploid, 4 aneuploid and 4 presented a chaotic arrangement. PGD/tag-SNP informativity testing in euploid embryos showed 2 mutation-free ones and 2 that presented the mutation in heterozygosis. Similar results were reported for the others cases. To sum up, the sample-tagging plan based on this framework will improve whole PGD/PGS in terms of turnaround time, reliability and cost-effectiveness.

Limitations, reasons for caution: Number of case-control studies is limited to the carriers of monogenic diseases. Higher throughput would be accomplished by multiplexing tag-SNPs genotyped over multiple candidate genes. Improving this power-based algorithm would be useful for an optimal selection of informative SNPs based upon maximizing the predictability of unmeasured SNPs or SNP haplotypes.

Wider implications of the findings: Conventional multiplex markers in polymerase chain reaction (PCR) protocols for PGD are laborious, expensive and requires large amount of DNA template. However, the application of tag-SNPs combined with Ion-AmpliSeq™ technology can be useful in capturing untyped SNPs information in a genomic region involved by mutation and improve PGD success.

Trial registration number: This is not a clinical trial so it not linked to a trial registration number.

P-641 Non invasive prenatal testing (NIPT) in IVF patients

G. Terzuoli[1,2], V. Furlan[1,2], C. Lapucci[3], F. Cro[3], C.E. Boschetto[4], V. Bianchi[1,2]
[1]*Casa di Cura Città di Udine, Obstetrics and Gynecology, Udine, Italy*
[2]*Future for Family, Obstetrics and Gynecology, Udine, Italy*
[3]*Geneticlab SRL, Genetics, Noventa Vicentina, Vicenza, Italy*
[4]*Ospedale Policlinico, Obstetrics and Gynecology, San Donato Milanese, Italy*

Study question: Is the non invasive prenatal testing (NIPT) a must to suggest to IVF population patients?

Summary answer: In a female population where invasive testing happen to increase the risk of miscarriage, we want to counsel patients for a non invasive alternative.

What is known already: Different companies developed NIPT to detect aneuploidies that are normally compatible with a live birth. Two main technologies

rule in these tests: the counting method and the single nucleotide polymorphisms (SNPs). This test is progressively become a first line choice during prenatal screening.
Study design, size, duration: This is a cohort study started on December 1st 2014 till November 30th 2015. Three thousand and seventy none couples performed a SNPs based NIPT and we analysed results and follow up. The test include either a basic panel with detection of trisomy 13, 18, 21 and sexual chromosomes X and Y or an expanded panel (NIPT+) that includes 5 microdeletions as well. Patients decided after counselling to undergo one or the other.
Participants/materials, setting, methods: In our centers, we counsel pregnant patients for:

- non invasive tests such as combined test and NIPT;
- invasive tests such as or chorionic villus sampling (CVS) and amniocentesis.

The NIPT is available after 9 + 0 weeks of gestation. The nurse withdraw two blood tubes from each woman and turn them upside down for 10 times. We keep the blood at room temperature. The cut off necessary to detect the fetal DNA signal is 4%.
Main results and the role of chance: Three thousand and seventy nine couples were tested, of that 1643 with the standard NIPT and 1436 used the panel with 5 microdeletion (NIPT+). The rate of no informative result due to low fetal fraction was 3.1% (51/1643) in the NIPT group and 4.2% (60/1436) in the NIPT+ arm. The number of high risk result was: 1.3% (20/1592) in NIPT and 2.3% (31/1376) in the NIPT+ group. Overall, we found 21 high risk for trisomy 21, 4 for trisomy 18, 6 for trisomy 13, 3 monosomy X, 1 triple X (XXX), 1 XXY, 4 XYY. As for the microdeletions we found 4 positive to Di George syndrome, 1 for p36, 3 positive for Angelman syndrome and 1 for cri du chat. When we obtain a positive result, the doctor always suggested an invasive follow up but a rate of patients did not accept it. Through CVS/amniocentesis 18 positive results were confirmed while 12 were false positive and not confirmed with invasive analyses. The remaining are either ongoing and did not accept invasive testing or lost of follow up. The microdeletion were confirmed in 1 case for a Di George syndrome. Up to this moment no false negative was detected.
Limitations, reasons for caution: The main limitation for this test is the cost. The Italian national health system pay only for combined test or, after 35 years old, for invasive tests. The NIPT does not show all the possible chromosomal abnormalities compatible with life. The NIPT+ evidenced a high rate of false positive results.
Wider implications of the findings: Pregnancies achieved through IVF treatments are often describes as "precious". Our results show that in the population (IVF and spontaneous pregnancies) the majority of foetuses are healthy. In fact, only 0.6% (17/2968) tests were positive for aneuploidies and just one for a microdeletion syndrome (0.03%).
Trial registration number: N/A.

P-642 Combined time-lapse imaging and preimplantation genetic screening: a valuable strategy for embryo selection

E. Rocafort[1], A. Leza[1], B. Ramos[1], M. Guijarro[1], L. Medrano[1], M. Enciso[2], J. Sarasa[2], M. Fernández[1], J. Aizpurua[1]

[2]*iGLS, Genetics Department, Alicante, Spain*

Study question: Is the time-lapse tool Eeva useful in a Preimplantational Genetic Screening (PGS) embryo-banking program to select among euploid embryos those with the highest implantation potential?
Summary answer: Eeva Test provides valuable information for embryo selection increasing the chances of pregnancy by accurately predicting the implantation potential of euploid embryos.
What is known already: Previous studies confirmed that genetic screening of human blastocysts significantly improves pregnancy rates per cycle diminishing the likelihood of miscarriage. Unfortunately, there is still a considerable number of euploid embryos that fail to implant. New embryo selection markers to improve ART-outcomes have been developed (mtDNA content, metabolomics or morphokinetic assessment). Time-lapse imaging (TLI) has emerged as an interesting non-invasive tool. No conclusive data about the utility of this technology for chromosome abnormalities determination is available; however, we wonder if combined TLI and PGS embryo selection may be a valuable strategy to identify those embryos with the best chances of success.
Study design, size, duration: This unicentric and retrospective study included 159 embryo-banking PGS-cycles from IVF and egg-donation patients seeking ART treatment at our centre between September 2013 and December 2015. The control group (*PGS-only)* comprised 70 cycles in which embryos had been selected for transfer following euploidy criteria only. The study group (*PGS + Eeva*) comprised 89 cycles in which embryo selection for transfer was based on combined PGS and Eeva predictions.
Participants/materials, setting, methods: All embryos were cultured, biopsied, and vitrified at the blastocyst stage. Genetic analyses of trophectoderm biopsies were performed by NGS. Single euploid blastocyst transfers were performed in all cases. Transfers were differed and under HRT. Within the control *PGS-only* group, the best morphological euploid embryo available was transferred. Within the *PGS + Eeva* group, the euploid blastocyst with the highest Eeva-prediction available was prioritized for transfer. Biochemical pregnancy rates of study groups were statistically compared.
Main results and the role of chance: Clinical characteristics were comparable between groups. There were no significant differences in terms of MII, fertilized eggs, blastocyst rate, high quality blastocyst rate and euploidy rate between the study groups. However, significant differences ($p < 0.05$) were found when comparing pregnancy rates of the control *PGS-only* group [52.9% (37/70)] and the *PGS + Eeva* group cases where euploid embryos with *high* implantation potential as predicted by Eeva were transferred [73.4% (47/64)]. No such differences were found when pregnancy rates from transfers of euploid embryos classified as *medium* or *low* by Eeva were compared to controls. Similar results were obtained when IVF and egg donation cycles were independently analysed. A significantly higher pregnancy rate was achieved in transfers were *high* Eeva prediction in addition to PGS were used for embryo selection [(48% vs 69.2% in IVF cycles ($p < 0.05$) and 54.1% vs 71.9% in egg-donation cycles ($p < 0.05$)]. These results show that Eeva Test provides valuable information for euploid embryo selection significantly increasing the chances of pregnancy in cycles where chromosomally normal embryos predicted by Eeva as *high* are prioritized for transfer.
Limitations, reasons for caution: The retrospective nature of this study may be a reason for caution. Data were collected from one laboratory using a specific culture system and protocols. Moreover, further data regarding clinical outcomes must be included to confirm the predictive value of the analyzed parameters.
Wider implications of the findings: To our knowledge, this is the largest dataset of single euploid embryo transfers selected by an automated time-lapse system. This analysis reveals the ability of early cleavage time-lapse parameters to predict embryo implantation potential and suggest that its combined use with genetic screening of embryos would significantly improve ART outcomes.
Trial registration number: A trial registration number was not required due to the retrospective study design.

P-643 A small trophectoderm biopsy sample is sufficient to detect most mosaicisms after analysis with high resolution next generation sequencing (NGS)

G.J. Garrisi[1], R. Walmsley[1], K. Bauckman[2], R. Mendola[1], P. Colls[2], S. Munne[2]
[1]*Institute for Reproductive Medicine and Science at Saint Barnabas, Livingston NJ, USA*
[2]*Reprogenetics- a CooperSurgical Company, Livingston, NJ, USA*

Study question: Does a biopsy specimen of 4–6 contiguous cells taken from the trophectoderm provide a reliable representation of the remainder of a mosaic human embryo?
Summary answer: When mosaicism was identified in a small trophectoderm biopsy, mosaicism was determined to be present in other embryonic locations in 25/28 (89%) of the embryos.
What is known already: A high percentage of human blastocysts are mosaic. Unlike other methods, it is possible to identify mosaicism in trophectoderm biopsy specimens with high resolution NGS testing. Recent preliminary studies indicate that some mosaic embryos are capable of implantation and normal term development, albeit with a lower implantation rate and higher miscarriage rate than euploid embryos. Little is known of the fate of cell lineages in the human preimplantation embryo after post-meiotic chromosomal malsegregation.
Study design, size, duration: From October to December of 2015, 39 patients underwent aneuploidy screening with NGS, with vitrification of all tested blastocysts. Mosaicism was detected in 48/157 (31%) embryos, alone or in

combination with full aneuploidy. Of these, 28 mosaic blastocysts donated for research were segmented into three sections and fully analyzed by NGS.

Participants/materials, setting, methods: Blastocysts were warmed and those with a well-defined inner cell mass (ICM) were divided into 3 sections with a modified biopsy procedure. First, the ICM was removed without allowing contamination with trophectodermal cells. Then, the trophectoderm was divided into two segments – the embryonic hemisphere, potentially with residual ICM cells, and the abembryonic hemisphere. The specimens were analyzed individually with NGS, and the results were compared to the original biopsy.

Main results and the role of chance: The initial diagnosis of mosaicism was confirmed in all but 3/28 (11%) of the embryos. The overall impact of mosaicism on the rate of false positive misdiagnosis in this group of embryos was low (3/157; 1.9%). While the original diagnosis of mosaic was confirmed in most cases, mosaic cell lines that differed from the original biopsy were frequently detected in one or more of the subsequent biopsies from the same embryo. Only 6/28 (21%) showed identical or substantially similar diagnoses in all 4 blastocyst segments. Mosaicism was confined to either the ICM or the trophectoderm in 11/28 (39%) of blastocysts. In 4/28 (14%) embryos, the ICM biopsy specimen was comprised of only euploid cells, with mosaicism limited to the trophectoderm. There were also 7 embryos (25%) with mosaic ICMs in which only euploid cells were detected in one or both of the trophectoderm hemispheres. None of the 3 types or locations of trophectoderm biopsy was more predictive of ICM mosaicism than the others.

Limitations, reasons for caution: The sample size is small, and should be expanded in order to refine the expectation of occurrence of misdiagnosis. In order to eliminate the possibility of contamination of the ICM during biopsy, the specimen size was sometimes small; a larger specimen may have detected additional mosaicisms.

Wider implications of the findings: The developmental impact of mosaicism limited to either ICM or trophectoderm is unknown, but may be related to decreased implantation rates and increased miscarriage rates observed after transfer of mosaic embryos. The low rate of false positive diagnoses indicates that transfer of mosaic embryos should be undertaken with caution.

Trial registration number: -.

P-644 Association of methylenetetrahydrofolate reductase c677t polymorphism with intervillous and decidual pathology in human cases with pregnancy loss

T. Mehandjiev[1,2], N. Tenno[1,3], Y. Nakura[1], T. Wakimoto[1,2], K. Mimura[2], M. Nakayama[4], T. Kanagawa[2], T. Tomimatsu[2], T. Fujita[3], Y. Onouchi[5,6], M. Takeuchi[4], T. Kimura[2], I. Yanagihara[1]

[5]*Chiba University Graduate School of Medicine, Department of Public Health, Chiba, Japan*

[6]*Center for Integrative Medical Science RIKEN, Laboratory for Cardiovascular Diseases, Tsurumi Yokohama, Japan*

Study question: Is there association between methylenetetrahydrofolate reductase (*MTHFR*) C677T polymorphism and intervillous and decidual pathology in patients with pregnancy loss (PL)?

Summary answer: The *MTHFR* C677T TT genotype and T allele are associated with severe intervillous and decidual pathologies in cases with PL.

What is known already: Although an association between PL and TT genotype of the *MTHFR* C677T polymorphism have been well known, the mechanism underlying this association remains obscure. It has been reported increase of placental pathological findings in late PL patients with *MTHFR* C677T TT genotype and another coexisting thrombophilia, but no studies have yet shown that the TT genotype alone could cause this effect. As *MTHFR* C677T polymorphism is common worldwide with at least 13% of the population carrying the TT genotype, the problem is of high importance.

Study design, size, duration: We performed a cross sectional observational study on patients experiencing PL between May 2010 and December 2013. All patients were Japanese ethnicity and had been treated by surgical evacuation. The study was approved by Osaka Medical Center for Maternal and Child Health (MCH) Ethics Committee. The minimum sample size for the study was calculated to be 199 patients and 243 patients were successfully recruited for the study.

Participants/materials, setting, methods: Hematoxylin–eosin stained samples from surgical evacuation were investigated for four pathologies: decidual fibrin (DF), intervillous fibrin (IF), decidual thrombosis (DT), and intervillous thrombosis (IT) and were classified into four degrees – 0, 1, 2, or 3 according to the extent and severity of the pathology. Patients' genotype for *MTHFR* C677T polymorphism was determined by PCR followed by *Hinf*I digestion and gel electrophoresis.

Main results and the role of chance: Out of 300 patients eligible and contacted for the study, 243 patients completed the informed consent and were enrolled into the study, which made a response rate of 81%. From them 83 (34.16%) patients were *MTHFR* C677T CC genotype, 116 patients (47.74%) were CT genotype and 44 patients (18.11%) were TT genotype. Kolmogorov–Smirnov analysis of patients' demographic characteristics showed no significant genotype difference in age, gravity, parity, or gestational age at presentation. There were significantly more T allele carriers [odds ratio (OR) 1.65; $p = 0.032$; 95% CI = 1.041 – 2.614] and TT genotype patients (OR = 2.175; $p = 0.039$; 95% CI = 1.028 – 4.606) among patients with severe (grade 3) IT. Among patients with both grade 3 IT and grade 3 DT, there were also significantly more T allele carriers (OR = 2.412; $p = 0.023$; 95% CI = 1.108 – 5.254) and TT genotype patients (OR = 3.536; $p = 0.021$; 95% CI = 1.148 – 10.892). The CC genotype was protective against the four studied pathologies (OR = 0.533; $p = 0.029$; 95% CI = 0.302 – 0.942). There were no cases without either IF or DF among *MTHFR* C677T TT genotype patients.

Limitations, reasons for caution: As we did not measure serum and red blood cells folate levels, as well as homocysteine levels, it is impossible to establish consecutive chain of events leading to intervillous and decidual pathology in MTHFR C677T T allele and TT genotype carriers. The power of the study was 1.0.

Wider implications of the findings: As *MTHFR* C677T polymorphism is widespread worldwide, our results could suggest a similar study in a country with folate enrichment of cereals, to check the preventive effect of folate on the observed pathologies, as well as a study searching for ultrasound markers based on the observed pathology.

Trial registration number: As the study was not RCT it had not been registered in an ICMJE-recognised trial registry.

P-645 Analysis of DNA from blastocoelic fluid (BF) and corresponding trophectoderm (TE) cells by array-CGH and NGS

A. Pomante[1], M.C. Magli[1], D. Wells[2,3], S. Alfarawati[2], E. Fragouli[2], V. Bianchi[4], A.P. Ferraretti[1], L. Gianaroli[1]

[3]*University of Oxford, Nuffield Department of Obstetrics and Gynaecology, Oxford, UK*

[4]*Casa di Cura Città di Udine, Reproductive Medicine Unit, Udine, Italy*

Study question: Can NGS determine the blastocyst chromosome condition through the analysis of DNA from BF and corresponding TE cells in a manner comparable to array-CGH?

Summary answer: NGS provided results on the DNA from BF and corresponding trophectoderm (TE) cells that were quite concordant with those derived by array-CGH.

What is known already: BF contains DNA that can be analyzed by array-CGH, potentially revealing the chromosome status of the corresponding embryo. Previous studies have demonstrated a high level of concordance (97%) between results obtained from TE cells (considered the optimal material for PGS) and those obtained from cytogenetic analysis of BF DNA from the same embryo, suggesting that BF could be used to predict the blastocyst chromosome condition. NGS was recently reported to be more efficient, sensitive and cost-effective than array-CGH. Its use for the study of BF DNA could add valuable information on the predictive capacity of this type of sample.

Study design, size, duration: Cohort study including 49 supernumerary blastocysts, which had been diagnosed by array-CGH on blastomeres from day 3 embryos. BF and corresponding TE cells were then tested to verify whether

the results predicted at the cleavage stage corresponded to the ploidy condition in BFs and TE cells. To confirm the results obtained from the blastocysts, the amplified DNA from 9 BFs and corresponding TE cells was analyzed by NGS by operators blinded to the previous results.

Participants/materials, setting, methods: Nine sets of BFs and corresponding TE cells were selected to undergo NGS. The choice of which samples to evaluate was guided by the following criteria based on the previous array-CGH results: 2 cases of full concordance between blastomere, BF and TE, one of which showed some evidence of mosaicism in BF; 5 cases with segmental abnormalities, including 2 in which mosaicism was suspected; and 2 cases of ploidy discordance between BF and corresponding TE.

Main results and the role of chance: Following reanalysis by NGS, of the two cases with full concordance after array-CGH, 1 was confirmed. The other case (BF and TE were called euploid by array-CGH, although there was some evidence of mosaicism involving 5 chromosomes in the BF) became discordant since the mosaicism suspected in the BF was clearly apparent after NGS; conversely, TE cells were euploid for both diagnostic methods. The 5 cases with segmental abnormalities were all confirmed by NGS, indicating that both techniques are able to identify this type of chromosomal anomalies. Finally, for the cases showing ploidy discordance between BF and TE cells by array-CGH, one remained as such after NGS (BF aneuploid and TE euploid), while the other became ploidy concordant (both BF and TE aneuploid for a single abnormality, although for a different chromosome). In all, NGS confirmed the results provided by array-CGH in 14 of the 16 samples analyzed. The two discrepancies were false-negatives by array-CGH and aneuploid by NGS. Interestingly, in one of these cases, the corresponding TE cells were called euploid by both methods.

Limitations, reasons for caution: BF DNA could derive from any blastocyst compartment, including apoptotic cells. Mosaicism could be present and consequently close attention should be payed to chromosome profiles, especially if using less sensitive methods (e.g., array-CGH). Extending the comparative analysis to more cases could provide additional information on the condition of BF DNA.

Wider implications of the findings: BF samples could be examined using both array-CGH and NGS. Results were concordant in most cases. Two discrepancies were probably due to mosaicism, which is detected more efficiently by NGS. The existence of mosaicism in the BF indicates that the DNA present is sometimes derived from more than one cell.

Trial registration number: Not applicable.

P-646 Fastest benchtop next-generation sequencing workflow for preimplantation genetic screening with Ion ReproSeq™ technology

L.A. Alcaraz[1], V. Penacho[2], S. González-Reig[3], D. Amoros[4], N. Castejón[4], B. Ramos[5], M. Enciso[6], M. Fernandez[5], J. Aizpurua[5]
[1]*Bioarray, Technical Direction, Elche Alicante, Spain*
[2]*Bioarray, R&D&I, Elche Alicante, Spain*
[3]*Bioarray, PGS/PGD, Elche Alicante, Spain*
[4]*Bioarray, Bioinformatics, Elche Alicante, Spain*
[5]*IVF Spain, Reproductive Medicine, Alicante, Spain*
[6]*iGLS, Genetic Department, Alicante, Spain*

Study question: Is the NGS Ion PGM™ System (Thermo-Fisher Scientific) along with Ion ReproSeq™ workflow reliable enough in terms of PGS for aneuploidy and unbalanced translocations detection?

Summary answer: This two-phase validation study demonstrates that Ion ReproSeq™ (Thermo-Fisher Scientific) is more accurate for aneuploidy and unbalanced translocation identification than others technologies and platforms.

What is known already: In PGS, one or more cells from embryos generated through in vitro fertilization (IVF) are removed and tested for overall chromosomal normalcy prior to embryo transfer. PGS was originally performed using fluorescent in-situ hybridization (FISH). This technique showed limitations in genome coverage that were solved by array-based 24sure™ technology with demonstrated accuracy and improved implantation rates. In this way, NGS is the latest breakthrough encouraging method for PGS, offering reliability, higher throughput and personalized assays. *T*he Ion ReproSeq™ PGS Kit with the Ion PGM™ System allows for rapid and affordable screening of aneuploidy and unbalanced translocations in all 24 chromosomes.

Study design, size, duration: This study comprised two phases. Firstly, a double-blinded retrospective validation tested 20 day-5 embryo biopsies in triplicate from 20 IVF cycles by Ion PGM™ platform along with Ion ReproSeq™ PGS as alternative NGS approach, Ion Aneuploidy workflow (Thermo-Fisher Scientific) as traditional NGS method, and array-based 24sure™ Microarrays (Illumina). Secondly, a prospective trial with Ion ReproSeq™ tested 2359 embryo biopsies (92 day-3, 2267 day-5) recruited in 428 clinical IVF cycles from June 2015 to January 2016.

Participants/materials, setting, methods: For retrospective validation, 60 blastocyst biopsies were performed after human oocyte insemination. Prospective study was constituted by 92 blastomeres and 2267 blastocysts biopsies. Whole genome amplification (PicoPlex®, Rubicon-Genomics) preceded traditional NGS and array-based method. CNV analysis for 24sure™ was performed with BlueFuse Multi software (Illumina). The Ion ReproSeq™ consists of whole genome amplification, library construction, isothermal amplification and semiconductor sequencing. Ion Reporter™ Software determined the ploidy status with 0.01X read coverage for both NGS assessments.

Main results and the role of chance: Along retrospective validation, 27 of 60 day-5 embryos resulted euploid, corresponding to 9 different embryos biopsied in triplicate. In respect to aneuploid embryos, 12 of 60 presented monosomies (20%), 9 trisomies (15%), 6 full gain and losses (10%) and 6 had partial imbalances (10%). Along the whole process, no technical failures, false positives and negatives were detected. Almost all triplicates showed the same ploidy status regardless of the PGS technique employed. This first phase provided a 98.3% concordance (99/100; 95% Confidence Interval [CI]: 91.1%-99.9%) for aneuploidy screening by alternative NGS Ion ReproSeq™ in contrast to well-established microarray-based 24Sure™ and traditional NGS Ion Aneuploidy workflow. The discordant result showed a monosomy on chromosome 7 by array, while both NGS approaches detected a partial gain on chromosome 7q. In the prospective study, 2040 of 4718 embryos were euploid; 62 euploid of 184 day-3 and 1978 euploid of 4534 day-5 embryos. A total of 651 aneuploid embryos presented monosomies (24.31%), 630 trisomies (23.52%), 654 full gain and losses (24.42%) and 743 had partial imbalances (27.75%). Moreover, 16 unbalanced translocations were accurately identified from 6 balanced translocation carriers. To date, estimated implantation rate is 60.69% related to 1238 embryos transferred.

Limitations, reasons for caution: Although reliability of NGS Ion PGM™ System along with Ion ReproSeq™ workflow for both aneuploidy and unbalanced translocations detection, further data in a randomized controlled trial are required in order to achieve a broad-based clinical application. Higher throughput would be accomplished by multiplexing more than 24 samples.

Wider implications of the findings: Ion ReproSeq™ is a rapid and cost-effective PGS workflow that provides throughput scalability. Turnaround time is substantially reduced in contrast to around 24 h-protocols (array and previous NGS). In less than 10 h, it's possible to go from 24 embryo biopsies to euploid selection for same day or frozen embryo transfer.

Trial registration number: This is not a clinical trial so it not linked to a trial registration number.

P-647 Chromosomal analysis from multiple biopsies on blastocysts

G. Cafueri[1], A. Pomante[1], M.C. Magli[1], S. Vitarelli[1], S. Colaci[1], A. Crippa[1], G. Russo[1], A.P. Ferraretti[1], L. Gianaroli[1]
[1]*S.I.S.Me.R., Reproductive Medicine Unit, Bologna, Italy*

Study question: Is there any evidence of mosaicism when testing different biopsies of the same blastocyst?

Summary answer: Mosaicism is present in blastocysts as demonstrated by different results when testing different parts of the same blastocyst.

What is known already: Although at a lower rate compared with cleavage stage embryos, chromosomal mosaicism is a common finding in blastocysts. These anomalies can undergo aneuploidy rescue during following development as demonstrated by the birth of healthy babies from embryos with a low level of mosaicism. As the most currently used method in PGT is trophectoderm (TE) biopsy, it is important to verify to which extent the biopsied TE cells are representative of the blastocyst chromosome status. Recent data have reported the presence of DNA in the blastocoelic fluid (BF) that could be analyzed by array-CGH do determine its chromosome condition.

Study design, size, duration: Cohort study including 9 supernumerary blastocysts, which had been diagnosed as aneuploid by array-CGH on blastomeres from day 3 embryos. BF and corresponding TE cells from two sequential biopsies were then tested to verify the correspondence of the ploidy condition in

BFs and the two TE cell biopsies from each blastocyst. To complete the information, the whole embryo was also tested accounting for a total of 4 analyses for each blastocyst.
Participants/materials, setting, methods: 9 blastocysts from 4 couples in our PGT program were selected for the study. After the aspiration of the BF, blastocysts were left to re-expand. Afterwards, TE cells were sequentially retrieved from two different points of each blastocyst (T1 and T2) following re-expansion of the blastocoelic cavity. BF, T1, T2, and the whole embryo were transferred into separate PCR tubes, submitted to amplification and array-CGH by independent operators. Results were then disclosed and compared.
Main results and the role of chance: Amplified DNA was obtained from 36/36 (100%) samples (9 BFs, 18 trophectoderm biopsies, 9 embryos). Following array-CGH gave only one TE biopsy did not provide an informative result accounting for an efficiency of 97.2% (35/36). In all 9 sets, the analysis of BF correctly predicted the ploidy status of the whole embryo. In 6/8 cases the 2 different TE biopsies gave exactly the same result. In one of the two remaining cases, the ploidy status of the blastocyst was correctly predicted, but the two TE biopsies showed aneuploidy for different chromosomes. In the other case, the results from T1 and T2 were discordant: T2 resulted euploid like the corresponding BF and the whole embryo, while T1 was aneuploid for 3 chromosomes. In both these 2 discordant cases, the profile of whole embryo scan images was not flat suggesting the possibility of mosaicism. In 4/9 cases TE biopsies showed a higher level of mosaicism than BF and the whole embryo. In 2 cases the embryo showed a low level of mosaicism for a segmental aneuploidy, that was detectable also in BF, T1 and T2.
Limitations, reasons for caution: Small size of samples analyzed. Need to validate the results with another analytic method.
Wider implications of the findings: These preliminary data confirm that mosaicism occurs in the blastocyst and this could lead to discordant results and consequently to misdiagnosis. BF, collecting DNA from all blastocyst compartments, could be more representative of the blastocyst ploidy condition.
Trial registration number: Not applicable.

P-648 Genome-wide haplotyping of preimplantation embryos in the clinic: principles guiding embryo selection in Leuven

E. Dimitriadou[1], C. Melotte[1], S. Debrock[2], K. Devriendt[1], T. de Ravel[1], E. Legius[1], T. D'Hooghe[2], J.R. Vermeesch[1]
[1]*University Hospital Leuven, Centre for Human Genetics, KU Leuven, Leuven, Belgium*
[2]*University Hospital Leuven, Leuven University Fertility Center, Leuven, Belgium*

Study question: Which are the biological and ethical criteria guiding embryo selection and prioritization following novel genome-wide methods for PGD and which is the clinical outcome?
Summary answer: As guided by the uprise of genome-wide approaches for PGD, a series of selection principles has been has been set and applied clinically.
What is known already: Preimplantation genetic diagnosis by genome-wide haplotyping provides a general overview of the embryonal genome and enable the simultaneous detection of multiple variants, mutations and imbalances genome-wide. The introduction in a diagnostic settings raises novel ethical questions.
Study design, size, duration: From June 2014 until November 2015, 314 embryos from 50 couples seeking PGD for 32 different indications were analyzed in 82 cycles using a novel genome-wide haplotyping-based embryo selection pipeline called siCHILD.
Participants/materials, setting, methods: Patients carrying familial inherited genetic variants and/or chromosomal rearrangements, in risk of obtaining progeny with serious developmental disorders, sought PGD in the University Hospital of Leuven, Belgium. Following consultation with clinical geneticists, fertility specialist and/or counselors, PGD using siCHILD was offered to them. Day 3 embryo biopsy and genetic testing, was followed by embryo selection according to guidelines approved by the local ethical committee. Unaffected embryo were transferred during a fresh or frozen cycle.
Main results and the role of chance: Thirty-two different indications, 28 for monogenic disorders, 3 chromosomal aberrations and 1 case of combined monogenic disorder with chromosomal aberration have been included. Following the analysis of 314 embryos in 82 cycles, at least one embryo was available for transfer in 55 cases. Following embryo transfer, 16 clinical pregnancies (36% clinical pregnancy rate per cycle) and the birth of 5 healthy babies have been achieved so far. No pregnancy was possible in 21 cycles. In 7 cycles, no ongoing pregnancy could be established, due to a biochemical or ectopic pregnancy or an early miscarriage. For the remaining 11 cycles, embryo transfer still needs to be planned. Ranking of embryos based on their carriership status and/or their genome-wide genetic background, has been used in 13 cycles. None of the 5 embryos of low ranking that have been used for transfer resulted in a pregnancy.
Limitations, reasons for caution: siCHILD is applicable whenever haplotype reconstruction is possible, that is the risk allele of interest had been inherited and DNA from family members is available. As novel genome-wide approaches for embryo selection are revolutionizing the field of reproductive genetics, broader discussions to set general guidelines are of outmost importance.
Wider implications of the findings: Our embryo selection principles are based on technical, biological and ethical criteria, have a profound impact on the organization of PGD and the information transferred amongst geneticists, clinicians and patients, are important for the organization of pre- and post-counselling and influence the way of interpreting and reporting preimplantation genotyping results.
Trial registration number: n/a.

P-649 First validation of a next-generation sequencing platform for preimplantation genetic diagnosis of reciprocal translocations using polar bodies

S. Taylor[1], S. Alfarawati[1], S. Knebel[2], K. Held[2], D. Wells[1,3], E. Fragouli[1,3]
[1]*Reprogenetics UK, Institute of Reproductive Sciences, Oxford, UK*
[2]*Reprogenetics Germany, Hamburg, Germany*
[3]*University of Oxford, The Nuffield Department of Obstetrics & Gynaecology, Oxford, UK*

Study question: Can next-generation sequencing (NGS) accurately detect imbalances associated with reciprocal translocations in first and second polar bodies (PBs), biopsied from human oocytes?
Summary answer: NGS is capable of detecting chromosome abnormalities resulting from the unbalanced segregation of reciprocal translocations in PBs and offers significant advantages over established PGD methods.
What is known already: Recently there has been much interest in using NGS for the cytogenetic assessment of embryos. Several studies have described the validation and clinical application of different NGS approaches for the analysis of cells biopsied from cleavage and blastocyst stage embryos in the context of preimplantation genetic screening (PGS). NGS protocols are reported to have cost and accuracy advantages over other methods. It is unclear, however, whether NGS can be employed for the preimplantation genetic diagnosis (PGD) of reciprocal translocations. It is also unknown if NGS can reliably assess the chromosome complement of first and second PBs biopsied from oocytes.
Study design, size, duration: First and second PBs were biopsied from 54 oocytes. The oocytes were derived from a total of 24 women undergoing IVF who were carriers of different reciprocal translocations. All PBs were classified as abnormal after microarray comparative genomic hybridization (aCGH) analysis. These PBs were subsequently re-analysed via an NGS platform. This analysis took place in a blinded manner.
Participants/materials, setting, methods: All biopsied PBs initially underwent a whole genome amplification approach, producing microgram quantities of DNA. The DNA generated was initially employed for comprehensive chromosome assessment using a well-established aCGH approach. Subsequently, a second aliquot of the amplified DNA was utilized for the purpose of NGS. Sequencing was focused on enumeration of chromosome copy number only, specific gene sequences were not investigated.
Main results and the role of chance: NGS succeeded in yielding results for all 54 first and second PBs, and reliably identified all unbalanced reciprocal translocation forms. The smallest unbalanced fragment assessed was ~2–5 Mb, indicating that the NGS resolution is at least as good as aCGH. The data obtained revealed that abnormal segregation of reciprocal translocations occurred most frequently during meiosis I (MI) (80%), although there were cases where translocation chromosomes segregated abnormally during meiosis II (MII) (9%), or during both meiotic divisions (11%). NGS was seen to have a greater dynamic range than aCGH, allowing single chromatid losses/gains to be readily distinguished from errors involving entire chromosomes in first PBs. We

were therefore able to determine that 59 of the 103 (57%) translocation-related structural abnormalities were due to single chromatid malsegregation, with the remaining 44/103 (43%) associated with entire chromosome malsegregation. Correction during the second meiotic division of translocation-related errors that had occurred in MI was observed in 21/54 (39%) second PBs, leading to a total of 6 (11%) chromosomally normal oocytes. NGS detected an additional 48 MI abnormalities that were unrelated to the translocation (29 involving chromatids and 19 affecting entire chromosomes) and 22 MII abnormalities. Comparison of NGS and aCGH showed a 96% concordance.

Limitations, reasons for caution: Assessment of a larger number of first and second PBs from translocation carriers will provide additional assurance that NGS can be reliably employed for the cytogenetic analysis of this type of cell. Assessment of an even greater variety of translocations will help to further define the resolution of the method.

Wider implications of the findings: Our findings indicate that NGS can accurately detect unbalanced products of reciprocal translocations in first and second PBs. The method was highly sensitive enabling accurate distinction between single chromatid and entire chromosome errors, and determined that translocation malsegregation affects chromatid sites more frequently than chromosome ones.

Trial registration number: N/A.

P-650 Validation of next generation sequence (NGS) for PGD of structural chromosome abnormalities

K. Bauckman[1], L. Ribustello[1], T. Escudero[1], E. Armenti[1], R. Capaldi[1], S. Munne[1]
[1]*Reprogenetics, Laboratory, Livingston, NJ, USA*

Study question: Can the VeriSeq PGS NGS assay detect unbalanced structural chromosome abnormalities and provide higher analytical depth in comparison to array comparative genomic hybridization (aCGH)?

Summary answer: NGS is capable of detecting unbalanced structural chromosome abnormalities in embryos and proves to have higher resolution than aCGH.

What is known already: Structural chromosome abnormalities in embryos were first detected via fluorescence *in situ* hybridization (FISH). In addition to being unable to test for the full complement of chromosomes, FISH required probe preparation following exhaustive analysis for each particular case. Array-CGH was validated for structural chromosome abnormalities and provided the advantage of being able to screen for aneuploidy of all the chromosomes while simultaneously detecting the translocation, typically without prior test preparation. However, aCGH cannot be used if 2 out of the 4 chromosome fragments involved in the translocation are below 6 Mb; therefore, FISH is still necessitated for some cryptic translocations.

Study design, size, duration: 75 embryos were reanalysed via Veriseq PGS Solution comprising of 300 regions of the genome involved in translocations. Since the amplification method for both array-CGH and NGS is identical, there was no need to rebiopsy any embryos. An aliquot consisting of 5 ul was used from the previously analysed array-CGH samples consisting of known structural chromosome abnormalities. A blinded analysis was then performed to evaluate the results.

Participants/materials, setting, methods: SurePlex whole genome amplification products from trophectoderm biopsies that were previously performed to evaluate for a known structural chromosome rearrangement by aCGH were processed using the Illumina VeriSeq PGS assay with the MiSeq sequencing platform. Results were interpreted through BlueFuse Multi analysis software.

Main results and the role of chance: NGS analysis provides accurate information regarding regions involved in the translocation because it can detect copy numbers of those regions ranging from 0 to N copies. NGS analysis revealed a higher resolution compared to aCGH by accurately detecting unbalanced embryos when the regions involved in the translocations were 3 Mb or above in 100% of segments 3–6 Mb (n = 39). The size of the breakpoints of the 75 embryos ranged from 1.6 Mb to 164.0 Mb. These embryos had been diagnosed as either "Unbalanced" with any gain or loss associated with chromosomes involved in the translocation or "Normal or Balanced". 74/75 samples were concordant with the analysis (98.67%). The discordant sample was a triploid embryo, which is undetectable by aCGH. Of the chromosomal regions involved in the translocations, 271/300 were concordant, and 29 were discordant. These 29 discordances were due to the inability of the aCGH technique to detect gains or losses in of less than 6 Mb, inaccuracy in giving the correct copy number, or mosaicism.

Limitations, reasons for caution: NGS does not allow the distinction between normal or balanced embryos; this is also a limitation of aCGH and FISH testing. Additionally, if two or more fragments involved in the translocation have a size less than 3 Mb, NGS would not be recommended.

Wider implications of the findings: This advancement can provide subtle structural chromosome rearrangement carriers the opportunity to use NGS over FISH so they can screen for all chromosomes and the detection of polyploidy. FISH is limited because it requires fixation of blastomeres whereas NGS allows for analysis of trophectoderm samples from a blastocyst biopsy.

Trial registration number: N/A.

P-651 Multinucleated embryos: to transfer or not to transfer?

M. Parriego[1], F. Vidal[2], M. Boada[1], S. Mateo[1], L. Coll[1], M. Tresánchez[1], B. Coroleu[1], A. Veiga[1]
[1]*Woman's Health Dexeus, Department of Obstetrics Gynaecology and Reproduction, Barcelona, Spain*
[2]*Universitat Autònoma de Barcelona, Department of Cell Biology, Physiology and Immunology, Bellaterra, Spain*

Study question: Is it justified to transfer multinucleated embryos although they have a reduced developmental potential and an increased rate of chromosomal abnormalities?

Summary answer: Multinucleated embryos show an altered morphokinetic pattern and a decreased developmental potential, however euploid blastocysts from multinucleated and non multinucleated embryos have similar implantation capacity.

What is known already: Multinucleation is a common phenomenon in *in vitro* human embryos and is associated to an impaired developmental capacity and increased chromosomal abnormalities. Time-lapse monitoring of embryo development allows a continous and detailed observation of fertilization and cleavage events. Multinucleated embryos are not usually transferred unless non multinucleated embryos are available.

Study design, size, duration: Retrospective analysis of 4192 embryos cultured in a time-lapse system from 534 ICSI cycles and 1908 embryos cultured in a time-lapse system from 199 PGS cycles performed between 2012 and 2014.

Participants/materials, setting, methods: Embryos were cultured in an Embryoscope incubator after ICSI. Presence of multinucleation in all developmental stages was retrospectively assessed. Embryo replacement was performed on D + 3. Multinucleated embryos were cultured to the blastocyst stage and cryopreserved for subsequent transfer.

In PGS cicles, embryos were biopsied on D + 3. One cell was analysed by a-CGH. Euploid embryos were transferred and/or cryopreserved at the blastocyst stage. Correlations between multinucleation and morphokinetics, developmental ability, chromosomal constitution and implantation capacity were established.

Main results and the role of chance: Twenty three point six percent of the studied embryos showed multinucleation. Multinucleated embryos presented delayed morphokinetic behaviour and reduced developmental capacity. Eighteen per cent of multinucleated embryos reached the blastocyst stage and were cryopreserved. The survival rate after thawing was 84.6%. From multinucleated KID replacements, the implantation rate was 39.1%.

The percentatge of embryos biopsied did not differ between multinucleated and non-multinucleated embryos (93.1% vs. 95.0%). Multinucleated embryos showed a lower euploidy rate (14.0% vs. 21.3%), and a higher percentatge of complex aneuploidy (58.2% vs. 45.4%) when compared to non multinucleated ones. No differences were observed in the percentage of aneuploidy with respect to the multinucleation type (81.1% binucleated vs. 85.5% multi/micronucleated) or percentatge of multinucleated cells (82.7% for ≤50% vs. 86.9 for >50%). Similar implantation rates were observed after transfer of euploid blastocists derived from multinucleated or non multinucleated embryos in 75 KID-PGS transfers.

Limitations, reasons for caution: In ICSI cycles, non multinucleated embryos were only cultured to D + 3 and thus do not represent a control group for the multinucleated embryos with respect to the blastocyst rate.

In PGS cycles, the chromosomal constitution has been assessed through one cell biopsy and thus embryo mosaicism could not be evaluated.
Wider implications of the findings: Multinucleated embryos that reach the blastocyst stage can be replaced and present a high implantation potential.
Trial registration number: –.

P-652 Preimplantation genetic diagnosis (PGD) for inherited disorders using Karyomapping with optional preimplantation genetic screening (PGS): diagnostic and clinical outcomes from 576 cycles

S. Jaroudi[1], R. Prates[1], D. Goldberg-Strassler[1], R. Cabey[1], E. Armenti[1], A. Jordan[1], M. Konstantinidis[1], S. Munne[1]
[1]*Reprogenetics, Molecular Genetics, Livingston, NJ, USA*

Study question: Is PGD using Karyomapping, a universal single nucleotide polymorphism (SNP)-array linkage analysis technique, a successful treatment strategy for patients requesting embryo testing for inherited disorders?
Summary answer: High accuracy diagnostic and implantation rates were observed with faster time to diagnosis/pregnancy. The majority of cases involved combined PGD + PGS and single embryo transfer.
What is known already: Karyomapping utilizes a universal protocol for linkage-based PGD applicable to virtually all patients. It eliminates the need to develop and optimize patient-specific protocols, drastically reducing the waiting time for initiation of IVF treatment. This technology was previously validated using the gold-standard polymerase chain reaction methodology (with 100% concordance) and has proven to be highly efficient for even the most complex of cases, including those not feasible using conventional PGD methods, such as deletions and duplications. Additionally, it is possible to combine Karyomapping with PGS using microarray comparative genome hybridization (aCGH) or next generation sequencing (NGS).
Study design, size, duration: Among the 576 Karyomapping cases performed between January 2014 and January 2016, clinical outcomes and follow-up data was collected for 447 PGD cycles with embryos suitable for transfer. Two hundred and seven cycles had undergone embryo transfer at the time of data collection, while the rest remain frozen or had no euploid and disease free embryos for transfer.
Participants/materials, setting, methods: A total of 3584 embryos were biopsied at the blastocyst stage and frozen for transfer in subsequent cycle(s). Samples were whole genome amplified and analyzed using Karyomapping. Additionally, most patients (87%) requested PGS, which was performed independently using aCGH (462 cases) or NGS (40 cases).
Main results and the role of chance: PGD was offered for over 90 different single gene disorders, deletions/duplications or translocations (10 different cases) and/or HLA-matching (14 cases). The Karyomapping diagnostic rate was 96.7%. The average numbers of embryos analyzed and eligible for transfer per cycle were 4.75 and 2.12 for cases undergoing PGD alone and 6.3 and 1.8 for PGD + PGS.

The implantation rate was 74.3% (135/183) for PGD + PGS (average maternal age: 34.1 years) and 66.7% (16/24) for PGD alone (average maternal age: 32.5 years). The proportions of cycles with transferable embryos and average number of transfers per cycle started were similar for PGD + PGS (75% and 0.98) and PGD alone (76% and 1.12). Most transfers involved a single thawed blastocyst, except for seventeen patients (9.4%) who had two embryos replaced together.

There were 23 healthy live births and 82 ongoing pregnancies at the time of analysis. Prenatal and perinatal testing when performed confirmed PGD in all instances. No misdiagnoses have been reported to date (0/105 misdiagnosed pregnancies).
Limitations, reasons for caution: The collection of clinical outcome and follow-up data can be challenging, particularly when dealing with large numbers of referring centers and overseas patients. Few patients elect to undergo prenatal testing to confirm the diagnosis. Ongoing follow-up data analyses will conclusively reveal the high accuracy of PGD using Karyomapping.
Wider implications of the findings: Karyomapping allows PGD laboratories to cope with the rapidly growing demand for embryo testing and diagnose a wider range of disorders. The high implantation rates were similar to outcomes achieved by the most successful *in vitro* fertilization programs. Simultaneous PGS speeds up the testing process and further improves clinical outcomes.
Trial registration number: Not applicable.

P-653 Abnormal serum dehydroepiandrosterone sulphate (DHEAS) concentration in *in vitro* fertilization patients increased embryo aneuploidy assessed by next-generation sequencing technology (NGS)

K. Lukaszuk[1,2], J. Liss[1]
[1]*Invicta Sp. z o.o., Reproduction and Fertility Centre, Gdansk, Poland*
[2]*Medical University of Gdansk, Department of Obstetrics and Gynecological Nursing, Gdansk, Poland*

Study question: To assess correlation between serum hormones concentration, ovarian reserve and ploidy status in *in vitro* fertilization patients.
Summary answer: Increased serum DHEAS concentration in women without DHEA suplementation increases the risk of aneuploid embryos compared to patients with normal serum DHEAS.
What is known already: Dehydroepiandrosterone (DHEA) has been demonstrated to improve embryo quality and pregnancy chances in women with diminished ovarian reserve (DOR). It is still unknown, how these effects are achieved. DHEA supplementation reduces aneuploidy in women with DOR.
Study design, size, duration: Retrospective study including the data analysis of 163 IVF/PGS cycles (median age 38 years, range 34–40) performed between January 2014 and September 2015 at INVICTA Fertility Centre, Poland. A total of 561 blastocysts were evaluated with the NGS protocol. No DHEA supplementation was used before IVF cycles. Only first IVF cycles were analysed.
Participants/materials, setting, methods: Normal serum DHEAS concentrations were found in 144 patients, higher in 19. The embryo ploidy status was assessed by dividing number of aneuploid embryos by the numbers of normal embryos. Two PGS groups were analysed: one with majority of aneuploid embryos (factor >1 of aneuploidy vs. normal embryos) and second with majority of normal blastocysts (factor ≤1 of aneuploidy vs. normal embryos).
Main results and the role of chance: Two PGS groups did not differ in age, serum AMH, InhibinB, TSH, T, SHBG concentration. 93 (64.6%) patients with normal serum DHEAS had advantage aneuploidy, while in the group with a higher serum DHEA rate of aneuploidy was statistically significant higher ($p = 0.05$) and amounted 84.2% (16 patients). The univariate regression analysis of variables studied for the prediction of advantage aneuploidy showed that serum DHEA is a predictor for advantage aneuploidy (OR 3.27; 95% CI, 1.06–10.12). The risk of increased advantage aneuploidy in all analysed embryos from one cycle is more than three times higher in women with increased serum DHEAS concentration ($p = 0.01$).
Limitations, reasons for caution: The study is limited by sample size. A higher sample size or a prospective randomized design could be used in future studies to corroborate the current findings.
Wider implications of the findings: Increased serum DHEAS concentration in *in vitro* fertilization patients may be an indication to perform PGD additionally. The risk of aneuploidy is higher in patient with increased serum DHEAS concentration than in normal.
Trial registration number: Not applicable.

P-654 Why do euploid embryos miscarry? A retrospective study comparing aneuploidy rates within presumed euploid embryos resulting in miscarriage or live birth using next-generation sequencing (NGS)

S. Maxwell[1], A. Coates[2], P. Colls[3], B. Hodes-Wertz[1], D.H. McCulloh[1], C. McCaffrey[1], R. Capaldi[4], F. Gouw[4], E. Liu[3], L. Ribustello[3], S. Munne[3], J. Grifo[1], S. Tormasi[4]
[1]*New York University Langone Medical Center Fertility Center, Reproductive Endocrinology and Infertility, New York, NY, USA*
[2]*Oregon Reproductive Medicine, Embryology, Portland, OR, USA*
[3]*Reprogenetics, Genetics Laboratory, Livingston, NJ, USA*
[4]*Reprogenetics, Genetics laboratory, Los Angeles, CA, USA*

Study question: Does undetected aneuploidy or mosaicism contribute to pregnancy loss after transfer of euploid embryos by array comparative genomic hybridization (aCGH)?
Summary answer: NGS detects more cases of mosaicism and triploidy than aCGH, and mosaicism rates are significantly higher among pregnancies resulting in miscarriage than live birth.
What is known already: Array CGH is widely used for pre-implantation genetic screening (PGS). NGS is capable of detecting more cases of mosaicism and triploidy (69XXY), which may assist in reducing the incidence of spontaneous abortion and increase ongoing pregnancy rates.

Study design, size, duration: Retrospective study of 183 patients undergoing PGS by aCGH between 8/2012 and 5/2015 at New York University Fertility Center and Oregon Reproductive Medicine.
Participants/materials, setting, methods: Saved amplified DNA samples from the 183 blastocyst trophectoderm (TE) biopsies previously diagnosed as euploid by aCGH were re-analyzed using the miSeq NGS platform (Illumina, USA) and VeriSeq NGS technology (Illumina, USA). 44 embryos resulting in a biochemical pregnancy, 62 resulting in miscarriage, and 77 resulting in live birth were available for re-analysis.
Main results and the role of chance: 25% (11/44) of embryos resulting in biochemical pregnancies were mosaic, and one embryo was found to be triploid (69, XXY) by NGS. 33.9% (21/62) and 3.2% (2/62) of embryos resulting in miscarriage were mosaic and triploid by NGS, respectively. In contrast, the mosaicism rate among embryos resulting in live birth was only 13% (10/77), which was significantly lower than the rate of mosaicism among miscarriages ($p = 0.0062$, RR 1.78 with 95% CI 1.23–2.5).
Limitations, reasons for caution: This study was limited by its retrospective design. Up to 10% of DNA samples that were undergoing re-analysis were excluded due to degraded DNA, although the frequency was similar in all three groups.
Wider implications of the findings: Undetected mosaicism may increase the risk of first trimester pregnancy loss. NGS is more sensitive at picking up mosaicism and triploidy than aCGH. Mosaic embryos can be considered for transfer after genetic counseling and informed consent, but they have a higher miscarriage rate as well as unknown post-natal genetic effects.
Trial registration number: N/A.

P-655 Utilizing CGG repeat length to determine Anti-Müllerian Hormone (AMH) levels in women without the Fragile X premutation

C. Mullin[1], A. Peyser[1], S. Solouki[1], S. Tomer[1], A. Hershlag[1]
[1]*Northwell Fertility, Hofstra Northwell School of Medicine, Manhasset, NY, USA*

Study question: Is there a correlation between the number of CGG repeats on the FMR1 gene and AMH values in women without the Fragile X premutation?
Summary answer: Our data set, the largest to date, shows that repeats deviating from the normal range, 29/30, correlate with decreased AMH levels.
What is known already: The number of CGG repeats on the Fragile X (FMR1) gene has been known to correlate with premature ovarian failure in patients with the premutation (CGG repeats of 55–200). Previous studies have discussed the relationship between CGG repeats less than 45 and diminished ovarian reserve using serum AMH levels, as AMH has been shown to be an accurate biomarker for ovarian reserve. Yet, the relationship remains inconclusive based on conflicting results.
Study design, size, duration: A retrospective cohort study of 1842 infertility patients seen at our University affiliated fertility center between June 2013 and July 2015.
Participants/materials, setting, methods: CGG repeats on allele 1, allele 2 and the average of both alleles were obtained as well as serum AMH values. The cohort was stratified based on age, (≤35 ($n = 936$), >35 ($n = 888$)) and further stratified based on the number of repeats (<29, 29/30, >30). Patients with AMH >10 and CGG repeats of 45–55 (grey zone) were excluded. AMH values of patients with CGG repeats <29 and >30 repeats were compared to the normal range of 29/30.
Main results and the role of chance: Allele 1 repeats <29 yielded lower AMH values than the normal repeat pattern in both the ≤35 and >35 age groups ($p = 0.03$, $p = 0.01$, respectively). Allele 1 repeats >30 in the >35 age group yielded lower AMH values ($p = 0.01$). Allele 2 repeats >30 in the ≤35 aged women yielded lower AMH ($p = 0.04$). When the average of both alleles was <29 in both younger and older age groups, AMH was decreased. ($p = 0.08$, $p = 0.01$, respectively).
Limitations, reasons for caution: All laboratory investigations were performed using commercial assays. (Counsyl, San Francisco, CA.)
Wider implications of the findings: Our findings are consistent with prior studies showing that deviations from the normal 29 and 30 CGG repeats on allele 1 and allele 2 correlated with decreased AMH. Departure from DNA's normal stability may cause fluctuations in patients' fertility profiles. Larger scale studies will be beneficial to confirm these results.
Trial registration number: NA.

P-656 Euploid and aneuploid rates on day 5 vs. day 6 of blastulation

T. Singer[1], J. Gottfried[1], A. Peyser[1], C. Mullin[1], J. Pan[1], J. Moschella[1], A. Hershlag[1]
[1]*Northwell Fertility, Hofstra Northwell School of Medicine, Manhasset, NY, USA*

Study question: Is there a higher rate of aneuploidy in blastocysts biopsied on day 5 compared to day 6?
Summary answer: Increased aneuploidy rates were observed on day 6 biopsied blastocysts compared to day 5 in patients less than 35-year-old.
What is known already: Comprehensive Chromosomal Screening (CCS) is used for aneuploidy analysis at different phases of embryo development. In the past decade, there has been a shift from cleavage stage biopsies to blastocyst biopsies, believed to be more reliable (less chance of mosaiscm) and associated with higher implantation rates. It is believed that embryos that are slower to progress (day 6) have a higher chance of Meiosis I and II non-disjunction, compared with faster developing embryos (day 5). Previous studies have indeed demonstrated an increased rates aneuploidy in day 6 biopsied embryos compared with day 5.
Study design, size, duration: Retrospective cohort study of 58 patients (69 cycles) who underwent IVF between April 2014 and December 2015 with a single physician at an University affiliated academic institution in New York City.
Participants/materials, setting, methods: Results obtained for embryos from patients who underwent CCS were reviewed. 358 embryos met the inclusion criteria, were biopsied as they reached the blastocyst stage and vitrified for future transfer. CCS was completed by Reprogenetics® (New Jersey) by array comparative genomic hybridization (aCGH) to determine euploid or aneuploid status. Euploidy and aneuploidy rates were then compared on day 5 vs. day 6 biopsy. In addition, aneuploidy rates were compared when controlled for age (≤35 and >35).
Main results and the role of chance: 358 embryos were included in the study. 110 were biopsied on day 5 and 248 were biopsied on day 6. Euploid rates was higher for day 5 embryos (61/110, 56%) compared to day 6 (111/248, 45%) ($p = 0.06$). When stratifying by age, euploid rates of day 5 embryos in the ≤35 age group were 75% (41/55), significantly higher than the euploid rate on day 6, 59% (63/107) ($p = 0.04$). In the >35 age group, the aneuploidy rates on day 5 (35/55, 63%) and day 6 (93/141, 66%) were not different statistically ($p = 0.71$).
Limitations, reasons for caution: Not applicable.
Wider implications of the findings: In younger patients undergoing CCS, day 5 embryos have significantly higher euploid rates compared with day 6. Larger studies are needed to support the data.
Trial registration number: NA.

P-657 Skewed X-inactivation and telomere content in premature ovarian failure: a preliminary study

C. Furtado[1], H. Luchiari[1], G. Kogure[1], L. Caetano[1], D. Pedroso[1], E. Ramos[1], R. Calado[1], R. Reis[1]
[1]*Faculty of Medicine of Ribeirao Preto, Obstetrics and Gynaecology, Ribeirao Preto, Brazil*

Study question: X-inactivation pattern and telomere content are related events in premature ovarian failure (POF)?
Summary answer: Telomere content was reduced in POF women that also presented skewed X inactivation profile.
What is known already: Anovulation in POF women can be related to structurally aberrant X-chromosomes or 45, X/46, XX mosaics, in which X chromosome inactivation (XCI) pattern could represent an epigenetic marker in cryptic mosaicism. Deregulation of epigenetic control, such as nonrandom X inactivation in female genome is related to telomere dysfunction and maybe an important feature of POF.
Study design, size, duration: Case–control study, in which 34 non-syndromic POF and 75 controls with regular menstrual cycle were included.
Participants/materials, setting, methods: POF (FSH > 40 IU/l) with 46, XX karyotype and control women with regular menstrual cycle (FSH < 10 IU/l) participated in this study. Height, age, weight, body mass index (BMI), and systemic (SAP) and diastolic arterial pressure (DAP) were measured. Telomere

content was measured using quantitative real time PCR (qPCR). XCI analysis was based on human androgen receptor (HUMARA) and X-linked retinitis pigmentosa 2 (*RP2*) assays. Statistical analyses were determined by Student's *t*-test and chi-square test (χ^2).

Main results and the role of chance: No statistical differences were observed between POF and controls in age, height, BMI, SAP and DAP. The POF group presented less weight than controls (65.03 ± 12.48 and 72.95 ± 18.53; $P = 0.02$). POF group showed reduced telomere content (0.90 ± 0.21; $n = 33$) when compared to control group (1.07 ± 0.29; $n = 75$) ($P = 0.01$). Skewed XCI (≥75%) was more frequent in POF (42.42%, $n = 14$) than control (15.8%, $n = 3$) group ($P = 0.02$). Random XCI was observed in 54.55% ($n = 18$) of POF and 86.49% ($n = 34$) of control group. XCI could not be detected in only one case of POF (3.03%) that was homozygote for both markers. Interestingly, from those POF women with skewed XCI, extreme skewing (≥90%) was observed in 50% ($n = 7$).

Limitations, reasons for caution: Limited number of cases of the study group (POF). An increase of sample size is recommended to make the data more robust and confirm the results.

Wider implications of the findings: Skewed XCI and reduced telomere content was observed in POF women, a condition that is maybe correlated. Also, extreme skewing is a rare phenomenon in the normal female population but is frequently observed in X-linked mutations and telomere dysfunction, suggesting a possible role in POF etiology.

Trial registration number: N/A.

P-658 Whole genome sequencing analysis reveals genes related to lipid metabolism and inflammation are disrupted in women across different infertility diagnoses

C. Clementi[1], E. Parfitt[1], S.T. Globus[1], A.B. Copperman[2,3], F. Arrendondo[4], B.T. Miller[5], J. Nulsen[6], J.N. Gutmann[7], P. Yurttas Beim[1]
[1]*Celmatix Inc., Research and Development, New York, NY, USA*
[2]*Reproductive Medicine Associates of New York, Clinic, New York, NY, USA*
[3]*Mount Sinai Medical Center, Obstetrics, Gynecology and Reproductive Science, New York, NY, USA*
[4]*Reproductive Medicine Associates of Texas, Clinic, San Antonio, TX, USA*
[5]*Reproductive Medicine Associates of Michigan, Clinic, Troy, MI, USA*
[6]*Center for Advanced Reproductive Services, Clinic, Hartford, CT, USA*
[7]*Reproductive Medicine Associates of Philadelphia, Clinic, Philadelphia, PA, USA*

Study question: Reproductive disorders, such as endometriosis and PCOS, share common phenotypes, such as increased miscarriage rates. We aimed to understand whether disruptions in the same molecular pathways underlie these common phenotypes.

Summary answer: Disruptions in genes playing a role in lipid metabolism and inflammation are frequently associated with a variety of reproductive phenotypes in patients undergoing fertility treatment.

What is known already: Research aimed at decoding the genetic basis of infertility phenotypes has typically focused on single genes or regions in the context of single diagnoses. For example, many studies demonstrate an association between inflammation and endometriosis, and studies focusing on PCOS often look at lipid metabolism. However, no studies have embarked on genome wide interrogation of the spectrum of reproductive disorders.

Study design, size, duration: We first built a genomic knowledgebase by performing a systematic literature review of 20,000 publications linking a genotype to a reproductive outcome. Then, we collected blood samples from 253 women with different diagnoses undergoing treatment at 5 fertility centers between November 2012 and March 2015. Women with a natural parity of ≥1, history of gynecological surgery, cancer treatment, genetic syndromes or major illness or trauma that would compromise fertility, were excluded.

Participants/materials, setting, methods: After obtaining IRB consent, blood samples were collected from all patients and whole genome sequencing performed on extracted DNA using Illumina sequencers. Bioinformatics tools were then applied to report variant calls, novel and deleterious variants. Patient variant signatures were then analyzed using phenotypic and genotypic data curated from our knowledge base.

Main results and the role of chance: Our analysis reveals that a relatively small number of genes recur in their association with multiple fertility-related pathologies. For example, deleterious mutations in GSTP1 and MALRD1 occur between 2.6 and 6.6 times more frequent in both endometriosis and PCOS patients than in the general population. These genes are known to play roles in the oxidative stress response and lipid metabolism, both of which contribute to hormonal regulation and inflammatory response mechanisms in the ovary and endometrium. Our results suggest that fertility-related pathologies can be associated with genetic variants among both diagnosis-specific genes and pathways, as well as a core set of variants common to all or many reproductive phenotypes. Such insight could facilitate the identification of patients at risk of infertility through conditions that we understand less, or that require more invasive diagnostic procedures.

Limitations, reasons for caution: While the biological effect of many genetic variants is well-established, epistatic effects of these variants on human fertility is not fully understood.

Wider implications of the findings: A genomic approach to reproductive dysfunction may aid in molecular characterization of disease, and when combined with the classical clinical phenotypic approach, may improve both diagnostic and therapeutic accuracy.

Trial registration number: None.

P-659 Aneuploidy screening on polar bodies: next generation sequencing versus array comparative genomic hybrization

A. Kotanidou[1], T. Harasim[1], A. Wagner[1], I. Rost[1], H.G. Klein[1]
[1]*Center for Human Genetics and Laboratory Diagnostics, Martinsried, Germany*

Study question: Can whole chromosome- and segmental aneuploidies be detected by Next Generation sequencing (NGS) in polar bodies? How is the result concordance between array comparative genomic hybrization (aCGH) and NGS?

Summary answer: NGS is able to detect aneuploidies with high accuracy and concordance compared to aCGH. NGS appears to be a robust methodology for 24-chromosome aneuploidy screening.

What is known already: Preimplantation genetic screening (PGS) improves implantation rate, decreases miscarriage rate and decreases the risk of abnormal offspring. PGS methodologies evolved from fluorescence *in situ* hybridization to aCGH and finally to NGS.

Study design, size, duration: NGS based aneuploidy screening was evaluated by analyzing pretested polar bodies. Therefore, 22 clinical polar bodies, which were screened by aCGH between November and December 2015, were selected. Selection criteria were based on clear or borderline whole chromosome- or segmental aneuploidies.

Participants/materials, setting, methods: 1 ng of whole genome amplification products were used NGS based aneuploidy screening (VeriSeq PGS, Illumina). Library preparation consisted of photometric quantitation, tagmentation and amplification of dual indexed fragments. Each library was normalised before pooling and loaded into a MiSeq instrument (Illumina, USA).

Main results and the role of chance: Overall, great concordance was observed between NGS and aCGH. All single, dual and complex (≥3) aneuploid samples were confirmed by NGS. 2 segmental aneuploidies were confirmed and detected with a much greater resolution compared to aCGH. Importantly, all polar bodies diagnosed as euploid by array-CGH were confirmed as euploid with NGS and *vice versa*.

Limitations, reasons for caution: Although NGS based PGS exhibited high concordance with aCGH for both numerical and structural chromosome abnormalities, further randomized control trials subsequent clinical validation studies are required to better define the sensitivity, specificity and positive and negative predictive values of NGS based polar body aneuploidy screening.

Wider implications of the findings: There were additional advantages with use of NGS, the high resolution NGS based PGS might be especially important for mosaicism detection. Additionally, it offers also the analysis of multiple samples from multiple patients with different indications on the same platform. Despite these advantages one major drawback of NGS

Trial registration number: N/A.

REPRODUCTIVE ENDOCRINOLOGY

P-660 Aberrant expression and DNA methylation of lipid metabolism genes in PCOS: a new insight into its pathogenesis

J. Pan[1], L. Ye[2], F. Wang[3], F. Qu[3], Z. Ke[3], J. Xu[3], X. Huang[1]
[1]*The First Affiliated Hospital of Whenzhou Medical College, Reproductive Medicine Center, Wenzhou, Zhejiang, China*
[2]*The First Affiliated Hospital of Whenzhou Medical College, General Surgery, Wenzhou, Zhejiang, China*
[3]*Women's Hospital, Medical School, Zhejiang University, Reproductive Endocrinology, Hangzhou, China*

Study question: The transcriptone profiling of granulosa cells (GCs) and related differential methylation in polycystic ovary syndrome (PCOS) remain to be illustrated.
Summary answer: The hypomethylated genes related to synthesis of lipid and steroid might dysregulate the expression of these genes and promote synthesis of steroid hormones including androgen.
What is known already: PCOS, characterized by chronic anovulation and hyperandrogenism, is one of the most prevalent endocrine disorders in women of reproductive age. The pathogenesis of PCOS is not fully illustrated, and several lines of evidence demonstrate that PCOS is a complex and multifactorial disorder with a high degree of heritability. The high degree of familial aggregation of PCOS suggests that genetic factor plays an important role in its etiology, and recent genetic studies have also been performed with not much added information to the field.
Study design, size, duration: Seventy-one women with PCOS and fifty women with normal ovulatory cycles (control) undergoing *in vitro* fertilization during September 2014–June 2015 participated in this case–control study.
Participants/materials, setting, methods: The subjects enrolled in this study from these two groups have comparable BMI levels and age. RNA-Seq was performed using Illumina Hiseq 2000. The transcriptome results for selected genes were confirmed by real-time quantitative PCR. 5-methycytosine analysis and MassArray EpiTYPER quantitative DNA methylation analysis were employed to determine the methylation level of global DNA and each CpG site or unit in the promoters of related genes, respectively.
Main results and the role of chance: RNA-seq identified 92 DEGs in PCOS GCs in comparison with the corresponding controls. Bioinformatics analysis indicated that synthesis of lipid and steroid was activated in PCOS GCs. 5-Methycytosine analysis showed that there was an approximate 25% reduction in global DNA methylation of GCs from PCOS women (4.44 ± 0.65%) compared with the controls (6.07 ± 0.72%, $P < 0.05$). Using the introduction of MassArray EpiTYPER quantitative DNA methylation analysis, we also found the hypomethylation in the promoters of several genes related to synthesis of lipid and steroid, which might result in the abberant expression of these genes.
Limitations, reasons for caution: A sample size of $n = 3$ for RNA seq study is inadequate. This could inevitably cause some false positive and false negative results. We validated some of the positive results, and got consistent results.
Wider implications of the findings: The hypomethylated alterations in follicular cells may results in permanent modifications of the offspring's epigonome and alterations of their gene-expression patterns, which may increase susceptibility of adult diseases.
Trial registration number: None.

P-661 The "normal" range of FMR1 triple CGG repeats may be associated with primary ovarian insufficiency in China

C. Lu[1]
[1]*Center for Reproductive medicine, Beijing, China*

Study question: What is the correlation between normal numbers of Fragile X mental retardation gene 1 (*FMR1*) CGG repeats and POI occurrence or subsequent resumption of ovarian function.
Summary answer: Fewer than 26 or more than 28 CGG repeats CGG repeat number in the smaller allele (allele1) of *FMR1* were significantly associated with POI occurrence.
What is known already: *FMR1* premutation was not a common explanation for sporadic POF in Han Chinese. Also, few studies have investigated the correlation between normal range of *FMR1* CGG repeats number and Chinese POI occurrence and no data on subsequent resumption of ovarian function.
Study design, size, duration: A retrospective study was performed at our center for reproductive endocrinology. A total of 122 occult POI cases and 105 controls were followed up and analyzed from 2012 to 2014 in our center.
Participants/materials, setting, methods: The number of *FMR1* CGG repeats were detected by capillary electrophoresis for each patient. The correlation between CGG repeats and the occurrence of POI or the resumption of ovarian function was evaluated by Chi-squared test or logistic regression analysis.
Main results and the role of chance: The prevalence of premutation and intermediate range of *FMR1* in Han Chinese POI patients was only 0.81% (1/122) and 1.64% (2/122), respectively. The risk of POI occurrence for <26 CGG repeats in allele1 was significantly higher than that for 26–28 CGG repeats ($P < 0.001$, odds ratio 13.50, 95% confidence interval: 3.21–56.77). The risk of POI occurrence for ≥29 CGG repeats in allele1 was also higher than that for 26–28 CGG repeats ($P < 0.001$, odds ratio 6.07, 95% confidence interval: 2.18–16.90). Furthermore, patients with a history of pregnancy had a higher ovarian function resumption rate (45.45% vs. 10.19%; Fisher, $P = 0.007$). However, there was no significant difference in the CGG repeat distribution (<26, 26–28, or ≥29) in *FMR1* allele1 between POI cases whose ovarian function resumed and those whose ovarian function did not.
Limitations, reasons for caution: The study focuses on the relationship between number of *FMR1* CGG repeats and POI occurrence or ovarian function resumption, but is absent of the mechanism study on why ovarian disturbance is so sensitive to small changes in CGG repeats.
Wider implications of the findings: The *FMR1* gene plays a more significant role in POI than was previously thought. Allele1, but not allele2, plays a major role in POI risk prediction. Fewer than 26 or more than 28 CGG repeats in *FMR1* allele1 may be used to predict the probability of POI occurrence.
Trial registration number: no.

P-662 Comparison of results treated with double stimulation protocol and short downregulation protocol for ovarian stimulation in poor ovarian responder: a prospective matched cohort study

Y. Li[1], Q. Zhang[1]
[1]*Xiangya Hospital, Central–South University, Center for Reproductive Medicine, Changsha, China*

Study question: What kind of protocol is better for ovarian stimulation in poor ovarian responder (POR)?
Summary answer: Double stimulation is a safe, patient-friendly, cost effective protocol for POR and relates good quality embryos.
What is known already: A dramatic lack of antral follicles contributes to reduced oocyte/embryo quantity and quality in POR. Double stimulation protocol provides two opportunities for retrieving oocytes in one menstrual cycle.
Study design, size, duration: From July 2014 to December 2015, a prospective matched cohort study recruited 300 patients were performed in an academic center for reproductive medicine.
Participants/materials, setting, methods: In the academic fertility center, POR were recruited in their first *in vitro* fertilization (IVF) cycles. Matched for age and body mass index, these 300 patients were divided randomly into two groups. After ovarian stimulation with different protocol, the stimulation parameters, accumulated clinical pregnancy rate and embryo implantation rate were compared.
Main results and the role of chance: By the end of the study, 266 patients (133 couples) reached to the stage of follicular puncture and accepted follow-up. The risk of failure in oocyte retrieval was higher in double stimulation protocol (6.02% vs. 0.75%, $p = 0.036$). No significant difference was detected between the two protocols regarding the number of retrieved oocytes (3.22 ± 2.60 vs. 3.03 ± 1.71, $p = 0.784$). But lower dose of exogenous gonadotrophin was administrated in double stimulation protocol (1475.31 ± 860.42 vs. 2605.21 ± 899.16, $p < 0.001$). The rate of two pronucleus (85.32% vs. 60.50%, $p < 0.001$) and formation of high-grade cleavage-stage embryos (45.52% vs. 34.75%, $p = 0.002$) were higher in double stimulation protocol. Ultimately, both the

calculated clinical pregnancy rate (28.87% vs. 19.81%, $p = 0.143$) and embryo implantation rate (20.69% vs. 14.55%, $p = 0.156$) were higher in double stimulation protocol in tendency, but without statistical difference.
Limitations, reasons for caution: It was a single-center study with small sample size.
Wider implications of the findings: Double stimulation protocol will become the first-line protocol for the ovarian stimulation in POR by the virtue of safer, lower-cost, and less side-effects.
Trial registration number: ChiCTR-IOR-14005521.

P-663 Hydrogen sulfide is an endogenous modulator of vaginal lubrication

Q. Sun[1,2,3], J. Huang[1], Y. Yue[1], J. Xu[1], P. Jiang[1], D. Yang[1], Y. Zeng[2,3], W. Zhou[1]
[1]Sun Yat-sen University, School of Life Sciences, Guangzhou, China
[2]Shenzhen Zhongshan Urology Hospital, Shenzhen Key Laboratory of Reproductive Immunology for Peri-implantation, Fertility Center, Shenzhen, China
[3]Shenzhen Zhongshan Urology Hospital, Reproduction and Genetics, Shenzhen, Guangdong, China

Study question: Our objective was to study the role(s) of H_2S in vaginal lubrication and to determine the mechanisms underlying it.
Summary answer: CSE/H_2S pathway participates in the regulation of vaginal lubrication, which is mediated by vaginal epithelial K^+ and Cl^- ion transport.
What is known already: Vaginal dryness is a common problem for women during and after menopause, which may result from inadequate vaginal lubrication. Vaginal fluid derived from transudate, glandular secretion and epithelial ion transport contributes to the vaginal lubrication. H_2S is not only a prosecretory gasotransmitter which regulates ion transport in colon, duodena and lung, but also play an important role in oocyte maturation, preeclampsia and smooth muscle relaxation in uterine and vagina. However, the role of H_2S in vaginal lubrication is not extensively studied.
Study design, size, duration: For *in vitro* experiments, isolated rat vaginal tissues were homogenized or treated with exogenous H_2S donor, NaHS with or without inhibitors and ion substitution, while vaginal canals were treated by NaHS in the presence or absence of inhibitors in anesthetized rats.
Participants/materials, setting, methods: The expression of enzyme, the production of H_2S, and the effect of H_2S on vaginal epithelial ion transport and fluid secretion was studied in rats by RT-PCR/western blot analysis, immunohistochemistry, H_2S synthesizing activity assay, short circuit current, vaginal lubrication measurement and ion chromatography.
Main results and the role of chance: Cystathionine γ-lyase (CSE) mRNA and protein were predominantly expressed in rat vaginal epithelium. NaHS caused concentration-dependent changes in I_{SC} across rat vaginal epithelium, which composed of an initial decrease phase and a following increase phase. Cl^- substitution and cystic fibrosis transmembrane conductance regulator (CFTR) inhibitor siginificantly abolished the increase phase in I_{SC}, suggesting this phase is Cl^- and CFTR dependent ($P < 0.05$), while the decrease phase was sensitive to ATP-sensitive K^+ (K_{ATP}) channels blocker ($P < 0.05$). In addition, NaHS significantly enhanced vaginal lubrication in the anesthetized rats ($P < 0.05$), of which the effect is prevented by CFTR and K_{ATP} channels inhibitors ($P < 0.05$). In addition, the ionic concentration of K^+ and Cl^- in rat vaginal fluid was significantly increased by NaHS treatment ($P < 0.05$).
Limitations, reasons for caution: Further studies on vaginal lubrication under the conditions of estrogen deprivation, a preclinical model of menopause, are urged to better delineate the role of endogenous H_2S in it.
Wider implications of the findings: The physiopharmacological effects of H_2S may provide an alternative, effective and potential therapy to alleviate vaginal dryness or inadequate lubrication in women during and after menopause by the application of exogenous H_2S donor to female vagina.
Trial registration number: Not applicable.

P-664 Low intensity laser therapy: possible strategy to restore fertility in premature ovarian failure induced by chemotherapy?

I. de Zuñiga[1], L. Scotti[2], N. Pascuali[2], J. Higuera[3], M. Fragomeno[2], G. Terrado[3], M. Horton[3], L. Kopcow[3], M. Di Pietro[2], G. Irusta[2], M. Tessone[2], D. Abramovich[2], F. Parborell[2]
[1]Pregna, Buenos Aires, Argentina
[2]IByME, Ovarian Pathology, Buenos Aires, Argentina
[3]Pregna, Endocrinology, Buenos Aires, Argentina

Study question: Premature ovarian failure (POF) is characterized by the disappearance of ovarian follicles in young women, which may be caused by chemotherapy.
Summary answer: Therefore, the biomodulator effect of LLLT improves follicular dynamics in the early stages and thus preserves ovarian reserve in the POF model induced with CTX.
What is known already: POF treatments, which consist mainly of hormone therapies, are not completely effective. The present work proposes photobiomodulation as a strategy to protect the ovary and restore fertility in cancer patients undergoing chemotherapy by local application of low level laser therapy (LLLT).
Study design, size, duration: Experimental animal model and basic science.
Participants/materials, setting, methods: The objectives were: (a) To evaluate the *in vivo* effect of LLLT in adult mice ovaries on follicular dynamics, (b) To analyze the *in vitro* effect of LLLT in a culture of rat granulosa on cell proliferation and expression of VEGF, (c) To evaluate the *in vivo* effect of LLLT in the POF model induced by chemotherapy on ovarian folliculogenesis and expression of Anti-Müllerian Hormone (AMH).
Main results and the role of chance: For objective a, F1 mice (BalbC × C57/BL6) (8 weeks) were used and LLLT (2, 4 and 8 J/cm^2) was applied. For objective b, a culture of rat granulosa cells (GC) (Sprague–Dawley, 21–23 days) was performed and LLLT (1–10 J/cm^2) was applied. For the purpose c, POF model was induced with cyclophosphamide (CTX) in F1 mice and LLLT (8 J/cm^2/ovary) was applied.
The results showed that in adult mice the LLLT (4 and 8 J) increased ovarian reserve compared to control ($p < 0.01$). LLLT (8 J) induced cell proliferation and expression of VEGF 121 isoform in CG compared to untreated group ($p < 0.05$). LLLT (8 J) increased the % of primary, primary and preantral follicles, and decreased the % of atretic follicles in the POF model compared to the untreated group ($p < 0.05$). Besides, LLLT increased the ovarian expression of AMH in POF model compared to the untreated group.
Limitations, reasons for caution: The investigation needs more time.
Wider implications of the findings: Therefore, the biomodulator effect of LLLT improves follicular dynamics in the early stages and thus preserves ovarian reserve in the POF model induced with CTX.
Trial registration number: No.

P-665 Cardiovascular risk profile of women beyond 45 years of age previously diagnosed with premature ovarian insufficiency compared to premenopausal women of comparable age

N. Daan[1], T. Muka[2], K. Maria[1], J. Roeters van Lennep[3], L. Cornelis[4], J. Laven[5], F. Clemens[6], C. Meun[5], D.R. Yolanda[7], E. Boersma[8], O. Franco[2], M. Kavousi[2], B. Fauser[1]
[1]University Medical Center Utrecht, Reproductive Medicine & Gynaecology, Utrecht, Netherlands
[2]Erasmus MC, University Medical Center Rotterdam, Epidemiology, Rotterdam, Netherlands
[3]Erasmus MC, University Medical Center Rotterdam, Internal Medicine, Rotterdam, Netherlands
[4]VU University Medical Center Amsterdam, Obstetrics & Gynaecology, Amsterdam, Netherlands
[5]Erasmus MC, University Medical Center Rotterdam, Obstetrics & Gynaecology, Rotterdam, Netherlands
[6]University Medical Center Utrecht, Cardiology, Utrecht, Netherlands
[7]Erasmus MC, University Medical Center Rotterdam, Clinical Chemistry, Rotterdam, Netherlands
[8]Erasmus MC, University Medical Center Rotterdam, Cardiology, Rotterdam, Netherlands

Study question: What are the differences in cardiovascular risk profile characteristics between women with premature ovarian insufficiency (POI) and premenopausal women of comparable age?
Summary answer: Women with POI exhibited few increased cardiovascular risk factors, and no signs of increased subclinical atherosclerosis compared to premenopausal controls of comparable age.
What is known already: Cardiovascular diseases (CVD) represent the world's leading cause of death amongst women. A young age at menopause has been associated with increased CVD.
Study design, size, duration: Cross-sectional case control study conducted within the University Medical Center Utrecht and Erasmus MC, University

Medical Center Rotterdam, the Netherlands, including women above 45 years of age who were previously diagnosed with POI ($n = 83$), and premenopausal controls from the general population of comparable age ($n = 266$).

Participants/materials, setting, methods: The outcome measures consisted of:

blood pressure, body mass index, waist circumference, electrocardiogram (ECG), bilateral carotid intima media thickness (C-IMT), estradiol, testosterone, androstenedione, dehydroepiandrosterone sulfate (DHEAS), sex hormone binding globulin (SHBG), insulin, glucose, lipids, thyroid stimulating hormone (TSH), freeT4, NTpro-BNP, C-reactive protein (CRP), uric acid, creatinine, homocysteine. Potential associations between POI status and cardiometabolic features, mean C-IMT and atherosclerotic plaque presence were assessed.

Main results and the role of chance: Women with POI exhibited an increased waist circumference (β = 5.7; 95% CI: 1.6, 9.9, $P = 0.007$), CRP (β = 0.75; 95% CI: 0.43, 1.08, $P < 0.001$) and free-T4 levels (β = 1.5; 95% CI: 0.6, 2.4, $P = 0.001$), and lower NTpro-BNP (β = –0.35; 95% CI: –0.62, –0.08, $P = 0.011$), estradiol (β = –1.98; 95% CI: –2.48, –1.48, $P < 0.001$), testosterone (β = –0.21; 95% CI: –0.37, –0.06, $P = 0.008$) and androstenedione (β = –0.54; 95% CI: –0.71, –0.38, $P < 0.001$) concentrations compared to controls, after adjusting for confounders. After adjustment, a trend towards increased hypertension (OR = 2.1; 95% CIs: 0.99; 4.56, $P = –0.05$) and decreased kidney function was observed in women with POI (creatinine β = 3.5; 95% CI: –0.05, 7.1, $P = 0.05$, GFR β = –3.5; 95% CI: –7.5, 0.46, $P = 0.08$). In addition, women with POI exhibited a lower mean C-IMT (β = –0.17; 95% CI: –0.21, –0.13, $P < 0.001$), and decreased odds of plaque presence compared to controls (OR = 0.08, 95% CI: 0.03; 0.26, $P = 0.006$).

Limitations, reasons for caution: The observed low adverse cardiometabolic profile in women with POI could be influenced by the inclusion of a relatively healthy POI population. Included women with POI were higher educated ($P < 0.001$) and had a lower BMI ($P = 0.001$), compared to controls from the general population.

Wider implications of the findings: Previous meta-analyses reported a modestly increased risk of ischemic heart disease in women with POI. Additional studies focusing on subclinical or manifest CVD at a later age are required to identify specific determinants of CVD risk in women with POI, in order to improve individualized counseling.

Trial registration number: www.clinicaltrials.gov, registration number NCT02616510.

P-666 Pharmacological inhibition of m-TORC1 prevents cyclophosphamide-induced over-activation of the primordial follicle pool through PI3K/AKT/m-TOR signaling pathway in mice

L. Zhou[1], Q. Qiu[1], Y. Liang[1], Y. Xie[1], H. Lin[1], Q. Zhang[1]
[1]*The Second Affiliated Hospital of Sun Yat-sen University, Department of Obstetrics and Gynecology, Sun Yat-Sen Memorial Hospital, Sun Yat-Sen University, Guangzhou, Guangzhou, Guangdong, China*

Study question: We investigated the protective effects of pharmacological inhibition m-TOR rapamycin against chemotherapeutic-induced ovarian toxicity in a rat model.

Summary answer: Our results provide a rationale for exploring the possible use of rapamycin as a drug for the preservation of chemotherapy induced premature ovarian failure (POF).

What is known already: A new emerging hypothesis proposes that increased activation of follicles from the resting pool after chemotherapy and the eventual premature "burnout" of the primordial follicle reserve can cause POF. Several environmental chemicals that cause POF in rodent models have been shown to enhance PI3K and mTORC1 signaling pathways and lead to over-activation of primordial follicles. And one study has shown that rapamycin treatment can prevent the complete loss of primordial follicles that would otherwise occur in mice with an oocyte-specific deletion of PTEN.

Study design, size, duration: Adult female mice aged 8 weeks ($n = 52$) housed under specific pathogen-free conditions were treated with varying doses of Cy, ranging from single doses of 75 to 150 mg/kg to four weekly doses of 75 mg/kg, and ovaries were collected at time points of 1, 3, or 7 days after final treatment. Others ($n = 66$) were treated with rapamycin (5 mg/kg) every day, beginning 1 week before Cy treatment and ending 1 week after treatment.

Participants/materials, setting, methods: BALB/c females aged 8 weeks were used. H&E staining was used for differential follicle counts and proliferation staining was conducted with Ki67 antibody. Staining for apoptosis with the *In Situ* Cell Death Detection Kit, POD. Immunohistochemical and immunofluorescence staining conducted to show the localization of these proteins. Protein analysis of whole ovaries was conducted to assess changes in phosphorylation of the key activation proteins. Plasma AMH concentration was quantified with an AMH ELISA kit.

Main results and the role of chance: Quantification of the different follicle populations in the ovaries 1 week after Cy administration showed that at all doses, dormant (primordial) follicles suffered a proportionally greater reduction than did early growing follicles. This difference is apparent in a comparison of the ratio of early growing vs. dormant follicles. Protein analysis of whole ovaries from 8-week-old mice removed 24 h after Cy or PBS treatment was conducted to assess changes in phosphorylation of the key activation proteins AKT, m-TOR, and rpS6. Western blotting showed an increase in the phosphorylated forms of each of these molecules 24 h after Cy treatment. Immunohistochemical and immunofluorescence staining conducted on ovaries confirmed the localization of these proteins within the cytoplasm of the oocytes and granulosa cells of activated small follicles. Coadministration of the specific mTORC1 inhibitor rapamycin reduced follicle activation, thereby increasing follicle reserve and reduced phosphorylation of the key activation proteins AKT, m-TOR, and rpS6. AMH concentration was significantly reduced with Cy four weekly doses of 75 mg/kg ($P < 0.01$), but with coadministration of rapamycin, the concentration of AMH remained normal. Rapamycin alone did not alter the concentration of serum AMH.

Limitations, reasons for caution: Protein analysis conducted on whole-ovary lysates limits our ability to localize protein changes to specific cell types. Chronic treatment with m-TOR inhibitors has been reported to increase the risk of menstrual-cycle disturbances and ovarian cysts in women. Thus, further studies are required to evaluate such possible adverse effects of rapamycin.

Wider implications of the findings: The implication is that rapamycin may be clinically useful in maintaining at least a portion of the primordial follicle pool in the ovaries of women who are otherwise at risk for POF. This is especially relevant for women who are being treated with ovotoxic chemotherapeutic agents.

Trial registration number: no.

P-667 Unravelling the role of extra- and intra-ovarian androgen receptor-mediated mechanisms driving the development of ovarian polycystic ovary syndrome (PCOS) traits

K. Walters[1,2], A. Caldwell[1], M. Edwards[1], D. Handelsman[1]
[1]*Anzac Research Institute, Concord Hospital, University of Sydney, Andrology, Sydney, NSW, Australia*
[2]*University of New South Wales, School of Women's & Children's Health, Discipline of Obstetrics & Gynaecology, Sydney, NSW, Australia*

Study question: Does PCOS originate by a disruption in extra- or intra-ovarian mechanisms?

Summary answer: Our findings implicate predominantly an extra-ovarian origin for PCOS traits.

What is known already: PCOS is a common endocrine disorder causing anovulation and infertility, and is associated with an increase in metabolic disturbances. Hyperandrogenism is a key and most consistent feature of PCOS, but the role of androgen actions *via* the androgen receptor (AR) in its development is unclear. Previously we proved that the global loss of AR in AR knockout mice (ARKO) protects females from the induction of PCOS features, providing strong evidence for AR actions in the etiology of PCOS. However, the site of these AR actions remains to be defined.

Study design, size, duration: PCOS was induced by subdermal DHT implant for 3 months in control, granulosa cell specific-ARKO, neuron specific-ARKO; and control and global ARKO females that have undergone reciprocal ovary transplants.

Participants/materials, setting, methods: After 3 months of DHT exposure oestrous cycles were assessed and ovaries collected for assessment of ovarian PCOS features.

Main results and the role of chance: Compared to blank treated controls, DHT-induced PCOS control mice exhibited acyclicity, as did DHT-induced PCOS neuron-ARKO females ($P < 0.01$ for both). Treatment of GCARKO mice with DHT did not cause complete acyclicity, but instead mice displayed irregular cycles (blank 2.7 ± 0.2 vs. DHT 1.0 ± 0.2 cycles in 2 weeks, $P < 0.01$). Anovulation was assessed by enumerating corpora lutea (CL). DHT treatment

significantly reduced CL numbers in control (blank 9.7 ± 3.0 vs. DHT 0.8 ± 0.8, $P < 0.01$) and GCARKO females (blank 6.0 ± 0.6 vs. DHT 1.0 ± 1.0, $P < 0.01$). However, the loss of neuron AR signalling protected against the effect of DHT, with neuron-ARKO females exhibiting no significant loss in CL numbers (blank 7.2 ± 1.3 vs. DHT 5.0 ± 1.4). This finding infers that extra-ovarian (neuroendocrine) AR actions are the origin for ovulation disruption observed in PCOS. In support of this, reciprocal ovarian transplants between control ($AR^{+/+}$) and ARKO females revealed that DHT treatment induced acyclicity in control females implanted with control or ARKO ovaries, while the transplantation of control ovaries into ARKO recipients protected against the disruption of oestrous cycles by DHT.

Limitations, reasons for caution: This study carried out in rodents may not be directly extrapolated into humans.

Wider implications of the findings: By determining the role and contribution of intra-and extra-ovarian AR-mediated mechanisms in the development of PCOS traits, this better defines the origins of PCOS which may define improved therapeutic targets for novel and mechanism-based treatments.

Trial registration number: NA.

P-668 The controlled ovarian stimulation outcome is affected by Anti-Müllerian Hormone Receptor II genotypes

L. Lazaros[1,2], A. Fotaki[2], C. Pamporaki[1], E. Hatzi[1], C. Kitsou[2], A. Zikopoulos[1], C. Virgiliou[3], I. Kosmas[4], I. Bouba[2], T. Stefos[1], G. Theodoridis[3], I. Georgiou[1,2]

[1]*Ioannina University Hospital, Department of Obstetrics and Gynecology, Medical Genetics and Assisted Reproduction Unit, Ioannina, Greece*

[2]*Ioannina University, Medical School, Laboratory of Medical Genetics of Human Reproduction, Ioannina, Greece*

[3]*Aristotle University of Thessaloniki, Department of Chemistry, Thessaloniki, Greece*

[4]*Ioannina State General Hospital G. Chatzikosta, Department of Obstetrics and Gynecology, Ioannina, Greece*

Study question: To investigate whether *AMHRII 10A>G*, *1749C>T* and *-482A>G* genetic variants influence the ovarian response of women undergoing standard gonadotropin stimulation for *in vitro* fertilization (IVF/ICSI).

Summary answer: *AMHRII 1749C>T* and *-482A>G* genetic variants were associated with the follicular recruitment and growth of women undergoing controlled ovarian stimulation for IVF or ICSI.

What is known already: Anti-Müllerian hormone (AMH) plays a major role on tissue growth and differentiation. AMH, which is produced by the ovarian granulosa cells of pre-antral and antral follicles as early as the 36th week of gestation, limits the formation of primary follicles by inhibiting excessive follicular recruitment by FSH. AMH constitutes a reliable marker of ovarian dysfunction, of granulosa cell tumours as well as of ovarian reserve in ageing women and in patients undergoing IVF/ICSI. AMH exerts its biological effect through two receptors, AMHRI and AMHRII. AMHRII is expressed by Müllerian ducts and gonads, showing its primary role in reproduction.

Study design, size, duration: Three hundred Greek Caucasian women, with tubal or male-factor infertility, undergoing IVF or ICSI in a period of 2 years constituted the study population. Furthermore, 300 women with at least one spontaneous pregnancy participated in this prospective study as the control group. A detailed medical history was obtained from all women, while a physical examination was performed. All subjects, aged 28–38 years, had normal body mass index, normal menstrual cycles and no signs of hyperandrogenism.

Participants/materials, setting, methods: The FSH, LH, AMH and E_2 levels were determined at the third day of the menstrual cycle. The follicular size, the follicle and oocyte numbers were recorded during oocyte retrieval. All embryo transfers were performed at the third day of each cycle. Pregnancy was assessed 2 weeks after embryo transfer by β-hCG quantification. Clinical pregnancy was confirmed by observing fetal cardiac activity. *AMHRII 10AG* (rs11170555), *1749C>T* (rs2071558) and *-482A>G* (rs2002555) genetic variants were genotyped.

Main results and the role of chance: Significant differences in the follicle number and size were observed among *AMHRII* genotypes. Specifically, *1749CT* women presented with higher total follicle numbers compared to *1749CC* women (16.45 ± 10.21 vs. 13.45 ± 6.89, $p = 0.04$). Furthermore, *1749CT* genotype was associated with higher numbers of small follicles comparing with *1749CC* genotype (8.31 ± 8.01 vs. 5.46 ± 3.68, $p = 0.01$). Finally, *1749CT* women were characterized by lower large follicle numbers and higher oocyte numbers than *1749CC* women (5.87 ± 3.68 vs. 6.55 ± 4.17, $p > 0.05$ and 10.16 ± 5.69 vs. 8.62 ± 4.90, $p > 0.05$, respectively). However, no statistical significance was observed in these associations.

Regarding *AMHRII -482A>G* polymorphism, *-482AG* women tended to have higher total follicle numbers compared to *-482AA* women (16.50 ± 10.86 vs. 13.67 ± 6.85, $p = 0.07$). An association of *-482AG* genotype with higher numbers of small follicles comparing with the *-482AA* genotype was also observed (9.00 ± 8.13 vs. 5.48 ± 3.75, $p = 0.004$). In addition, *-482AG* women were characterized by slightly lower large follicle numbers and higher FSH levels compared to *-482AA* women (5.69 ± 4.30 vs. 6.53 ± 4.08, $p > 0.05$ and 7.58 ± 2.45 mIU/ml vs. 6.37 ± 2.2 mIU/ml, $p < 0.05$, respectively).

The *AMHRII 10A>G* genetic variant analysis showed no association with the hormonal profile and the COS outcome. Finally, no significant associations were observed between the *AMHRII* genotypes and the serum AMH levels or the clinical pregnancy rates.

Limitations, reasons for caution: Our study population was limited in Greek Caucasian women. Further studies in other ethnic groups and multicenter populations are needed to confirm our preliminary findings.

Wider implications of the findings: The current study pointed out the significance of *AMHRII* genotypes for the follicular recruitment and development. *AMHRII 1749C>T* and *-482A>G* genotype analysis could help in the tailoring of the COS protocols in order to achieve synchronization in the follicular growth and subsequently higher numbers of mature oocytes.

Trial registration number: N/A.

P-669 Acetyl-L-Carnitine (ALC) and L-Carnitine (LC) effects on neuroendocrine control of reproductive axis in hypogonadotropic women with functional hypothalamic amenorrhea (FHA)

A. Genazzani[1], B. Meczekalski[2]

[1]*University of Modena and Reggio Emilia, Department of Obstetrics & Gynecology, Center of Gynecological Endocrinology, Modena, Italy*

[2]*University of Poznan, Department of Gynecological Endocrinology, Poznan, Poland*

Study question: To evaluate the efficacy of the combined administration of Acetyl-L-Carnitine and L-Carnitine on gonadotropins secretion in patients with functional hypothalamic amenorrhea.

Summary answer: Our data show a positive effect of ALC and LC administration on the stress-induced abnormalities in patients affected by functional hypothalamic amenorrhea.

What is known already: Functional hypothalamic amenorrhea (FHA) is characterized by neuroendocrine impairment that negatively modulates endocrine function, mainly within the reproductive axis. FHA typically shows normal or hypo LH and hypoestrogenism. Up to now, a definite therapeutic strategy has not yet been found. Up to now stressors removal and the administration of naltrexone cloridrate, estriol have been reported to counteract the neuroendocrine impairment of FHA.

Study design, size, duration: A group of 24 patients with FHA were enrolled after informed consent and were administered ALC (250 mg/day) and LC (500 mg/day) for 12 weeks.

Participants/materials, setting, methods: Patients with FHA were subdivided in 2 groups according to LH plasma levels: Group A, hypo LH (LH < 3 mIU/ml) ($n = 14$) and Group B, normo LH (LH > 3 mIU/ml), ($n = 10$). All patients underwent to: baseline hormonal assessment, pulsatility test (for LH and FSH), GnRH stimulation test (bolus of 10 μg) (for LH and FSH) both before and at the 12th week of integrative treatment.

Main results and the role of chance: Under ALC + LC integrative treatment hypo LH patients showed a significant increase in LH plasma levels (from 1.7 ± 0.3 to 3.1 ± 0.5, $p < 0.01$) and in LH pulse amplitude ($p < 0.05$). Maximal LH response and AUC under GnRH stimulation were significantly increased in hypo LH patients ($p < 0.05$). Amylase and cortisol plasma levels were significantly decreased while insulin plasma levels were significantly increased ($p < 0.05$) only in hypo-LH patients. No changes were observed in the normo LH Group.

Limitations, reasons for caution: The only limit might be the number of the patients enrolled for this study

Wider implications of the findings: Our data are in agreement with previous reports on *in vitro* (pituitary cells) and *in vivo* (rat model and humans)

concerning the efficacy of ALC or LC on the stress-induced abnormalities of gonadotropin secretion. These are the first data on the combined administration of ALC + LC in stres-induced FHA
Trial registration number: Ethical Commitee no. 181/2012.

P-670 The impact of thyroid autoimmunity on IVF/ICSI outcome: a systematic review and meta-analysis

A. Busnelli[1], A. Paffoni[1], L. Fedele[1], E. Somigliana[1]
[1]IRCCS Ospedale Maggiore Policlinico Regina Elena, Obstet-Gynecol, Milano, Italy

Study question: Does thyroid autoimmunity (TAI) per sé impact on the outcome of *in vitro* fertilization (IVF)/intracytoplasmic sperm injection (ICSI) cycles?
Summary answer: Thyroid autoimmunity seems to have a detrimental impact on the course of pregnancy achieved through IVF/ICSI but not on the main outcomes of IVF/ICSI treatment.
What is known already: Thyroid autoimmunity is the most frequent autoimmune condition and the first cause of thyroid dysfunction among women of reproductive age. Notably, it has been associated with adverse obstetric outcomes during all trimesters of pregnancy. Furthermore, since most studies showed an increased prevalence of TAI among women attending infertility clinics, a detrimental impact of this condition on natural fertility and on the rate of success of assisted reproductive techniques (ART) has been suggested. However, to date, results are inconsistent.
Study design, size, duration: A systematic literature review and meta-analysis were conducted. A Medline search was performed to identify studies published from 1990 to 2015 on IVF/ICSI outcome in women with and without TAI. The primary outcome was delivery rate (DR). Our secondary outcomes were number of oocytes retrieved (NOR), fertilization rate (FR), implantation rate (IR), clinical pregnancy rate (CPR) and miscarriage rate (MR). We also extracted data on age and basal serum concentrations of thyroid stimulating hormone (TSH).
Participants/materials, setting, methods: Studies were excluded if: (i) only women with positive TAI were described without a comparison group of women without TAI, (ii) women were known to have hypothyroidism or hyperthyroidism or were receiving any treatment for thyroid dysfunction, (iii) serum TSH was not evaluated before starting the IVF/ICSI cycle, (iv) the participants were involved with donor oocytes treatment, (vi) each women performed more than one IVF/ICSI cycle. The study was conducted according to the PRISMA guidelines.
Main results and the role of chance: We selected 12 studies for the meta-analysis. Six of the included studies were prospective cohort studies and six were retrospective cohort studies. Compared with women with negative TAI, women with positive TAI had a lower DR (OR 0.65; 95% CI [0.49, 0.87]; $p = 0.004$; 9 studies; 4396 women; $I^2 = 66\%$); a higher MR (OR 1.44; 95% CI [1.06, 1.95]; $p = 0.02$; 12 studies; 4876 women; $I^2 = 35\%$) and a similar CPR (OR 0.90; 95% CI [0.77, 1.06]; $p = 0.22$; 12 studies; 4876 women; $I^2 = 7\%$), NOR (SMD 0.10; 95% CI [–0.09, 0.29]; $p = 0.28$; 5 studies; 1506 women; $I^2 = 47\%$), FR (OR 1.11; 95% CI [0.97, 1.27]; $p = 0.13$; 3 studies; 1082 women; $I^2 = 0\%$) and IR (OR 0.98; 95% CI [0.73, 1.32]; $p = 0.91$; 2 studies; 918 women; $I^2 = 0\%$). Both mean age (SMD 0.96; 95% CI [0.66, 1.27]; $p < 0.00001$; 9 studies; 3256 women; $I^2 = 85\%$) and serum TSH (SMD 0.24; 95% CI [0.15, 0.34]; $p < 0.00001$; 6 studies; 2098 women; $I^2 = 59\%$) resulted higher in women with TAI.
Limitations, reasons for caution: In the process of systematic review and meta-analysis the inferences assumed by the data are subject to the limitations of the primary studies. Furthermore, giving the possible confounding effects of age and serum TSH, further evidence is warranted prior to draw inferences on causality.
Wider implications of the findings: Thyroid autoantibodies do not impact on IVF/ICSI outcome in terms of number of oocytes retrieved and likelihood of fertilization, implantation and clinical pregnancy. On the contrary, TAI may have a detrimental effect on the course of pregnancy determining an increased risk of miscarriage and a decreased chance of delivery.
Trial registration number: Not applicable.

P-671 Majority of young females with occult premature ovarian insufficiency menstruate regularly: why we should not rely on menstrual status as a marker of ovarian reserve

Y. Güzel[1,2], Y.A. Aba[2], B. Urman[3], O. Oktem[3]
[1]ppi, Istanbul, Turkey
[2]Istanbul Aydin University, School of Medicine and the Graduate School of Health Sciences, Istanbul, Turkey
[3]Koc University School of Medicine, Obstetrics and Gynecology, The division Reproductive Endocrinology and Infertility, Istanbul, Turkey

Study question: Is there any characteristic menstrual history that heralds the onset of occult premature ovarian insufficiency (POI) in young females?
Summary answer: No. Majority of the young females with occult POI (AMH ≤ 1 ng/mL) continue to menstruate regularly and report no menstrual abnormality in the last year.
What is known already: Diminished ovarian reserve or occult premature ovarian insufficiency (POI) may develop spontaneously and insidiously in young females. Even though its exact prevalance is unknown, it is believed that one in every 250 women <35 is diagnosed with occult POI. We aimed in this study to determine (1) the prevalence of previously undiagnosed occult POI in a specific population of young females using serum AMH level and (2) the percentage of these patients that have menstrual irregularities or other symptoms related to POI.
Study design, size, duration: Population based prevalence study in young female college students.
Participants/materials, setting, methods: A total of 1013 young female college students voluntarily participated in this study. The participants were asked to fill a questionnaire regarding the status of their menstrual cycles, menstrual symptoms, life style, exercise, contraceptive use, personal and family history of endocrine and metabolic diseases, and premature ovarian failure (POF). A blood sample was obtained during the first visit and serum AMH was measured with ELISA method using a commercially available kit.
Main results and the role of chance: Overall the mean ± SD for age and AMH of the patients were 20.3 ± 2.7 years and 3.2 ± 0.9 ng/mL, respectively. There was a strong negative association between age and AMH shown by correlation ($r = –0.134$, $p < 0.001$) and linear regression ($R^2 = –0.12$ $p < 0.001$) analyses. Thirty-five (3.4%) of 1013 students were diagnosed with occult POI as they had serum AMH levels ≤1 ng/mL (mean: 0.81 ± 0.2, range: 0.3–1). The mean age of these women was 24.5 ± 1.4 years. Thirty (85.7%) of them reported no menstrual irregularity in the previous year. The remaining five (14.3%) had at least one skipped menses in the last 6 months. 28 (80%) cases with POI denied any family history of premature ovarian failure in their mothers or other first degree relatives. All cases with POI had their diagnoses confirmed by early follicular elevated FSH (22 ± 2.5 mIU/mL) and lower antral follicle counts (2.6 ± 0.4) and were advised for additional tests and fertility preservation options during a second visit.
Limitations, reasons for caution: It is unclear whether these findings can be extrapolated to a larger population. AMH levels were measured only once in these patients. Serial measurements are not available. Long term follow-up is not available and thus fertility outcome and the timing of menopause cannot be assessed.
Wider implications of the findings: This study emphasizes that menstrual status is not a reliable marker of ovarian reserve and young females with critically diminished ovarian reserve may continue to menstruate regularly without any characteristic menstrual abnormality heralding POI. It also underscores the importance of screening young females for possible occult POI.
Trial registration number: None.

P-672 Anovulatory patients demonstrate a sharp drop in LH levels in response to GnRH antagonist administration in IVF cycles

O. Fainaru[1], L. Segal[1], S. Kol[1]
[1]Rambam Medical Center, IVF Unit, Obstetrics and Gynecology, Haifa, Israel

Study question: Are anovulatory patients hyper-responsive to GnRH antagonist administration as compared to normal cycling patients undergoing IVF treatment?
Summary answer: The drop in LH concentration from stimulation start to that observed before ovulation triggering was almost two fold greater in anovulatory vs. ovulatory patients.

What is known already: The ideal ovarian stimulation protocol is under constant debate. The need for threshold LH levels during ovarian stimulation is clearly demonstrated in hypogonadotropic hypogonadic patients, as well as in cycling patients treated with high doses of gonadotropin-releasing hormone (GnRH) antagonists. The Ganirelix dose-finding study showed very low implantation rates in the high-dose groups (1 mg, 2 mg). In that study, the stimulation dynamics in LH suppressed subjects was remarkable for very low estradiol levels. Importantly, we have recently found that 25% of patients receiving only 0.25 mg of GnRH antagonists displayed "over-suppression" and may benefit from LH supplementation.
Study design, size, duration: A retrospective study analyzing IVF cycles (n = 305) at a tertiary center IVF unit. Patients were (n = 190) or were not (n = 115) scheduled by estradiol 2 mg bid before gonadotropin stimulation. GnRH-antagonist (0.25 mg) was administered once a lead follicle of 14 mm was observed. The response to GnRH-antagonist was calculated as the percent change in LH concentration from stimulation start to that observed before ovulation triggering. This result was compared between ovulatory (n = 270) and anovulatory patients (n = 35).
Participants/materials, setting, methods: In this study, we included all consecutive IVF cycles during the year 2015, at Rambam Hospital IVF unit, in which downregulation with GnRH antagonist (Cetrotide 0.25 mg) was used. Excluded were cycles with pituitary down regulation protocols not using GnRH antagonist, concurrent medical conditions that may interfere with pregnancy outcome, and cycles where all embryos were frozen. The primary endpoint was the percentage of drop in LH levels following antagonist administration.
Main results and the role of chance: Anovulatory patients were younger (28.3 ± 5.6 vs. 34.3 ± 6.5 years; $p < 0.001$), with higher BMI (27.3 ± 6.0 vs. 24.5 ± 4.9; $p = 0.002$) and demonstrated higher ovarian reserve parameters (AFC: 19.9 ± 10.3 vs. 9.9 ± 5.5; $p < 0.001$, basal FSH: 5.3 ± 1.5 vs. 7.2 ± 2.8 IU/L; $p < 0.001$) compared to ovulatory patients. The drop in LH concentration from stimulation start to that observed before ovulation triggering was almost two fold greater in anovulatory vs. ovulatory patients (66.4 ± 26.3 vs. 38.9 ± 65.0 percent; $p = 0.01$). Number of oocytes (8.7 ± 5.8 vs. 7.7 ± 5.6) fertilizations (4.7 ± 4.3 vs. 4.3 ± 3.6), cleavage stage embryos (3.2 ± 3.1 vs. 2.8 ± 2.2) and transferred embryos (1.5 ± 0.8 vs. 1.7 ± 0.8) were similar (p = NS). Implantation rates (27.8 ± 42.2 vs. 11.5 ± 28.6%; $p = 0.003$) were higher in anovulatory vs. ovulatory patients.

Cycle scheduling with estradiol pretreatment increased LH levels on the day of stimulation start (6.7 ± 4.5 vs. 5.6 ± 3.4 IU/L; $p = 0.03$) however the drop in LH concentration from stimulation start to that observed before ovulation triggering was similar (42.8 ± 52.1 vs. 42.9 ± 76.5%; p = NS). Number of oocytes (7.6 ± 5.4 vs. 8.1 ± 5.9) fertilizations (4.4 ± 3.6 vs. 4.3 ± 3.7), cleavage stage embryos (2.8 ± 2.3 vs. 2.9 ± 2.4) transferred embryos (1.6 ± 0.8 vs. 1.6 ± 0.8) and implantation rates (14.5 ± 32.3 vs. 11.8 ± 28.4%) were all similar (p = NS).
Limitations, reasons for caution: This is a descriptive retrospective study and therefore direct cause and effect relationships between the measured parameters cannot be fully established.
Wider implications of the findings: Over-suppressing endogenous LH levels leads to poor reproductive outcome. We now demonstrate that anovulatory patients are more susceptible to this detrimental effect of GnRH-antagonist administration. We suggest that in these patients LH supplementation may be beneficial. Moreover, estradiol based cycle scheduling does not affect pituitary response to GnRH antagonists.
Trial registration number: NA.

P-673 Clinical pregnancy and implantation rates decline gradually and insidiously with small rises in serum progesterone on the HCG day: an analysis of 3,767 IVF cycles

O. Oktem[1,2], K. Yakin[1,2], R. Mercan[1,2], B. Balaban[2], B. Urman[1,2]
[1]*Koc University School of Medicine, Obstetrics and Gynecology, Istanbul, Turkey*
[2]*American Hospital Women's Health Center, Assisted Reproduction Unit, Istanbul, Turkey*

Study question:
Is it possible that even small rises in serum P before ovulation trigger have subtle detrimental effects on the success of pregnancy in IVF cycles?
Summary answer:
Yes. The CPR and IR begin to decrease gradually and insidiously with small increments of serum P on the hCG day.
What is known already:
Serum P may prematurely rise before ovulation trigger during multifollicular development in IVF cycles and reduce the CPR and IR by impairing endometrial receptivity. But it is unclear whether small rises in serum P have also subtle deleterious effects on the success of pregnancy. It is also unknown if the relative contributions of AFC ≥ 14 mm, E2 on the HCG day and the number of eggs retrieved are the same in predicting serum P on the hCG day in stimulated IVF cycles. We aimed to address these issues in the current study.
Study design, size, duration:
A non-interventional, retrospective cohort data of a single center between 2006 and 2015.
Participants/materials, setting, methods:
3,767 IVF cycles with GnRH agonist long protocol were included. Of these IVF cycles 2,971 were fresh embryo transfer (ET) and the remaining 796 were frozen ET cycles. The patients were divided into 9 different groups based on their serum P level on the hCG day (<0.5/0.5–0.9/1–1.4/1.5–1.9/2–2.4/2.5–2.9/3–3.4/3.5–3.9/4–4.5 ng/mL). The primary outcome measure of the study was to analyze the individual impact of each of these P threshold intervals on the CPR and IR per ET.
Main results and the role of chance:
Serum P on the hCG day was significantly associated with the success of pregnancy (OR (95%CI): 0.74 (0.67–0.82), $p < 0.001$) in fresh ET cycles. Such an association was not found in frozen ET cycles (0.84 (0.75–1.31), $p > 0.05$). The CPR and IR began to decline gradually and insidiously with rising serum P, but were not significantly compromised up to 3.5 ng/mL in fresh ET cycles. The proportions of low responders (<6 oocytes) decreased and high-responders (>12 oocytes) increased along with rising serum P on the hCG day. There were no cases who produced <6 oocytes and had a serum $P \geq 3.5$ ng/mL. Starting from this level serum P significantly decreased the success of pregnancy in normo-responders (6–12 oocytes) (OR:0.32 (0.16–0.54), $p < 0.001$), but not in high-responders (OR:0.32, (0.27–1.44), $p = 0.36$). Serum P was significantly associated with AFC ≥ 14 mm on day 10th of the stimulation ($R2 = 0.68$ $p < 0.001$), E2 on the hCG day ($R2 = 0.72$ $p < 0.001$) and the numbers of total ($R2 = 0.45$ $p < 0.01$), and mature oocytes retrieved ($R2 = 0.38$, $p < 0.01$). Zero order, partial and part correlations, and multi-collinearity statistics with tolerance and variance inflation factor revealed that the relative contribution of AFC ≥ 14 mm is similar to E2 (hCG day) and oocyte number in predicting serum P on the hCG day.
Limitations, reasons for caution:
It is unclear why some patients have premature P elevations while the others do not despite both have similar IVF characteristics. Furthermore, AFC ≥ 14 mm, E2 on the hCG day and oocyte number can collectively explain only 70% of the variance in serum P with the remaining 30% belonging to unknown factors.
Wider implications of the findings:
Serum P on the hCG day is strongly associated with the magnitude of ovarian stimulation. Therefore, premature rise in serum P is likely to occur as a result of the inability of the ovary to handle high input precursor steroids generated during multifollicular development in stimulated IVF cycles.
Trial registration number:
None.

P-674 Analysis of the XIST gene C43G mutation in relation to X-chromosome inactivation patterns in patients with idiopathic primary ovarian insufficiency

S.H. Yoon[1], K.R. Hwang[2], Y.J. Kim[3]
[1]*Graduate School of Medicine, Dongguk University, Obstetrics and Gynecology, Seoul, South Korea*
[2]*Seoul National University Boramae Medical Center, Obstetrics and Gynecology, Seoul, South Korea*
[3]*College of Medicine, Korea University, Obstetrics and Gynaecology, Seoul, South Korea*

Study question: Is the X-inactive specific transcript (*XIST*) gene promoter mutation associated with idiopathic primary ovarian insufficiency (POI) which shows skewed X-chromosome inactivation (XCI)?
Summary answer: The *XIST* gene mutation was not associated with XCI patterns of POI, implying that the role in the pathogenesis of POI is not clear yet.

What is known already: Cryptic abnormalities of X-chromosome or gene mutations may lead to skewed XCI and result in POI. There were reports that incidence of skewed XCI was significantly higher in the POI group and a promoter C43G mutation of the *XIST* gene was associated with skewed XCI. Therefore, the *XIST* gene is an attractive candidate gene for underlying skewed XCI which has been documented in the structural abnormalities of X-chromosome and could have a role in the pathogenesis of idiopathic POI.
Study design, size, duration: Case–control study. The subjects consisted of 126 idiopathic POI patients (35.3 ± 13.9 years old, mean ± SD) and 126 healthy controls (35.2 ± 13.9 years) that had normal menstrual cycles. The women recruited as control were age-matched.
Participants/materials, setting, methods: The XCI status was evaluated by the methylation assay of androgen receptor locus in cases and controls. For the promoter C43G mutation in the *XIST* gene, genotyping was identified using polymerase chain reaction (PCR)-restriction fragment length polymorphism (RFLP) analysis. The incidence of skewed XCI and the *XIST* gene mutation in POI group were compared with those of control, and the *XIST* gene mutation was also evaluated in relation to XCI patterns in POI population.
Main results and the role of chance: The incidence of skewed XCI on all three levels (≥90%, ≥80% and ≥70%) was similar between POI patients and controls, and showed random pattern. Within POI population, the patterns of skewed XCI were not associated with age at the time of POI and LH, FSH, estradiol levels. There was no C43G mutation in the *XIST* gene, on the contrary to our expectation, in both idiopathic POI patients and controls. Result of no mutation was confirmed by sequence analysis. Therefore, the *XIST* gene promoter mutation was not associated with XCI patterns and also not idiopathic POI in a Korean population. Small deletions or mutations in X-linked genes do not appear to be a common feature of POI and X-linked genes involved in POI may be too few or not able to interfere with XCI.
Limitations, reasons for caution: Study is limited to a Korean population, so other studies from different populations will be helpful to replicate and confirm these results in the idiopathic POI.
Wider implications of the findings: Our findings suggest that genetic variants in X-inactivation pathway may not influence the susceptibility of idiopathic POI. This is the first report regarding the association between the *XIST* gene variations and XCI patterns in idiopathic POI.
Trial registration number: N/A.

P-675 The rate of ovarian failure in 12 months following adjuvant chemotherapy in breast cancer patients according to age group

J.J. Shin[1], H.Y. Choi[1], K. Hwang[1], Y.M. Choi[1], W. Han[2], K.H. Lee[3], T.Y. Kim[3], S.A. Im[3]
[1]Seoul National University Hospital, Department of Obstetrics and Gynecology, Seoul, South Korea
[2]Seoul National University Hospital, Department of Surgery, Seoul, South Korea
[3]Seoul National University Hospital, Department of Internal Medicine, Seoul, South Korea

Study question: What is the rate of chemotherapy induced ovarian failure (CIOF) in 12 months following completion of chemotherapy in breast cancer patients in different age groups?
Summary answer: The CIOF rate in age groups 20–24, 25–29, 30–34, 35–39, and 40–44 were 0% (0/1), 0% (0/8), 3.8% (1/26), 12.9% (13/95), and 20.8% (35/168), respectively.
What is known already: In the previous studies that assessed the rate of CIOF in breast cancer, the overall rate was reported to be between 22 and 85.2%. The majority of studies did not assess the rate according to age group, and in one study, the rate in age group 35–45 years was as high as 95%.
Study design, size, duration: Retrospective study of women who underwent adjuvant chemotherapy between January 2009 and December 2012 in a tertiary medical center.
Participants/materials, setting, methods: This study included 296 women of age 20–44 who have agreed to have their serum follicle stimulating hormone (FSH) levels tested between 9 months and 15 months following completion of chemotherapy. Any concurrent use of gonadotropin releasing hormone agonists for fertility preservation were excluded.
Main results and the role of chance: The overall rate of CIOF was 16.2%. The rate of CIOF in age groups 20–24, 25–29, 30–34, 35–39, and 40–44 were 0% (0/1), 0% (0/8), 3.8% (1/26), 12.9% (13/95), and 20.8% (35/168), respectively. There was a significant increasing trend of CIOF with increasing age ($P = 0.006$). The CMF chemotherapy regimen showed a higher rate of CIOF compared to anthracycline and/or taxane containing chemotherapy regimen, but the difference was statistically not significant (36.4% and 15.4%, respectively, $P = 0.084$).
Limitations, reasons for caution: This was a retrospective study.
Wider implications of the findings: This is the largest study up to date that assessed the rate of CIOF diagnosed by serum FSH level. The rate of CIOF reported in our study is lower than that reported in other previous studies.
Trial registration number: Not applicable.

P-676 Recombinant FSH plus highly purified hMG versus recombinant FSH on ovarian response and clinical outcomes in long GnRH agonist protocol: A prospective, randomized, controlled trial

N. Li[1], J. Shi[1], L. Tian[1], L. Yu[1], T. Wang[1], B. Meng[1], H. Zhou[1], W. Shi[1], W. Zhao[1], X. Xue[1]
[1]Northwest Women's and Children's Hosptial, reproductive centre, Xi'an-Shaan'xi, China

Study question: Could the treatment of recombinant FSH (r-FSH) *plus* highly purified (HP-hMG) improve the ongoing pregnancy rate (PR) compared with r-FSH in long GnRH agonist protocol?
Summary answer: Non statistical differences were found in terms of ongoing pregnancy rate between r-FSH *plus* HP-HMG group and r-FSH group.
What is known already: The FSH isoform were different in r-FSH and hP-HMG, moreover hCG driven LH activity added to HP-hMG. There was no large randomized trial compared r-FSH with r-FSH *plus* HP-hMG on ovarian response and clinical outcomes in IVF/ICSI cycles.
Study design, size, duration: A single-centre RCT was performed between June 2014 and June 2015 with 579 women undergoing IVF/ICSI cycles. The patients were randomly assigned to one of the two groups,, by giving them a code number from a computer generated randomization list, in order of enrolment. The randomization was took place on the first day of ovarian stimulation.
Participants/materials, setting, methods: All the patients were less than 38 years old in their first cycle for IVF/ICSI with luteal phase long GnRH agonist protocol. Two hundred and seventy five patients were treated with r-FSH in combination with hP-HMG from the beginning of stimulation, and three hundred and four patients were treated with r-FSH. Depending on the allocation group, received either ovarian stimulation with 75~150 IU r-FSH + 75 IU hP-hMG or only 150~225 IU r-FSH.
Main results and the role of chance: The main outcome measures were ongoing PR and number of oocytes retrieved. Ongoing pregnancy rates were 126/211 (59.7%) in the r-FSH *plus* hP-hMG group vs. 105/188 (55.9%) in the r-FSH group [odds ratio (OR) 1.17, 95% CI 0.79–1.75, $P = 0.435$]. The number of oocytes retrieved was significant lower in the r-FSH *plus* HP-hMG group than r-FSH group (13.7 ± 6.1 vs. 15.1 ± 7.2, $P = 0.008$).
Limitations, reasons for caution: This was a open labeled study and all the patients were from a single IVF center.
Wider implications of the findings: Our results demonstrated that no differences in terms of ongoing PR between r-FSH *plus* HP-hMG group and r-FSH group, in long GnRH agonist protocol for IVF/ICSI cycles. R-FSH had the higher potency of follicular recruitment than r-FSH *plus* hP-HMG.
Trial registration number: ChiCTR-TRC-14004965.

P-677 The usage of Utrogestan and hMG protocol in patients with polycystic ovarian syndrome undergoing controlled ovarian hyperstimulation during IVF/ICSI treatments

X. Zhu[1], Y. Fu[1]
[1]Shanghai Ninth People's Hospital, Department of Assisted Reproduction, Shanghai, China

Study question: Could the delivery of progesterone soft capsules (Utrogestan) from the early-follicular phase inhabit the premature LH surges in polycystic ovarian syndrome (PCOS) women undergoing controlled ovarian hyperstimulation (COH) during IVF/ICSI treatments?
Summary answer: Consistent LH suppression was achieved along with improved pregnant outcomes following frozen-thawed embryo transfer (FET) in PCOS women undergoing COH with Utrogestan and hMG protocol.

What is known already: Although a variety of protocols are used for COH in PCOS women, the clinical outcomes still remains unsatisfactory. Our previous study showed that Utrogestan was feasible for preventing premature LH surges in normalovulatory women with component oocytes and embryos. So far, there were no publications reporting the usage of Utrogestan and hMG protocol in PCOS patients during IVF/ICSI treatments.
Study design, size, duration: 200 PCOS women were recruited from April 2013 to April 2015 in this retrospective study including 123 patients using Utrogestan and hMG protocol and 77 patients using short protocol.
Participants/materials, setting, methods: PCOS patients with 25–40 years old were eligible to participate. Utrogestan 200 mg/d and hMG 225 IU were administered from cycle day3. When the dominant follicles reached mature, GnRH-a 0.1 mg was used for trigger. The clinical results were compared in terms of the hormone profile, embryo results and pregnant outcomes.
Main results and the role of chance: No premature LH surges were detected in all the participants. No significant between-group differences were observed in the number of oocytes retrieved (13.27 ± 7.46 vs. 13.1 ± 7.98), the number of viable embyos (5.57 ± 3.27 vs. 5 ± 2.79), the mature oocyte rate (90.14% ± 11.81% vs. 93.02% ± 8.95%), and cleavage rate (97.69% ± 6.22% vs. 95.89% ± 9.57%). However, the fertilization rate (76.11% ± 19.04% vs. 69.34% ± 21.81%, $P < 0.05$), viable embryo rate per oocyte retrieved (39.85% vs. 34.68%, $P < 0.05$), biochemical pregnancy rate (71.72% vs. 56.67%, $P < 0.05$), clinical pregnancy rate (64.65% vs. 51.65%, $P < 0.05$), and implantation rate (46.46% vs. 31.35%, $P < 0.05$) in the Utrogestan and hMG protocol were significantly higher than that in the short protocol.
Limitations, reasons for caution: A major limitation of our study is the retrospective design of this study. In addition, the limited number of participants enrolled also decreased the power of this study.
Wider implications of the findings: Our findings provide new insights for the treatment of PCOS women undergoing COH in combination with FET. The optimization of this novel protocol remains to be explored to warrant the follicle development in an appropriate microfollicular milieu and improve the reproductive outcomes in PCOS patients.
Trial registration number: No trial registration number.

P-678 The expressions of ovarian steroidogenic enzymes do not increase proportionally after FSH, creating a shunting that promotes progesterone output in the granulosa cells without luteinization

N. Akin[1], G. Bildik[1], A. Seyhan[2], I. Keles[2], D. Urman[1], E. Ayhan[1], B. Balaban[2], B. Urman[2,3], O. Oktem[2,3]
[1]*Koc University School of Medicine, Graduate School of Health Sciences, Reproductive Biology, Istanbul, Turkey*
[2]*American Hospital Women's Health Center, Assisted Reproduction Unit, Istanbul, Turkey*
[3]*Koc University School of Medicine, Department of Obstetrics and Gynecology the division Reproductive Endocrinology and Infertility, Istanbul, Turkey*

Study question:
If premature rise in serum P before ovulation may occur in stimulated IVF cycles can gonadotropin stimulation possibly play a role in this scenario?
Summary answer:
Yes. FSH alters the expression patterns of the enzymes involved in ovarian steroidogenesis that facilitates premature rise in serum P in a dose-dependent manner.
What is known already:
Serum progesterone may prematurely rise before ovulation trigger during multi-follicular development and reduce pregnancy rate in stimulated IVF cycles. The underlying molecular pathogenetic mechanism is unclear. We aimed in this study to explore if gonadotropin stimulation alters the expression of the ovarian steroidogenic enzymes (stAR, SCC, 3β-HSD, 17α-OH, 17β-HSD and aromatase) in a way that creates a relative shunting in steroidogenetic pathways leading to premature rise in serum P before ovulation.
Study design, size, duration:
A translational research study combining *in vivo* and *in vitro* models of human ovarian cortical samples and granulosa cells.
Participants/materials, setting, methods:
Ovarian cortical samples ($n = 10$) and non-luteinizing mitotic granulosa cells (HGrC1) were stimulated with rec-FSH at 12.5–25– 50 mIU/mL concentrations for 24 and 48 h. Then they were compared for the expressions of the steroidogenic enzymes at mRNA level by real-time quantitative qRT-PCR and protein level by western blot and ELISA.
Main results and the role of chance:
FSH significantly increased the expressions of its own receptor (4.22 fold, $p < 0.01$), stAR (1.82 fold, $p < 0.01$), SCC (2.19 fold, $p < 0.01$), 3β-HSD (2.63 fold, $p < 0.01$), and aromatase (5.19 fold, $p < 0.001$) in a dose-dependent manner when compared to their unstimulated controls at the same time point. By contrast, there were no meaningful changes in the expressions of 17α-OH and 17β-HSD after stimulation with FSH (ranging from 1.01 to 1.13). In line with FSH induced upregulation in the expressions of 3β-HSD and aromatase, *in vitro* P production from the samples increased along with E2. The mean levels at 24, 48, 72 and 96 h were 770 ± 45, 1222 ± 134, 1670 ± 167 and 1920 ± 245 pg/mL, respectively for E2; and 0.65 ± 0.1, 0.87 ± 0.2, 1.23 ± 0.4 and 2.13 ± 0.5 ng/mL, respectively for P. Such increases were not noted in unstimulated samples as their E2 (156 ± 22 to 255 ± 34 pg/mL) and P levels (0.2 to 0.4 ng/mL) were only slightly increased during the same culture period. Quantitative immunoblotting confirmed that protein levels of 3β-HSD and P were also increased after FSH stimulation, indicating that FSH induced upregulation in the transcription was accompanied by increased translation at protein level.
Limitations, reasons for caution:
It would be the most reliable and informative model to obtain granulosa cells of the growing antral follicles during the course of ovarian stimulation and compare the expression of these enzymes between the patients with and without premature progesterone rise before ovulation. Unfortunately this is not possible for ethical reasons.
Wider implications of the findings:
Disproportional increases in the expressions of these steroidogenic enzymes after FSH and high input precursor steroids generated during multifollicular development in stimulated IVF cycles may create a relative shunting in the ovarian steroidogenesis that diverts these precursors into progesterone pathway and causes premature rise in serum P before ovulation trigger.
Trial registration number: None.
StAR: Cholesterole uptake
SCC: Cholesterole → Pregnenolone
3β-HSD: Pregnenolone → Progesterone
17α-OH: Pregnenolone → 17-OH Pregnenolone; Progesterone → 17-OH Progesterone
17β-HSD: DHEAS → Androstenedione; Androstenedione → Testosterone
Aromatase: Androgens → Estrogens

P-679 The comparison of Utrogestan 100 mg or 200 mg per day used for controlled ovarian hyperstimulation in normalovulatory women: a prospective, randomized, controlled trial

Y. Fu[1], X. Zhu[1], H. Ye[1]
[1]*Shanghai 9th People's Hospital, Department of Assisted Reproduction, Shanghai, China*

Study question: Was the delivery of progesterone soft capsules (Utrogestan) 100 mg per day from the early-follicular phase feasible to suppress the premature LH surge in normalovulatory women undergoing IVF/ICSI treatments?
Summary answer: Utrogestan 100 mg per day can effectively block the premature LH surge in normalovulatory women undergoing controlled ovarian hyperstimulation (COH).
What is known already: Our previous study shows that Utrogestan 200 mg per day is an effective oral alternative for preventing premature LH surges in normalovulatory women undergoing COH, with optimal pregnant outcomes in frozen-thawed embryo transfer (FET) cycles. However, the LH value was found to be excessively suppressed, leading to an increased hMG dose compared with the short protocol. There were no reports published investigating the appropriate dose of Utrogestan.
Study design, size, duration: 150 women were recruited from September 2014 to October 2015 in this prospective trial and participants were allocated randomly to the low dose group (Utrogestan100 mg per day)and the high dose group (Utrogestan 200 mg per day).
Participants/materials, setting, methods: Normal ovulatory patients with 25- to 40-year-old were enrolled. Utrogestan 100 mg or 200 mg per day and hMG 225 IU were administered from cycle day3. When the dominant follicles reached mature, GnRH-a 0.1 mg was used for trigger. The hormone profile,

embryo results and pregnant outcomes were analysed exhaustively to discriminate the differences between the two groups.
Main results and the role of chance: Consistent LH suppression was achieved during COH with Utrogestan 100 mg per day, and the number of patients with profound LH suppression (LH < 1.2 IU/L) in the low dose group was significantly less than that in the high dose group. The low dose group was characterized by a reduced hMG dose (1646 ± 223.95 IU vs.1747 ± 366.76 IU, $P > 0.05$), without statistic difference. The number of oocytes retrieved in the low dose group was comparable with that in the high dose group (9.87 ± 5.77 vs.10.25 ± 5.43, $P > 0.05$). No significant between-group differences were observed in the number of mature oocytes (8.24 ± 4.88 vs. 9.01 ± 4.87, $P > 0.05$), fertilized oocytes (6.73 ± 4.23 vs. 6.85 ± 4.19, $P > 0.05$), viable embryos (3.73 ± 2.34 vs. 4.15 ± 3.17, $P > 0.05$), the clinical pregnancy rate (50% vs. 51.32%, $P > 0.05$), or implantation rate (38.67% vs. 36.05%, $P > 0.05$).
Limitations, reasons for caution: A major limitation of our study is the limited number of participants enrolled which may decrease the power of this study.
Wider implications of the findings: Our finding confirmed Utrogestan 100 mg per day was able to prevent premature LH surges, and implied the profound LH suppression was correlated with the dose of Utrogestan, which may provide new insights for the optimization of this novel protocol by individuals.
Trial registration number: The trial was registered with the Chinese Clinical Trial Registry (ChiCTR-ONRC-14005277).

P-680 Oocyte developmental competence in women younger than 35 is independent from the ovarian reserve measured by antral follicular count

M.J. Lopez Martin[1], D. Garcia[2], R. Vassena[1], V. Veraneve[1]
[1]*Clinica Eugin, Clínica Eugin, Barcelona, Spain*
[2]*Fundacio EUGIN, Fundacio EUGIN, Barcelona, Spain*

Study question: Is higher ovarian reserve associated with higher oocyte developmental competence, measured as the ability to give rise to viable pregnancy following assisted reproduction (ART)?
Summary answer: Ovarian reserve is not associated with oocyte developmental competence following ART.
What is known already: Antral follicular count (AFC) is a good marker of ovarian reserve, but its relationship with oocyte developmental competence is debated. Women with higher AFC on average give rise to more oocytes and embryos, leading to a more efficient embryo selection, and higher pregnancy rates. Ideally, oocyte quality could be tested by separating oocyte yield from AFC, i.e., producing embryos from a pool of oocytes of the same size across different AFC. The oocyte donation model, where recipients are allocated a number of oocytes independent from donor AFC, allows testing the developmental competence of oocytes from women with differing AFC.
Study design, size, duration: Retrospective cohort study of 1985 oocyte donation cycles, corresponding to 3316 embryo transfers (ET) in recipients performed between January 2010 and May 2014. Each recipient received a number of MII ranging from 4 to 15, based on medical need and irrespectively of donor AFC. Oocyte donors were between 18 and 35 years old, and were stimulated using GnRH antagonist protocol triggered with GnRH-agonist. Recipient's endometrial preparation was performed with estrogens, administered either orally or transdermally.
Participants/materials, setting, methods: The effect of AFC on stimulation outcomes was assessed by linear regression. Effect of AFC on biochemical, clinical, ongoing, and live birth rates was assessed by logistic regression adjusting for age, BMI, phenotype, smoking habit, sperm origin (partner or donor), sperm status (fresh or frozen), number of embryos transferred, day of ET, and embryo quality score of the cohort produced.
Main results and the role of chance: The mean AFC in oocyte donors was 19.5, and SD 8.1, ranging from 4 to 60. Oocyte donors with higher AFC needed less total gonadotropin dose to reach trigger criteria (B −23.02, 95% CI [−25.72; −20.33], $p < 0.001$), and yielded a higher number of both cumulus-oocyte complexes (B 0.47, 95% CI [0.41, 0.53], $p < 0.001$) and MII oocytes (B 0.36, 95% CI [0.32, 0.41], $p < 0.001$). Oocyte donors with lower AFC had more cancellation of ovarian stimulation (OR 0.93, 95% CI [0.90, 0.96], $p < 0.001$), while donor's AFC did not affect either fertilization rate (B 0.001, 95% CI [0.000, 0.002] $p = 0.11$) or embryo quality score of the cohort of embryos produced (B -0.004, 95% CI [−0.009, 0.001] $p = 0.09$).

The number of MII oocytes assigned to each recipient, as well as the number of total embryos in cleavage stage for each recipient, were comparable across the range of donor AFC ($p = 0.09$ and $p = 0.08$, respectively). No association was found between AFC and biochemical pregnancy (OR 1.01, 95% CI [1.00, 1.02], $p = 0.20$), clinical pregnancy (OR 1.00, 95% CI [0.99, 1.01], $p = 0.63$), ongoing pregnancy (OR 1.00, 95% CI [0.99, 1.01], $p = 0.63$), and live birth (OR 1.00, 95% CI [0.99, 1.01], $p = 0.79$).
Limitations, reasons for caution: The main limitation of this study is its retrospective nature. Caution should be exerted when generalizing the results to infertile and/or older populations, where there is an age-related decline in oocyte quality, and to women <35 with an extremely low ovarian reserve (AFC <4).
Wider implications **of the findings:** The results suggest that, within the AFC range analyzed, the size of the ovarian reserve does not relate to the developmental competence of the oocytes in women younger than 35. This should be taken into account by gynecologists and first line physicians when prescribing, and interpreting, ovarian reserve tests.
Trial registration number: NA.

P-681 Amphiregulin mediates hCG-induced StAR expression and progesterone production in human granulosa cells

L. Fang[1], Y. Yu[1], R. Zhang[1], J. He[1], Y. Sun[1]
[1]*The First Affiliated Hospital of Zhengzhou University, Reproductive medicine, Zhengzhou-Henan, China*

Study question: To investigate the role of Amphiregulin (AREG) in human chorionic gonadotropin (hCG)-induced progesterone production and the underlying molecular mechanism in human granulosa cells.
Summary answer: AREG mediates hCG-induced StAR expression and progesterone production in primary human granulosa cells through binding Epidermal growth factor receptor (EGFR) and activating ERK1/2 signaling pathway.
What is known already: After ovulation, luteinizing hormone (LH) stimulates granulosa cells to produce progesterone, which plays a critical role in maintaining a successful pregnancy at the early embryonic stage. LH and/or hCG in granulosa cells rapidly induce AREG, a member of the epidermal growth factor (EGF) superfamily. However, whether AREG mediates LH/hCG-induced progesterone production remains unknown.
Study design, size, duration: Primary human granulosa cells were used as the study model to examine the involvement of AREG in hCG-induced StAR expression and progesterone production. Human serum and follicular fluid samples were obtained from 14 infertile women treated with *in vitro* fertilization (IVF) or intracytoplasmic sperm injection (ICSI).
Participants/materials, setting, methods: Real-time quantitative PCR (RT-qPCR) and western blot were used to measure mRNA and protein levels, respectively. The levels of AREG in human follicular fluid were measured using an enzyme-linked immunosorbent assay (ELISA). The progesterone levels in human follicular fluid and serum were measured using a electrochemiluminescence immunoassay (ECLIA).
Main results and the role of chance: Inhibition of EGFR and knockdown of AREG abolished hCG-induced StAR expression and progesterone production. Importantly, follicular fluid AREG levels were positively correlated with progesterone levels in follicular fluid and serum on oocyte-pick up (OPU) day and 2 days after OPU day. Treatment with AREG increased StAR expression and progesterone production. The stimulatory effects of AREG on StAR expression and progesterone production were abolished by inhibition of EGFR. Moreover, activation of ERK1/2, but not PI3K/Akt, signaling was required for AREG-induced upregulation of StAR expression and progesterone production.
Limitations, reasons for caution: Despite our study demonstrated that AREG mediates hCG-induced StAR expression and progesterone production in human granulosa cells, some other functions of AREG in the regulation of steroidogenesis remain undefined. In addition, future studies using a large clinical sample are needed to confirm the role of AREG in female reproduction.
Wider implications of the findings: To our knowledge, it is the first study revealing the physiological roles and molecular mechanisms of AREG in the regulation of StAR expression and progesterone production in human granulosa cells, which might help for developing new strategies for the treatment of clinical infertility.
Trial registration number: N/A.

P-682 Clinical outcomes of frozen–thawed embryo transfer in hyper responder patients who had final follicular maturation triggered by GNRH-agonist or hcg and all embryos cryopreserved

S. Pereira Gonçalves[1,2], R. Mirisola[1,2], P. Petersen[1], J. Miorin[1], M. Fugii[3], A. Gomes[3], T. Bonetti[4], P. Monteleone[2,5]
[1]*Centro de Reprodução Humana Monteleone, Clinical, Sao Paulo, Brazil*
[2]*Faculdade de Medicina da Universidade de São Paulo FM-USP, Departamento de Obstetrícia e Ginecologia, Disciplina de Ginecologia, São Paulo, Brazil*
[3]*Centro de Reprodução Humana Monteleone, Embryology, Sao Paulo, Brazil*
[4]*Universidade Federal de São Paulo, Escola Paulista de Medicina UNIFESP-EPM, Departamento de Ginecologia, Disciplina de Ginecologia endocrinológica, São Paulo, Brazil*
[5]*Centro de Reprodução Humana Monteleone, Clinical Head, Sao Paulo, Brazil*

Study question: Are clinical outcomes better in frozen–thawed embryos transfers when final follicular maturation in stimulation cycle were triggered by GnRH-agonist compared to hCG-trigger in hyper-responder patients?
Summary answer: Multiple regression analysis confirmed higher pregnancy chance in the following frozen–thawed embryo-transfer (ET) when GnRH-agonist for final follicular maturation is used, even adjusted for confounders.
What is known already: The use of GnRH-agonist for final oocyte maturation in clinical practice of IVF cycles has opened a new possibility to avoid ovarian hyperstimulation syndrome (OHSS) in hyper-responder patients. The administration of GnRH-agonist induces the release of gonadotropins that leads to LH surge, with the advantage of more physiological trigger and in a shorter extend compared to hCG. It has been reported that the use of GnRH-agonist trigger can prompt more MII oocytes in hyper-responder patients; on the other hand, a significant luteal phase defect may occur. The approach of freeze all embryos, following by frozen–thawed cycles can drive this issue.
Study design, size, duration: Retrospective observational study evaluating 127 frozen–thawed ICSI cycles between 2011 and 2015. Patients undergoing their first or second ovarian stimulation cycle, had at least 8 oocytes picked-up and didn't have embryos transferred in the fresh cycle. All embryos were cryopreserved and frozen–thawed transfers were placed in subsequent endometrial prepared cycle.
Participants/materials, setting, methods: Pituitary downregulation was obtained with GnRH-antagonist, and ovarian stimulation with rFSH associated or not with uFSH. Patients were split into two groups according with trigger: hCG ($n = 46$) or GnRH-agonist ($n = 81$). Oocytes were fertilized by ICSI, and all embryos were vitrified using standard protocols. For the frozen–thawed ET, endometrium preparation was performed with estradiol valerate plus vaginal micronized progesterone during 15 days. Embryos were thawed and evaluated for survival, morphology and transferred following standard protocols.
Main results and the role of chance: Laboratorial and clinical outcomes for hCG and GnRH-agonist groups were, respectively: patients age ($34.4 \pm 3.6 \times 33.3 \pm 4.4$; $p = 0.158$), FSH dose ($1722.6 \pm 312.1 \times 1611.2 \pm 321.8$; $p = 0.073$), MII oocytes collected ($13.0 \pm 4.9 \times 20.8 \pm 8.2$; $p < 0.001$), fertilization rate (79.4% × 81.5%; $p = 0.450$), number of embryos frozen ($9.7 \pm 3.8 \times 13.6 \pm 4.2$; $p < 0.001$) and post-thaw survival rate (91.8% × 95.6%; $p = 0.152$) and embryos transferred ($1.7 \pm 0.5 \times 1.6 \pm 0.5$; $p = 0.736$). In the frozen–thawed embryo transfer, patients who received hCG presented lower ongoing pregnancy rate (26.1%) than GnRH-agonist group (46.9%; $p = 0.021$). The logistic linear regression demonstrated that when GnRH-agonist was used, the chance of become pregnant is almost three times higher (OR: 2.8, $p = 0.033$), adjusted for patients age, dose of FSH administered, number of oocytes collected, fertilization rate, embryo survival rate and embryos transferred. No OHSS was observed.
Limitations, reasons for caution: Besides the retrospective characteristic of study, the number of patients is somewhat small and number of oocytes in the hCG group was smaller, showing much higher ovarian response in the GnRH-agonist group. On the other hand, we used multiple regression model to confirm the results adjusted for those possible confounders.
Wider implications of the findings: Hyper-responder patients who received GnRH-agonist trigger for final oocyte maturation plus all embryos-frozen can avoid OHSS, but the GnRH-agonist trigger also contribute to better oocyte quality, and hence a better prognosis in the following frozen–thawed ET. Our findings support the use of GnRH-agonist for final follicular maturation in hyper-responder patients.
Trial registration number: Not applicable.

P-683 Temporal effects of testosterone on expression of the circadian gene and steroidal acute regulatory protein gene in human luteinized granulosa cells

M.H. Chen[1], Y. Xu[1], B. Miao[1], H. Zhao[2], J. Gao[1], C. Zhou[1]
[1]*The First Affiliated Hospital of Sun Yat-sen University, Reproductive medicine center, Guangzhou, Guangdong, China*
[2]*the Third Affiliated Hospital of Sun Yat-sen University, Department of Hepatic Surgery, Guangzhou, Guangdong, China*

Study question: How are the temporal effects of testosterone in expression of circadian genes and steroidogenesis related genes in cultured human luteinized granulosa cells?
Summary answer: Testosterone induces oscillating expression of the circadian gene PER2 and steroidal acute regulatory protein (STAR) gene in cultured luteinized human granulosa cells.
What is known already: Rhythmic expression of the circadian gene in granulosa cells can be induced *in vitro* in animal models. Moreover, circadian clocks may be involved in steroidogenesis in granulosa cells.
Study design, size, duration: Human luteinized granulosa cells were obtained from follicle fluid of ten patients during ovum aspiration undergoing IVF for each experiment which was replicated thrice.
Participants/materials, setting, methods: Accumulation patterns of circadian genes and steroidogenesis related genes mRNAs in cultured human luteinized granulosa cells were observed during 48 h after testosterone treatment by quantitative PCR.
Main results and the role of chance: The circadian genes CLOCK, PER2 and BMAL1 were expressed in cultured human luteinized granulosa cells. Among these genes, only expression of PER2 displayed oscillating patterns with a 20-h period in these cells after stimulation by testosterone. Expression of the other two genes did not show significant oscillating patterns. Expression of the STAR gene showed an oscillating pattern with a 16-h period. Testosterone repressed expression of CYP19A1 significantly but did not show apparently effect on expression of HSD3B2 and CYP11A1.
Limitations, reasons for caution: Mechanism under such phenomenon needs further study.
Wider implications of the findings: Circadian rhythm and steroidogenesis rhythm in human granulosa cells may be influenced by hormone signal from adjacent theca cells.
Trial registration number: not RCT

P-684 Comparative analysis of structural differences of GONAL-f and Bemfola: *in vivo* bioactivity and site-specific glycosylation mapping

R. Mastrangeli[1], A. Satwekar[2], F. Cutillo[2], C. Ciampolillo[3], S. Longobardi[4]
[1]*Merck Serono S.p.A., Analytical System Center of Expertise, Roma, Italy*
[2]*Merck Serono S.p.A., Protein Chemistry, Roma, Italy*
[3]*Merck RBM S.p.A., Biological Quality Control, Ivrea, Italy*
[4]*Merck Serono S.p.A., Fertility Medical Affairs, Roma, Italy*

Study question: Are there any differences between biosimilar (Bemfola®) and originator (GONAL-f®) recombinant-human follicle-stimulating hormone (r-hFSH) based on *in vivo* bioactivity and on site-specific glycosylation mapping?
Summary answer: Bemfola's bioactivity was within the range stated in the product label, however, there are significant differences in glycosylation between Bemfola and GONAL-f or pituitary FSH.
What is known already: In the EMA assessment report, Finox declared the stated biological activity of 600 IU/ml from 526 to 648 IU/ml for Bemfola finished product, and from 555 to 595 IU/ml for GONAL-f, with a variance of 19% vs. 7% respectively. In addition, mapping of neutral sugars also indicates that Bemfola displays slightly more higher antennary structures than GONAL-f. On the other side it is well known that sugars at αAsn-52 affect bioactivity and that pituitary FSH does not show tetra-antennary sugars at this position.
Study design, size, duration: Bioassay: eight batches of Bemfola were assessed (PNS30388, PNS30230, PPS30400, PPS30021, PNS30390, PNS30228, PNS30389, PNS30229B; Expiry dates September 2016–September 2017), in order to evaluate biopotency range of Bemfola. Glycopeptide mapping: two batches of Bemfola were assessed (PNS30226, PPS30403; Expiry dates September 2016 and September 2017, respectively), and compared with three batches of GONAL-f (199F005, 197F049, 197F051; Expiry dates July–September 2017). Bemfola batches tested had 9–21 months to expiry.

Participants/materials, setting, methods: The *in vivo* bioassay for FSH potency (based on European Pharmacopoeia requirements) compared the effect of the test compound on ovary weight in immature rats vs. a reference standard r-hFSH preparation, which had been calibrated against the International Standard in International Units. Glycopeptide mapping was performed on the chymotryptic digest, and separation achieved with 0.1% TFA in acetonitrile/water on a HILIC column using Acquity UPLC coupled to Synapt G1 Mass Spectrometer (Waters, Milford, MA, USA).
Main results and the role of chance: The *in vivo* bioassay found that 6 out of 8 Bemfola batches showed higher bioactivity than expected, with activity up to 116.6%. In addition, significant differences were observed in the glycosylation patterns of Bemfola and GONAL-f. Tetra-antennary species, which have not been found in human pituitary FSH, were detected at αAsn-52 in in Bemfola (5.7–6.1%) whereas only traces (<1%) were observed in GONAL-f. A higher proportion of bi-antennary species at αAsn-52 was observed for GONAL-f (~75%) than for Bemfola (~53%). Furthermore, a lower degree of sialylation at αAsn-52 was observed for GONAL-f compared with Bemfola. A similar trend was observed at αAsn-78 and βAsn-7, with a greater proportion of bi-antennary species and a lower proportion of tri- and tetra-antennary species at these sites with GONAL-f compared with Bemfola. These results demonstrate that GONAL-f is structurally closer to pituitary FSH.
Limitations, reasons for caution: The analyses described were not performed in humans, and any clinical interpretations would need to be confirmed in a human model.
Wider implications of the findings: Glycosylation is a critical quality attribute of gonadotropins. The observed glycosylation differences between Bemfola and GONAL-f can impact both FSH signalling, gene expression profile and metabolic stability. The potential impact and clinical relevance of these differences on efficacy and risk of AEs should be further investigated in clinical settings.
Trial registration number: N/A.

P-685 Follicles environmental trace element pollution: Interaction and effects in infertile women undergoing ovarian hyperstimulation, and its correlation with IVF outcome

Z. Al-Mudamgha[1], A. DeCherney[1]
[1]*National Institute of Health/National Institute of Child Health and Human Development, Program in Reproductive and Adult Endocrinology, Bethesda, MD, USA*

Study question: What is the correlation and interaction of trace elements in women undergoing ovarian hyperstimulation and *in vitro* fertilization (IVF) and their correlation with pregnancy outcome?
Summary answer: Follicular microenvironment reflects environmental trace element exposure interactions having an impact on IVF outcome which can be increased by protective elements treatments prior to IVF.
What is known already: Environmental pollutants are found in highest concentrations in oocytes, sperm, ovaries and testes. These pollutants may lead to hormonal disorders and infertility by directly affecting the pituitary gland, causing abnormalities in sperm production and preventing ovulation and pregnancy. IVF outcomes are affected by toxic elements in follicular fluid levels. Reducing oocyte toxicity from lead, cadmium and nickel by concentrating the beneficial elements may counteract environmental pollutant toxicity. Pre-IVF mineral supplementation with protective elements may help to increase IVF success rates.
Study design, size, duration: A retrospective cohort study of 120 infertile women undergoing IVF were conducted. Participants were divided according to the cause of infertility into three groups: ovulatory, tubal, and unexplained infertility, and were compared to the male factor control group and the pregnant group. Trace element levels in serum and follicular fluid were measured to study the effect of toxic minerals and their interaction with each other in correlation with the IVF outcome.
Participants/materials, setting, methods: 120 women's serum and follicular fluid trace elements (Zinc, Copper, Selenium, Cadmium, Nickel, Cobalt, Lead)) were measured on ovum pick up day in women aged (22–44 years) who underwent IVF and ovarian hyperstimulation. Trace elements were measured using an Atomic absorption spectrophotometer. Statistical analysis was done using SPSS. Correlation matrix and Test were performed. The correlation between trace elements was analyzed. A comparison of their levels in the infertile, control, and the pregnant group was conducted.
Main results and the role of chance: There are trace elements interactions within certain mechanisms of depletion of toxic elements and concentrating the protective ones in the follicular fluid (FF) within follicles. Zinc levels ranged between 0.325 and 0.581 μg/ml in both serum and FF, Copper (1.011–1.363 μg/ml), Selenium (0.123–1.074), Cadmium (0.021–0.044 μg/ml), Nickel (0.53–0.074 μg/ml), Cobalt (0.049–0.061 μg/ml), Lead (0.046–0.07 μg/ml). Serum Zinc levels were half the normal value in all groups (0.054 ± 0.58 μg/ml), serum Copper levels were higher than FF in the infertile group (1.368 μg/ml). FF Selenium was highest in the control group (2.400 μg/ml). The highest levels of Cadmium were in the infertile group FF (0.44 μg/ml). Control group serum had the highest FF Nickel levels (0.082 μg/ml). The highest levels of Cobalt were in serum of the infertile group (0.06 μg/ml). The highest Lead levels were in the serum of the control group (0.096 μg/ml). The unexplained infertility group had the highest FF Cadmium & Lead levels 0.44, 0.53 μg/ml respectively, which was associated with high Progesterone levels in all infertile groups. Clinical pregnancy outcomes were 36% with 10% healthy deliveries. The highest pregnancy rate occurred in the control group and was associated with high FF Selenium level (2.38 ± 1.91 μg/ml), the lowest serum Cadmium levels (0.02 ± 0.01 μg/ml), higher FF Nickel levels (0.018 ± 0.24 μg/ml), the highest FF Cobalt levels (0.05 ± 0.03 μg/ml), and half the serum FF Lead levels (0.08 ± 0.01 μg/ml).
Limitations, reasons for caution: Infertile male partners were considered as the control group, since it is unethical for healthy women who don't want to have babies nor reserve their eggs to undergo ovarian hyperstimulation; or withdraw FF from healthy women who were unstimulated, thus healthy fertile women enrolled here served as a control.
Wider implications of the findings: IVF outcomes are affected by environmental pollution with toxic elements reflected in their FF and affected by ovarian stimulation by the presence of certain concentrating or depleting mechanisms within the follicle. Pre-IVF mineral supplementation with concentrated protective elements will counteract and reduce oocyte toxicity and increase IVF success rate.
Trial registration number: N/A.

P-686 Defining molecular mechanisms involved in the ovarian aging for clinical applications

Y. Lee[1], S. Kim[1], E. Choi[1], Y. Kim[1], H.G. Park[1], Y.H. Roh[1], H.G. Park[2], P.N. Kang[2], D.J. Chung[2], N.Y. Kim[2], M.J. Kim[2], J. Yoo[2], S.I. Roh[2], Y.P. Cheon[3]
[1]*Mizmedi Women's Hospital, iDream Research Center, Seoul, South Korea*
[2]*Mizmedi Women's Hospital, iDream Clinic, Seoul, South Korea*
[3]*Sungshin Women's University, School of Bioscicences and Chemistry, College of Natural Sciences, Seoul, South Korea*

Study question: Our objective was to dissect molecular pathways of ovarian aging that result in menopause or premature ovarian failure to develop new strategies or treatment options.
Summary answer: Significant changes of gene expression were detected between young and aged ovaries, which could be target genes to treat or delay ovarian aging.
What is known already: Ovarian aging has been proposed one of the factors that are involved in pregnancy failure, and premature ovarian failure (POF) is also another cause of female infertility. Due to modern trends postponing child-bearing in women, ovarian aging increased pregnancy failure and other complications. Although several theories have been suggested such as mitochondrial malfunction, DNA damage/repair/methylation, caloric restriction, studies regarding ovarian aging-related molecular mechanism for development of therapeutic methods are insufficient so far.
Study design, size, duration: This is an experimental study that is consisted of two parts: in Phase I stage, we analyzed distinct gene expression profile between young and aged mouse ovaries, and in Phase II stage several preferentially expressed genes in both ovaries were selected and analyzed their physiological functions and involved molecular networks related to ovarian aging for development of diagnostic markers and therapeutic methods.
Participants/materials, setting, methods: Ovaries from 10-week- and 11-month-old FVB/NJ female mice with synchronized estrus cycle were collected for this study. A half of each ovary was used for RNA preparation and the other half for histological analysis. The expression profile analysis of young and aged ovaries was performed using the Illumina HiSeq 2000 System and functional annotation database-based gene-set enrichment analyses were employed

to evaluate aging-related molecular mechanisms. These findings were confirmed through qRT-PCR and immunohistochemistry.

Main results and the role of chance: We present the gene expression profile in young (10 weeks) and aged (11 months) ovaries by RNA-Seq. Based on Fragment per kilobase of transcript per Million mapped reads (FPKM) of each ovary from RNA-Seq experiments, 876 genes were identified that were preferentially expressed in young or aged ovary. Regarding molecular functions by GOTERM analysis, they were involved in growth factor binding ($p < 0.001$), cytoskeletal protein binding ($p < 0.001$) and platelet-derived growth factor binding ($p < 0.001$). In addition, these preferentially expressed genes code extracellular matrix (ECM) ($p < 0.001$), chromatin ($p < 0.001$) and nucleosome ($p < 0.001$)-related cellular components. In terms of biological process, nucleosome assembly ($p < 0.001$), regulation of hormone level ($p < 0.001$), chromatin organization ($p < 0.001$), response to reactive oxygen species ($p < 0.001$) and cellular macromolecular complex assembly ($p < 0.001$)-related genes might be involved in ovarian aging. Meanwhile according to KEGG Pathway analysis, signal pathways related to ECM-receptor interaction ($p < 0.001$), systemic lupus erythematosus ($p < 0.001$), focal adhesion ($p < 0.01$), steroid hormone biosynthesis ($p < 0.05$) and androgen/estrogen metabolism ($p < 0.05$) might play crucial roles in ovarian aging process. Further analyses are scheduled to produce transgenic animal models and with human ovarian tissues and cell lines.

Limitations, reasons for caution: This study does not include results from human materials, therefore it will be needed to verify their roles in ovarian aging using human ovarian tissues or cell lines for future clinical applications.

Wider implications of the findings: This study will provide new tools and enable formulation of new strategies to diagnose causes of ovarian aging and improve treatment options. It will be also providing new biomarkers useful to predict ovarian ages and reserve to care or rejuvenate aged ovaries.

Trial registration number: N/A.

P-687 GnRH-agonist triggering for final oocyte maturation in GnRH-antagonist IVF cycles induces decreased LH pulse rate and amplitude in early luteal phase: a possible luteolysis mechanism

S. Kol[1], S. Tannus[1], Y. Burke[1]
[1]*Rambam Health Care Campus, Department of Ob/Gyn, Haifa, Israel*

Study question: What is the mechanism of luteolysis in gonadotropin releasing hormone (GnRH) antagonist IVF cycles, triggered with GnRH agonist (GnRH-a) for final oocyte maturation?

Summary answer: Decreased baseline luteinizing hormone (LH) concentration, slowed pulse rate and reduced pulse amplitude may explain the mechanism of early luteal phase (ELP) luteolysis.

What is known already: GnRH-a ovulation triggering in GnRH-antagonist IVF cycles has been shown to reduce or even eliminate the incidence of ovarian hyperstimulation syndrome (OHSS) in high risk women. Following GnRH-a triggering menses can start as early as 4 days after ovulation, if no supplementation is given. The exact mechanism of this luteal phase insufficiency is still not fully understood.

Study design, size, duration: A prospective cohort study of ten patients who had IVF cycle with GnRH antagonist protocol, and were considered at high risk for developing OHSS (E_2 > 12,000 pmol/l and/or ≥15 follicles of ≥12 mm in diameter on trigger day). Ovulation was triggered with a bolus of 0.2 mg triptorelin when ≥3 follicles were ≥17 mm in diameter. Oocyte retrieval was performed 36 h later. Embryo transfer was performed 2 days post oocyte retrieval.

Participants/materials, setting, methods: Repeated blood samples were taken every 20 min for 6 h to measure serum LH, estradiol and progesterone. Women were divided into 2 groups: patients in group 1 ($n = 5$) were followed on the day of oocyte retrieval and patients in group 2 ($n = 5$) were followed 48 h after oocyte collection. LH pulse analysis was done with the deconvolution program. Pearson correlation coefficient was used to analyze hormone changes over time. Data are presented as mean ± SEM/SD

Main results and the role of chance: LH secretion: Mean LH and basal LH secretion rate were significantly higher in group 1 compared to group 2 (5.17 ± 1.97 IU/l vs. 0.616 ± 0.14 IU/l, $p = 0.049$) and (0.39 ± 0.036 IU/L/min vs. 0.0042 ± 0.0027 IU/L/min, $p = 0.0001$), respectively. The mean number of LH secretion pulses (0–2 pulses per women in 6 h follow up) was similar between the groups (1 ± 0.70 vs. 1.2 ± 0.83, $p = 0.48$) and the pulse amplitude was similar (1.13 ± 0.79 IU/l vs. 0.44 ± 0.44 IU/l, $p = 0.18$) for group 1 and 2 respectively. This LH secretion pattern represents a significant deviation from physiology where in ELP, pulse frequency rate is one pulse every 103 min and the mean LH pulse amplitude is 14.9 IU/l.

Estradiol (E_2): There was a significant decrease of E_2 over time in group 1 (5.442 ± 907 pmol/l to 3.376 ± 612 pmol/l, $r = –0.95$, $p < 0.00001$) and this decrease continued although more modestly in group 2 (3.036 ± 481 pmol/l vs. 2.642 ± 580 pmol/l, $r = –0.78$, $p < 0.01$).

Progesterone (P): There was a steady increase in P levels in group 1 (17.4 ± 3.73 nmol/l to 18.80 ± 5.80 nmol/l, $r = 0.53$, $p = 0.023$), followed by a sharp decline of P in group 2 (50.52 ± 8.97 nmol/l to 35.90 ± 6.25 nmol/l, $r = –0.94$, $p < 0.0001$). This decrease is in contrast to physiology where P levels increase to peak in the mid luteal phase.

Limitations, reasons for caution: The small number of participants (5) in each group.

Wider implications of the findings: Post GnRH-a triggering LH secretion pattern is aberrant in ELP, which may explain the dramatic luteolysis that follows. Luteal phase supplementation with intensive E_2 + P or LH (either LH itself or small hCG doses) is crucial to ensure receptive endometrium.

Trial registration number: NCT02449642.

P-688 Comparison of follicular fluid from natural and stimulated IVF cycles in the same women using antibody microarrays

M. Von Wolff[1], N.A. Bersinger[1], M. Eisenhut[1], B. Laborde[1], A. Vaucher[1]
[1]*University of Berne Inselspital, Obstetrics and Gynaecology, Berne, Switzerland*

Study question: Is the protein profile in follicular fluid (FF) different in Natural Cycle IVF (NC-IVF) in comparison to conventional gonadotropin stimulated IVF (c-IVF)?

Summary answer: Sixteen out of 179 examined FF proteins were differently expressed in NC-IVF compared to c-IVF, suggesting gonadotropins to induce alterations in the FF protein profile.

What is known already: In c-IVF the implantation rate of unselected embryos is lower than in NC-IVF, which is possibly due to negative effects of the stimulation regimen on follicular metabolism. Accordingly, the endocrine follicular milieu and the concentration of putative markers of oocyte quality such as AMH have been shown to be significantly altered in FF by the gonadotropin stimulation in conventional IVF. These differences also suggest alterations in the FF protein profile induced by stimulation regimens in c-IVF. However, hardly any proteins with other functions such as cell signalling have been studied so far in this context.

Study design, size, duration: Retrospective cohort study involving 15 women who each underwent one NC- and one c-IVF treatment cycle between 2010 and 2015. c-IVF was performed by controlled ovarian stimulation with HMG and GnRH antagonists.

Participants/materials, setting, methods: Follicular fluid was collected from the leading follicles, and albumin and IgG removed with PROTIA immunoaffinity columns (Sigma). The flow-throughs (250 µL, >1 mg/mL) were labelled with Cy3 (NC-IVF) and Cy5 (c-IVF) reactive dyes (LKB), or *vice versa* to obtain a true duplicate. The samples were incubated on CSAA1 Panorama® arrays (Sigma) which contain antibodies against 224 proteins and which were then scanned for fluorescence at 552 (Cy3) and 650 (Cy5) nm. Normalisation required 6/21 array pairs.

Main results and the role of chance: Normalisation and standardisation was performed at several levels. First and foremost, the same women provided a NC- and a c-IVF cycle each. The Cy3/Cy5 dye swap allowed to remove staining bias. The arrays of 6 of the 21 couples were used to establish the normalisation algorithms. All protein signals were between those from negative and positive controls. Housekeeping proteins included 90 spots (45 proteins of the cytoskeleton), and the smoothing was applied over all spots with protein down weighting. The analysis of the selected 15 FF samples revealed 16 proteins which were found to show significantly ($P < 0.05$) higher ($n = 7$) or lower ($n = 9$) expression levels in NC-IVF when compared with c-IVF treatment cycles. These included cystatin A, DAP- and MAP-kinase and glutamic acid decarboxylase (NC-IVF higher than c-IVF), and active caspase-3, NF-κB and nerve growth factor receptor (NC-IVF lower than c-IVF).

Limitations, reasons for caution: Inclusion criteria were very strict to generate the most precise study results possible. Consequently the number of analysed samples was limited. The proteins with the highest differential expression will have to be quantified using single ELISA approaches.

Wider implications of the findings: The alteration of the protein profile could be a cause or a result of some metabolic differences induced by gonadotropins resulting in lower oocyte quality in c-IVF compared to NC-IVF. Cell signalling and apoptosis will be better understood with the identification of the most important players amongst the FF proteins.
Trial registration number: Not applicable.

P-689 Intramuscular progesterone (IM-P4) administration is associated with better pregnancy rates in frozen–thawed blastocyst transfers, regardless of progesterone serum levels

F. Torelli[1,2], C. Padilla[3], M. Cavagnoli[3], T. Bonetti[4,5], P. Serafini[6,7], E. Motta[5,6]

[7]*Faculdade de Medicina da Universidade de São Paulo FM-USP, Departamento de Obstetrícia e Ginecologia, Disciplina de Ginecologia, Sao Paulo, Brazil*

Study question: Does IM-P4 administration 5–7 days before embryo transfer enrich the endometrium in a way that progesterone-in-oil enhances pregnancy rates in frozen–thawed embryo transfer cycles (FET)?
Summary answer: There is no difference in pregnancy rates according to P4 levels. However, IM-P4 route seems to induce better pregnancy outcomes.
What is known already: Many IVF practitioners' use high doses of IM-P4 in the luteal phase to enhance implantation in FET cycles. It appears that serum estradiol (E2) and P4 pave the endometrium in order to establish an artificially prepared lining. Luteal support is essential to maintain endometrium favorable to embryo implantation. Several P4 luteal phase support protocols for FET are routinely used and safely administered. There are P4 preparations available for vaginal, oral or intramuscular (IM) administrations with no clear correlation to serum levels or enhanced pregnancy rates.
Study design, size, duration: Retrospective study included 297 FET cycles between July 2014 and November 2015. Patients underwent endometrium preparation using E2 starting from 1st to 3rd day of menstrual cycle. P4 was administered when a proper endometrium was measured above 8 mm in thickness. P4 was placed vaginal ($n = 229$), vaginal + oral ($n = 30$) or vaginal + im ($n = 22$). Levels of progesterone were measured at the embryo transfer day. Patients were allocated into groups according to P4 levels as <10 ng/ml ($n = 59$), 10–20 ng/ml ($n = 157$) and >20 ng/ml ($n = 41$).
Participants/materials, setting, methods: All embryos were frozen at blastocyst stage. The blastocysts were warmed and checked for survival and quality; and one to four frozen–thawed embryos were transferred. The demographic characteristics of patients and pregnancy rates were compared among groups according to P4 route and P4 levels categories. Also, regression model was applied to assess the influence of P4 levels and route in pregnancy rates and adjusted for confounders.
Main results and the role of chance: Patients ages were 36.8 ± 4.4 with a mean of 1.9 ± 0.8 embryos warmed and 1.8 ± 0.6 embryos transferred. P4 levels according with P4 route groups were higher in the vaginal + IM group (vaginal: 16.9 ± 27.5; vaginal + oral: 14.0 ± 5.4; vaginal + im: 32.6 ± 44.2; $p = 0.039$), but there was no difference on endometrial thickness (vaginal: 9.0 ± 1.8; vaginal + oral: 8.9 ± 1.6; vaginal + im: 8.9 ± 1.2; $p = 0.996$). Patients who received P4 through vaginal + im route presented higher pregnancy rates (72.7%) than vaginal (51.5%, $p = 0.052$) or vaginal + oral (56.7%, $p = 0.013$). When patients were split into groups according to P4 levels, the clinical pregnancy rates were similar (P4: <10: 50.8%; P4:10–20: 56.1%; P4:>20: 53.7%; $p = 0.786$). A multiple logistic regression model were built to evaluate the P4 level or route in the pregnancy rates adjusted to patients age and number of embryos transferred. The P4 levels were not associated to pregnancy chance (OR: 1.0, $p = 0.852$), on the other hand, when patients received P4 vaginal + IM the chance of became pregnant was 2.5 higher and marginally significant (OR: 2.5; $p = 0.061$).
Limitations, reasons for caution: This is a retrospective study, without randomization according to P4 route of administration, and then the groups were not homogenously distributed. A multiple regression was applied to adjust for confounders, but a randomized prospective study would be necessary to better conclusions regarding differences in pregnancy according to P4 administration route.
Wider implications of the findings: Despite of subsequent higher progesterone levels, it seems that IM-P4 route, and do not progesterone levels itself, has a positive effect in pregnancy rates. It is known that IM-P4 can present a higher progesterone level stability and it might be the reason for those results.
Trial registration number: Not applicable.

P-690 The impact of excision of benign non-endometriotic ovarian cysts on ovarian reserve: a systematic review and meta-Analysis

A.A. Mohamed[1], T.K. Al-Hussaini[2], M.M. Fathalla[2], I.I. Abdelaal[2], T. El Shamy[3], S.A. Amer[4]
[1]*University of Nottingham, Obstetrics and Gynecology, Derby, UK*
[2]*Assiut University, Department of Obstetrics and Gynecology, Assiut, Egypt*
[3]*Royal Derby Hospital, Department of Obstetrics and Gynaecology, Derby, UK*
[4]*Royal Derby Hospital, University of Nottingham, Obstetrics and Gynecology, Derby, UK*

Study question: Does excision of benign non-endometriotic ovarian cysts cause damage to ovarian reserve as determined by Anti-Müllerian Hormone (AMH)?
Summary answer: Excision of benign non-endometriotic ovarian cysts seems to markedly reduce circulating AMH. It remains uncertain whether this reflects a real decline in ovarian reserve.
What is known already: Benign non-endometriotic ovarian cysts are very common and often require surgical excision. However, there has been a growing concern over the possible damaging effect of this surgery on ovarian reserve with potential compromise to fertility potential.

To date, several studies have investigated the impact of ovarian cystectomy on ovarian reserve as determined by circulating AMH. Most of these studies showed a postoperative decline in circulating AMH. However, given the relatively small size of these studies, further evidence is required to allow a firm conclusion.
Study design, size, duration: This meta-analysis included all cohort studies and randomized trials that analyzed changes of serum AMH concentrations after excision of benign non-endometriotic ovarian cysts. The included studies were conducted in the period between January 2000 and November 2015.
Participants/materials, setting, methods: The meta-analysis included nine studies with 305 patients who underwent excision of benign non-endometriotic ovarian cysts. Primary outcome was postoperative change in serum AMH level. Secondary outcomes were changes in postoperative serum follicle-stimulating hormone (FSH) concentration and antral follicle count (AFC).
Main results and the role of chance: Pooled analysis of 305 patients showed a statistically significant decline in serum AMH concentration after ovarian cystectomy (weighted mean difference (WMD) −1.00 ng/ml; 95% confidence interval (CI) −0.35 to −1.66), although heterogeneity between studies was high. Subgroup analysis including studies with a three-month follow-up, studies using Gen II AMH assay and studies using Immunotech (IOT) AMH assay improved heterogeneity and still showed significant postoperative decline of circulating AMH (WMD −1.50, −0.88, and −1.56, respectively). Sensitivity analysis including studies with low risk of bias and excluding studies with possible confounding factors still showed a significant decline in circulating AMH.
Limitations, reasons for caution: Given the high heterogeneity between included studies, this meta-analysis should be interpreted with caution. More well designed studies with long-term follow-up are needed, to draw a firm conclusion.
Wider implications of the findings: Women in reproductive age group presenting with benign non-endometriotic cysts should be counselled properly regarding the effect of surgical excision of ovarian cysts on ovarian reserve and reproductive performance in the future.
Trial registration number: None.

P-691 Granulosa cells of insulin resistance pcos women over express foxo 1 and it is linked with insulin signaling dysfunction

A. Salinas[1], P. Kohen[1], A. Muñoz[1], A. Godoy[1], F. Orge[1], L. Devoto[1]
[1]IDIMI-Hospital San Borja Facultad de Medicina, Universidad de Chile, IDIMI, Santiago-RM, Chile

Study question: ¿ Which is the status or the transcription factor forkhead box O1 (FOXO1) and its inactive isoform pFOXO1 in granulosa cells of Insulin Resistance PCOS women?
Summary answer: Granulosa Cells of PCOS–IR women over express FOXO1, the decrease of the inactivated form pFoxo1 in is related with the impairment of the Insulin signal.
What is known already: Metabolic disorders such as hyperinsulinemia, insulin resistance and obesity are features of Polycystic Ovary Syndrome (PCOS), with a relevant role in the pathogenesis of this disease. The transcription factor forkhead box O1 (FoxO1) plays roles in insulin-mediated glucose metabolism and have been linked to the pathogenesis of insulin resistance. Studies show that modulation of FoxO1 is essential for extra-hepatic insulin signaling to maintain glucose homeostasis. FOXO 1 is also expressed in granulosa cells (GC) and plays a critical role in promoting follicular atresia and cell apoptosis. However, it physiologic significance in reproductive tissue and PCOS women is unknown.
Study design, size, duration: A prospective case–control study conducted from March 2012 to June 2014. Local Institutional Review Board approved the study. Case: Insulin resistance PCOS (NHI) women: 20.

Control: Normal ovulatori women with male factor infertility as exclusive cause: 30.
Participants/materials, setting, methods: GC were issolated from the follicular fluid from NHI-PCOS-IR patients $n = 20$ and from normal women with male factor infertility control = 30 participants of the IVF program at our university center in Santiago. Insulin signaling in GC were evaluated measuring IRS1/p-IRS1, Akt/pAkt levels by Western blot. FoxO1/pFoxo1 levels and location were assesed by Inmunohistochemistry and Western blot GC were incubated with an Insulin-sensitizer drug Rosiglitazone Rz to asses the effect on insulin signaling pathway and FoxO1/pFoxo1 status.
Main results and the role of chance: PCOS GCs express higher levels of pIRS1 in serine residues (inactivating phosphorylation of insulin signaling) and low levels of total Akt and phospho Akt compared with control cells $p < 0.05$, reflecting and impairment in the insulin signaling pathway function. IR PCOS GCs express higher levels of FOxO1 and lower levels of pFoxO1. *In vitro* treatment with 0.1 µM Rz decreases IRS1serine phosphorylation and improve pAKT levels in PCOS CG. Rz decreases FOXO1 levels and improved pFOXO1 after stimulation with insulin in PCOS GC.
Limitations, reasons for caution: *In vitro* study, small sample.
Wider implications of the findings: These results may suggest that over expression FOxO1 in IR-PCOS-GCs is involved in the arrest of follicular development of PCOS, Insulinosensitizer administration as Rz can take important therapeutic rol, contributing to a better oocyte quality in this group of patients.
Trial registration number: None.

P-692 Impact of gonadotropin-type on progesterone elevation on the day of hCG during ovarian stimulation with corifollitropin alpha (CFA) or recombinant follicle-stimulating hormone (rFSH)

B. Lawrenz[1], F. Beligotti[2], D. Gates[3], H. Fatemi[1]
[1]IVI Fertility Clinic Abu Dhabi, IVF, Abu Dhabi, United Arab Emirates
[2]MSD Italy, Research Department, Rome, Italy
[3]MSD USA, Statistical Department, Rahway, NJ, USA

Study question: Does hormonal stimulation in a GnRH-antagonist protocol, using CFA-only, has a lower incidence for premature progesterone rise on the day of hCG-trigger, compared to rFSH-only?
Summary answer: Controlled ovarian stimulation for IVF with CFA-only leads to a significantly lower incidence for progesterone rise on day of hCG-trigger, compared to stimulation with rFSH-only.
What is known already: An emerging body of evidence suggests that premature progesterone rise during the late follicular phase of stimulation for IVF has a negative impact on the outcome. However, the mechanism, by which the rise of progesterone reduces pregnancy rates is still not fully understood. It seems, that elevated progesterone does not have any negative impact on the oocyte or embryo quality. Its impact seems to be on the endometrium, leading to asynchrony between the endometrium and the developing embryo. Some studies suggest, that the cause of premature progesterone rise might be enhanced FSH stimulation in ART cycles.
Study design, size, duration: This study is a retrospective analysis of the data of the ENGAGE and PURSUE study, which were conducted from 2006 to 2008 and 2010 to 2012, respectively. Both were randomized, double-blind, double-dummy, active-controlled, non-inferiority trials, comparing CFA and rFSH during the first seven days of ovarian stimulation in a GnRH antagonist protocol. Data regarding stimulation medication used, stimulation duration, number of retrieved oocytes and incidence of elevated progesterone on the day of hCG-trigger were extracted.
Participants/materials, setting, methods: The ENGAGE and PURSUE trial included women aged 18–36 and 35–42 years, respectively, with a body weight of >60 – <90 kg and ≥ 50 kg, respectively, with a cycle length of 24–35 days and an indication for controlled ovarian stimulation before IVF. Patients were allocated to CFA-only or to rFSH-only-stimulation for the first 7 days. Blood was taken for hormonal assessment of progesterone on the day of hCG-trigger.
Main results and the role of chance: In the ENGAGE and the PURSUE trial, 1450 patients were randomized to CFA-treatment and 1446 patients to rFSH-treatment. Blood results of progesterone levels on the day of hCG administration were available from 1409 patients (CFA-treatment) and 1412 patients (rFSH-treatment), respectively. 5.4% (13/239) of patients that received CFA-stimulation and required no additional rFSH after day 8 to meet the criteria for final oocyte maturation, had progesterone level above 1.5 ng/ml compared to 18.5% (62/339) of patients that received rFSH-stimulation and no additional rFSH after day 8 ($P < 0.001$).

The analysis of patients with different ovarian response regarding the numbers of retrieved oocytes (0–5, 6–9, 10–13, 14–18, >18 oocytes) in regards to different stimulation-medications (CFA or rFSH) revealed the following incidence of premature progesterone rise: CFA-treated patients, without additional rFSH after day 8, had a 2.7–7.5% incidence of progesterone level above 1.5 ng/ml, independent from the number of retrieved oocytes (P = NS). In rFSH-treated patients without additional rFSH after day 8, the incidence of progesterone above 1.5 ng/ml levels was 6.3% (0–5 oocytes) and 31.6% (>18 oocytes) ($P < 0.001$).
Limitations, reasons for caution: The theory that step-down of FSH-stimulation-dosage in late follicular phase of controlled ovarian stimulation could lower the incidence of progesterone elevation has to be confirmed in future randomized controlled trials.
Wider implications of the findings: The pharmacokinetic profile of CFA is characterized by a rapid absorption, peak concentrations 2 days after injection, followed by decreasing FSH-activity, mimicking a step-down protocol. This reduces the thriving pressure on the growing follicle, resulting in a significantly lower incidence of premature progesterone rise, compared to daily stimulation with rFSH.
Trial registration number: The trials were registered under ClinicalTrials.gov identifier NTC00696800 (ENGAGE) and NCT01144416 (PURSUE).

P-693 does ulipristal acetate administration for symptomatic uterine fibroids impact ovarian reserve?

F. Raga[1], I. Moscardo[1], S. Cholvi[1], C. Pascual[1], C. Llinares[1], D. Boigues[1], C. Martinez[1], A. Carratala[1], A. Cano[1]
[1]Hospital Clinico Universitario, Obstetrics, Gynecology and Reproductive Medicine, Valencia, Spain

Study question: The purpose of this study was to evaluate whether the use of ulipristal acetate to treat women with symptomatic myomas might compromises the ovarian reserve.
Summary answer: Using 3D-ultrasound technology and serum AMH concentrations we have been able to rule out a possible deleterious effect of ulipristal acetate on women ovarian reserve.
What is known already: Ulipristal acetate (UA) is a selective progesterone receptor modulator (SPRM) that presents a distinctive range of clinically advantageous properties in female reproductive tissues. Accordingly, the uterus is a significant therapeutic target for UA because of its action in reducing fibroid size and associated symptomatology. However, the possible impact of the UA on the ovarian reserve of premenopausal women has not been explored previously. Currently, this reserve can be evaluated by two different methods:

ovarian ultrasonography (Antral Follicle Count) and measurement of endocrine markers (Anti-Müllerian Hormone), as both have a notable agreement with histologically.

Study design, size, duration: A prospective longitudinal study was conducted at our Department of Obstetrics, Gynecology and Reproductive Medicine, from September 2013 to January 2016. The study was approved by the institutional review Board and all participants gave informed consent for the trial.

Participants/materials, setting, methods: The study was carried out involving premenopausal women ($n = 40$) with uterine leiomyomas who were judged to have a sufficient problem to justified surgical treatment. All the patients want to preserve fertility and therefore requested a conservative surgery (myomectomy). All patients were treated with UA (Esmya®) 5 mg daily before surgery for either 3 ($n = 20$) or 6 months ($n = 20$). 3D-ultrasound AFC, ovarian volume and AMH level were determined before and after the treatment with UA.

Main results and the role of chance: Serum AMH levels before (3.9 ± 0.2 ng/mL) UA were not statically significantly different from those after 3 months (4.1 ± 0.3 ng/mL) or 6 months (4.0 ± 0.2 ng/mL) treatment. In addition, no statistically significant difference in median Antral Follicle Count (28 ± 3.1 vs. 29 ± 2.8 vs. 27 ± 2.6) and median ovarian volume (7.06 ± 1.1 cm^3 vs. 6.89 ± 1.3 cm^3 vs. 7.09 ± 0.9 cm^3) were detected in the treatment groups between pretreatment 3D-ultrasonographic ovarian reserve evaluation and after 3 or 6 months of treatment with UA.

Limitations, reasons for caution: Our study do not conclusively rule out a possible detrimental effect on the ovarian reserve since this can only be achieved through an invasive and destructive method such as the remove of ovaries and carry out a histomorphometry-based follicle count.

Wider implications of the findings: Our findings can be useful when counselling young women with symptomatic myomas that desire to preserve fertility and we decided to treat them with ulipristal acetate before surgery. Consequently, ulipristal acetate is a safe treatment choice for these women as it does not compromise the ovarian reserve.

Trial registration number:.

P-694 Cluster analysis of metabolic risk factors in women of reproductive age: a prospective study

S. Kanta Goswami[1], P. Chakraborty[2], H.S. Sarkar[1], B.N. Chakravarty[1]
[1]*Institute of Reproductive Medicine, ART, Calcutta, India*
[2]*Institute of Reproductive Medicine, Infertility, Calcutta, India*

Study question: Is there any association between endocrine disturbances and metabolic complications in women seeking gynecological care at their reproductive age?

Summary answer: Hyperhomocysteinemia (HHcy), followed by obesity, is the major determinant of cardio-metabolic disturbances in reproductive age women.

What is known already: The most well known correlation between metabolic syndrome (MS) and reproductive disorders is in women with polycystic ovary syndrome (PCOS). Recent reports suggest cardiovascular health in women is not improving as fast as that of men. Women of reproductive age often present with increased incidence of MS and cardiovascular disease (CVD) risk factors. Although studies of PCOS allied metabolic complications have been widely reported, the understanding of the correlation between endocrine status and metabolic complications in reproductive-age women remain limited and controversial.

Study design, size, duration: A prospective study including 1543 reproductive aged women was conducted for a period of 24 months. PCOS and MS were defined according to Rotterdam consensus and National Cholesterol Program Adult Treatment Panel III respectively. Participants were evaluated for MS and selected patients were randomly divided into two groups on the basis of high risk ($n = 143$) and low risk ($n = 711$) as classified by hierarchical cluster analysis by within-group linkage method.

Participants/materials, setting, methods: The participants were recruited at out-patient department of Institute of Reproductive Medicine, Kolkata. Serum concentrations of testosterone, insulin sensitivity and prolactin with metabolic parameters like C-reactive protein, lipid profile, homocysteine, sex-hormone binding globulin (SHBG), glucose and liver enzymes were evaluated between the two groups by chemiluminescence. Anthropometric measurements were recorded at the beginning of study. Odds ratio (OR) is computed. Poisson regression was used to generate risk ratio (RR) and 95% confidence intervals (CI).

Main results and the role of chance: For clinical diagnosis, 50.7% ($n = 433$) subjects had PCOS, 8.89% ($n = 76$) had hyperprolactinemia, 26.11% ($n = 223$) had tubal factor infertility and 3.39% ($n = 29$) had premature ovarian failure (POF). In terms of metabolic complications, 23.53% ($n = 201$) had MS, 11.12% ($n = 95$) had impaired glucose tolerance, and 4.8% ($n = 41$) had diabetes mellitus. Risk factors for metabolic disease are associated with a low age (<12 years) of menarche (RR, 1.26; 95% CI: 1.07–1.49) and a combination of high levels of C-reactive protein, homocysteine, and low levels of SHBG (RR, 1.44; 95% CI, 1.24–1.67). All metabolic indices excepting serum prolactin, alanine transferase and triglycerides were significantly ($p < 0.01$) different in high risk group. Hyperhomocysteinemia (>14 mmol/L) associated metabolic disturbance supersedes other clinical characteristics to set the strongest association between the two (OR, 20.1; 95% CI, 11.4–31.2). Overweight/obese status (OR, 11.2; 95% CI, 7.9–15.7) PCOS (OR, 1.6; 95% CI, 1.3–1.9), oligo/amenorrhea (OR, 1.3; 95% CI, 1.1–1.4), and hyperandrogenism (OR, 1.4; 95% CI, 1.2–1.6) were also found to increase the risk of cardiometabolic disease. However, tubal factor (OR, 0.7; 95% CI, 0.3–1), hyperprolactinemia (OR, 0.6; 95% CI, 0.3–1.1) and POF (OR, 0.3; 95% CI, 0.1–1.5) were not associated with the risk of cardiometabolic disease.

Limitations, reasons for caution: Although androgen excess may signal a risk for CVD, different types of androgens are not evaluated separately. Women were recruited from the outpatient clinic of a tertiary care center; hence, do not reflect true distribution of the general population. Therefore, results should be applied to the general population with caution.

Wider implications of the findings: Hyperhomocysteinemia was the major determinant of cardiovascular and metabolic disturbances in reproductive-age women. Even though many studies have shown an elevation in surrogate biomarkers of cardiovascular disease in PCOS women, it is still not clear as to what extent and magnitude the elevation precipitates more frequent and earlier events.

Trial registration number: Not applicable.

P-695 The different impact of stimulation duration on oocyte maturation and pregnancy outcome in fresh cycles with GnRH antagonist protocol in poor responders and normal responders

Y.P. Li[1], Y.C. Yang[1], J.H. Yang[1], M.J. Chen[1], C.H. Chang[2], S.U. Chen[1], Y.S. Yang[1]
[1]*National Taiwan University Hospital, Department of Obstetrics and Gynecology, Taipei, Taiwan R.O.C.*
[2]*National Taiwan University Hospital, Department of Medical Research, Taipei, Taiwan R.O.C.*

Study question: What is the different impact of stimulation duration on fresh cycles in poor and normal responders during controlled ovarian stimulation (COS) using gonadotropin antagonist protocol?

Summary answer: Unlike normal responders, poor responders may have shorter stimulation duration with good oocyte maturation rate and clinical pregnancy rate.

What is known already: The gonadotropin stimulation is important for follicular growth, oocyte maturation, oocyte quality and endometrial development. Insufficient gonadotropin exposure may lead to nuclear or cytoplasmic immaturity of oocytes. On the other hand, prolonged stimulation may cause post-maturity of oocytes or apoptosis of granulosa cells and oocytes. It may also result in elevated progesterone and estradiol levels and impaired endometrial receptivity.

Study design, size, duration: This is a retrospective cohort study at a tertiary, university-affiliated medical center from January 2009 to June 2012. ICSI cycles using GnRH-antagonist protocol, without any pre-treatment, were included for analysis. Only the first stimulated cycles with fresh embryo transfer were included. The cycles with freezing all embryos were excluded from this study. A total of 443 women undergoing ICSI-ET cycle were included in this study.

Participants/materials, setting, methods: The starting dose of recombinant FSH was 200 IU with flexible antagonist protocol. The follicles reaching 18 mm with corresponding estradiol levels were used to determine hCG timing. Ovum pick-up number ≤3 were defined as poor responders ($n = 75$); ≥4 and ≤20 were normal responders ($n = 368$). End-points were oocyte maturation and clinical pregnancy rates. Both poor and normal responders were divided into four groups according to stimulation duration: ≤6, 7–8, 9–10, and ≥11 days.

Main results and the role of chance: The mean stimulation duration was significantly shorter in poor responders than normal responders (8.4 ± 2.0 vs.

9.0 ± 1.5, $p < 0.01$). Besides, the mean stimulation duration was significantly shorter in the pregnant group as compared with the non-pregnant group in poor responders (7.8 ± 2.4 vs. 8.5 ± 1.8, $p = 0.04$) and the mean stimulation duration was similar in normal responders (9.0 ± 1.5 vs. 9.1 ± 1.5, $p = 0.21$). Poor responders with a shorter stimulation duration seems to have a higher clinical pregnancy rate (≤6 days: 50.0%, 7–8 days: 31.3%, 9–10 days: 13.6%, and ≥11 days: 27.3%, $p = 0.19$), whereas the oocyte maturation rates were similar among them (≤6 days: 88.2%, 7–8 days: 85.0%, 9–10 days: 88.0%, and ≥11 days: 88.9%, $p = 0.98$). On the contrary, normal responders with the shortest stimulation durations (≤6 days) had the lowest clinical pregnancy rate (≤6 days: 27.3%, 7–8 days: 56.7%, 9–10 days: 47.5%, and ≥11 days: 50.0%, $p = 0.16$) and the lowest oocyte maturation rate (≤6 days: 69.0%, 7–8 days: 79.1%, 9–10 days: 82.1%, and ≥11 days: 78.3%, $p < 0.001$). Both poor and normal responders with shorter stimulation duration had a higher baseline estradiol levels and lower hCG-day progesterone levels ($p < 0.05$).

Limitations, reasons for caution: A larger sample size will be needed to demonstrate the proposed association between stimulation duration and ICSI outcome in poor and normal responders. With the retrospective nature of this study, it is inevitably influenced by some selection bias and the potential confounders related to COS and pregnancy outcome.

Wider implications of the findings: The higher baseline estradiol level may reflect earlier follicular recruitment by endogenous gonadotropin in late luteal phase. This may lead to relatively shorter follicular phase. The shorter stimulation in poor responders may reflect better granulosa cell function. Stimulation duration might be considered as adjunct parameters in determination of hCG timing.

Trial registration number: nil.

P-696 Putative functional link between FMR1 expression and mTOR/AKT–signal pathway during follicular control in human granulosa cells

J. Rehnitz[1,2], D.D. Alcoba[2,3], I.S. Brum[3], T. Strowitzki[1], P.H. Vogt[2]
[1]*University Women Hospital, Department of Gynecological Endocrinology and Fertily Disorders, Heidelberg, Germany*
[2]*University Women Hospital, Reproductive Genetics Unit, Department of Gynecological Endocrinology and Fertility Disorders, Heidelberg, Germany*
[3]*Laboratório de Biologia Molecular Endócrina e Tumoral, Instituto de Ciências Básicas da Saúde, Departamento de Fisiologia, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil*

Study question: Assessment of *FMR1*/FMRP expression and the putative linked mTOR-AKT-signal-pathway in human granulosa cells modulated by FSH-stimulation.

Summary answer: FSH-stimulation activates *AKT-/mTOR*-expression but represses *S6K*- and *FMR1*-expression, while FMRP-expression increases during granulosa-cellular-growth. Results suggest a functional-link between them during follicular-maturation-process. Specific-pathway-inhibitior-assays support these findings.

What is known already: In rodents mTOR/AKT regulates early folliculogenesis by maintaining primordial follicles in dormancy induced by FSH for further differentiation and maturation. Consequently, FSH is used to stimulate oocyte-maturation in women for ART. Increased FSH-dosages are used in cases of diminishing ovarian reserve (DOR). Increased *FMR1*-expression in women carrying an *FMR1*-CGG_n-premutation ($n > 54$) in exon1 is known to reduce FMRP-expression and is associated with premature ovarian insufficiency/failure (POI/F). FMRP is mainly expressed in human granulosa cells within female ovary. As further studies suggest that CGG-triplet-numbers below or above $n = 26–34$ also affect ovarian reserve, the level of *FMR1*/FMRP-expression can be considered as novel ovarian-reserve-marker.

Study design, size, duration: Human COV434 granulosa-cell-line was used as model-system for FSH-stimulated cell-growth-control. Specific gene-expression-profiles of *AKT, mTOR and S6K,* as part of the mTOR-AKT-signaling pathway are compared to profiles of *FMR1*/FMRP before and after inhibiting specific mTOR/AKT-components.

Participants/materials, setting, methods: COV434 cell-line was treated with recFSH or the AKT-, mTOR-specific inhibitors MK-2206-2HCL and Rapamycin, respectively. TaqMan-analysis was performed to compare mRNA-expression-levels of *AKT, mTOR, S6K* and *FMR1* genes before and after FSH-stimulation and inhibitor-treatment. Protein-expression was determined using specific ELISAs. Statistical analysis including Mann–Whitney *U* and *T*-test were carried out with SPSS statistic software; statistical significance was set as $P \leq 0.05$.

Main results and the role of chance: Expression-profiles of *AKT, mTOR* in COV434 increased significantly ($P = 0.05$, $P = 0.015$ and $P = 0.05$) after treatment with recFSH. Surprisingly, *S6K*-expression decreased during the same treatment like *FMR1*-expression. After cell-line treatment with mTOR/AKT-inhibitors *FMR1*- and *S6K*-expression both significantly increased ($P = 0.031$). These findings suggest a putative functional link between expression of the mTOR/AKT signaling-pathway and the ovarian-reserve-marker-gene *FMR1* indicated by the *S6K*-expression level. Both are potentially involved in human folliculogenesis and oocyte maturation, as well as in ovarian reserve. Results are helpful to elucidate how FSH affects molecular mechanisms during follicular growth and under controlled ovarian stimulation. This suggests new starting points for functional research of human folliculogenesis and its disorders like POI/POF and DOR.

Limitations, reasons for caution: Presented description of a putative link of mTOR/AKT signal-pathway to *FMR1*-expression after FSH-stimulation is based on the use of the COV434-granulosa-cell-line-model. Before drawing conclusions for any clinical application these results have to be confirmed on primary granulosa-cell-cultures of women with different ovarian reserve.

Wider implications of the findings: Besides suggesting a potential functional link of *FMR1*- and mTOR-AKT-expression in human granulosa-cells, presented data offer novel starting points for further functional assays of human folliculogenesis. They reveal putative novel interferences between follicular maturation and molecular control to maintain the follicular pool after FSH stimulation.

Trial registration number: not applicable.

P-697 Fertility outcomes following single ideal blastocyst transfers in women less than 40 years of age as a function of ovarian reserve

A. Zakhari[1], S. Ates[1], T. Shaulov[1], M.H. Dahan[1]
[1]*McGill University Health Centre, Reproductive Centre, Montreal, QC, Canada*

Study question:
Does ovarian reserve affect outcomes in single ideal blastocyst transfers in women less than 40 years of age?

Summary answer:
Whereas basal follicle stimulating hormone (FSH) levels had no impact, antral follicle count (AFC) and total gonadotropin dose used were correlated with live birth rates.

What is known already:
Several established methods are currently used to quantify ovarian reserve including: basal FSH levels, anti-mullerian hormone (AMH) levels, AFC, and total gonadotropin stimulation dose required. It is heavily debated whether decreased ovarian reserve represents a decrease in quality or quantity of oocytes, with the majority of data suggesting quantity is decreased and not quality. To test this theory, women with ideal quality single blastocyst transfers were evaluated when controlling for confounding effects, to see the role of ovarian reserve on live birth rates.

Study design, size, duration:
This is an ethics approved retrospective cohort study, which included 507 women undergoing their first ideal quality single embryo transfer between August 2010 and March 2014. Subjects were included only once. Analysis was done with logistic regression controlling for female age, duration of infertility, parity, Body Mass Index (BMI), and smoking status. It is the first study to evaluate the effect of ovarian reserve on pregnancy outcomes with ideal grade single blastocyst transfer.

Participants/materials, setting, methods:
The study was performed at a University Health Centre. Exclusion criteria included endocrine disorders, congenital uterine anomalies, endometrial polyps, intrauterine synechiae, adenomyosis, or hydrosalpinx. Subjects were stratified to normal or diminished ovarian reserve (DOR) on the basis of basal FSH levels (DOR ≥ 13 IU/L), basal AFC (DOR ≤ 8), and quartiles of dose of exogenous stimulation (DOR with increasing quartile). Basal analysis was performed between day 2 and day 5 of a spontaneous or induced menstrual cycle.

Main results and the role of chance:
In stratifying the subjects by AFC ≤ 8 ($N = 105$) to 8 ($N = 402$), the pregnancy rate (47% vs. 49%, $p = 0.25$) did not differ in these groups. However the

clinical pregnancy rate (32% vs. 40%, $p = 0.026$) and live birth rate (29% vs. 37%, $p = 0.037$) were superior in the group with a higher AFC. In repeating the analysis using basal serum FSH levels (<13 vs. ≥ 13 IU/L), the pregnancy rate (50% vs. 31%, $p = 0.27$), clinical pregnancy rate (40% vs. 13%, $p = 0.45$) and live birth rate (38% vs. 13%, $p = 0.48$) did not differ in these groups, when controlling for confounding effects. They do differ if confounders are not controlled for. A third analysis was performed using quartiles of FSH stimulation. The dose ranges were 200–1050 ($N = 127$), 1075–1575 ($N = 127$), 1600–2400 ($N = 127$) and 2425–7200 ($N = 126$) Units. The pregnancy rate ($p = 0.13$) did not differ in these groups. However, the clinical pregnancy rate ($p = 0.003$) and live birth rate ($p = 0.005$) were superior in the three groups requiring lower FSH doses combined, than the group which required the highest quartile of FSH to stimulate. The pregnancy rates in each quartile from lowest to highest were 45%, 52%, 54% and 41%. The clinical pregnancy rates were 36%, 43%, 47% and 25%.

Limitations, reasons for caution:
This retrospective study contradicts the assumption that ovarian reserve is solely a measure of quantity, not quality. The issue of quantity was bypassed with the initial selection of a population having produced ideal blastocysts, leaving quality as the remaining variable. Further evidence is needed, including relationship to AMH levels.

Wider implications of the findings:
The findings of this study suggest that ovarian reserve does affect quality of the embryo and outcomes when measured by AFC and exogenous stimulation but not by basal FSH levels. In this case, however, oocyte quality is measured by implantation potential and pregnancy outcome as opposed to embryo grade.

Trial registration number:
None.

P-698 The ultrasonographic "black crown": a new ovarian aspect pathognomonic of altered follicular ovarian status in infertile women

M. Valiere[1], H. Gronier[2], M. Vatel[2], E. Nataf[1], C. Sonigo[2], M. Grynberg[2]
[1]*Centre d'exploration de la fertilité, 75, paris, France*
[2]*Department of Reproductive Medicine and Fertility Preservation, Hopital Jean Verdier –APHP, Bondy, France*

Study question: To investigate whether the presence of an ultrasonographic hypoechogen crown surrounding the ovaries is associated with a specific profile of markers of the follicular ovarian status.

Summary answer: Present finding shows that the ovarian « black crown» is strongly associated with a reduced serum anti-Müllerian hormone (AMH) level and antral follicle count (AFC).

What is known already: Ovarian ageing is a natural phenomenon characterized by a continuous decay in the follicular stockpile and oocyte competence, thereby contributing to a gradual fertility decline. The reduction of the antral follicle cohort is best represented by decreasing levels of AMH. The identification of women who have severely decreased ovarian reserve for their age is clinically relevant, in particular for predicting response to ovarian stimulation in the assisted reproductive technology setting. Ultrasonographic antral follicular counting currently represents a pivotal marker of the follicular status. We recently identified an un-described aspect of the ovaries on ultrasound scan: the "black crown."

Study design, size, duration: Case–control study. From May 2015 to January 2016, 132 infertile normo-ovulatory women, 18 to 43 years of age, underwent transvaginal ultrasound scan and measurement of serum FSH and AMH levels. Ultrasound examination were performed by a two trained operators who were blinded to the results of hormone assays.

Participants/materials, setting, methods: We compared AFC and AMH values in 69 women showing the "black crown" sign and 63 age- and BMI-matched patients devoid of that ultrasonographic aspect.

The ovarian « black crown » was characterized by an hypoechogen, avascular, 1–2 mm thick aspect, completely or partly surrounding both ovariesPatients with a history of unilateral oophorectomy, ovarian surgery, or chemotherapy, as well as those displaying ovarian cysts were excluded of the present investigation.

Main results and the role of chance: As expected, by design, mean ages, duration of infertility and BMI were similar in both groups (35.3 ± 3.7 vs. 34.3 ± 3.9 years, $p = 0.13$), duration of infertility (32 ± 26 vs. 29 ± 29 months, $p = 0.13$), and BMI (22.5 ± 3.7 vs. 22.8 ± 3.8 Kg/m^2, $p = 0.6$). Interestingly, patients of the « black crown » group displayed shorter cycles when compared to controls. In addition, the presence of an ultrasonographic « black crown » was significantly associated with lower AFC (10.4 ± 5.2 vs. 21.3 ± 8.5, $p < 0.0001$) and reduced ovarian surface (3.5 ± 1.4 vs. 4.5 ± 1.9 cm^2, $p = 0.002$). On an hormonal standpoint, lower serum AMH levels were observed in women showing a "black crown" (1.2 ± 0.9 vs. 3.8 ± 3.1, $p < 0.0001$) while FSH values were higher (8.7 ± 4.2 vs. 6.8 ± 2.4, $p = 0.002$).

Limitations, reasons for caution: Our study was performed in a population of infertile normo-ovulatory patient. The sample size remain limited.

Wider implications of the findings:
Present findings shows that the new ultrasonographic sign "black crown" is tightly associated with reduced values of the ovarian reserve tests. Further prospective investigations are needed to determine intra- and inter-operator reliability. And whether the "black crown" is predictive of ovarian response to exogenous FSH and assisted reproductive techniques outcome.

Trial registration number: CEROG 2014-GYN-0302.

P-699 Levothyroxine replacement therapy for infertile patients with Hashimoto's disease may improve serum Anti-Müllerian hormone levels

M. Kuroda[1], K. Kuroda[2], J. Yoshimura Noh[3], H. Osada[1], T. Segawa[1], S. Teramoto[1]
[1]*Shimbashi Yume Clinic, Gynecology, Tokyo, Japan*
[2]*Juntendo University Faculty of Medicine, Obstetrics and Gynecology, Tokyo, Japan*
[3]*Ito hospital, Endocrinology, Tokyo, Japan*

Study question: To investigate whether levothyroxine (LT4) supplementation for infertile patients with subclinical or overt hypothyroidism has an impact on Anti-Müllerian hormone (AMH).

Summary answer: After LT4 replacement, no significant change of serum AMH was recognized, but in the infertile patients with Hashimoto's disease, the AMH level was significantly increased.

What is known already: Thyroid dysfunction and thyroid autoimmunity are related to adverse impact on pregnancy as well as fertility. Subclinical hypothyroidism, aberrant high serum thyroid stimulating hormone (TSH) concentration with a normal free thyroxine level, is also responsible for subfertility. An elevated TSH level is associated with diminished ovarian reserve in women of reproductive age. However, the utility of LT4 replacement for subclinical hypothyroidism in infertile patients is still under discussion and a conclusion has not been reached.

Study design, size, duration: This study was approved by the Local Ethics Committee. Levels of serum thyroid-related hormones and AMH were measured in infertile women from 2014 to 2015 in Shimbashi Yume Clinic. Infertile patients with a high TSH level (>2.5 μIU/mL) were given a detailed thyroid examination in Ito hospital. We evaluated the relationship between AMH and TSH levels and the alteration of AMH levels in 1 and 3 months of LT4 supplementation during assisted reproductive technology treatment.

Participants/materials, setting, methods: Out of 1431 infertile patients, subclinical or overt hypothyroidism was found in 311 patients (21.7%). We excluded the patients with adverse factors on thyroid hormone and AMH, including polycystic ovary syndrome, premature ovarian dysfunction, treated thyroid dysfunction, ovarian tumor, post-ovarian surgery and smoking. Hashimoto's disease was detected in 37 patients out of the patients with elevated TSH level.

Main results and the role of chance: Serum AMH level correlated inversely with TSH concentration among all infertile patients. After LT4 supplementation, no significant change in AMH levels was detected in the patients with high TSH. The serum AMH level in the 37 patients with Hashimoto's disease (anti-thyroid peroxidase and/or thyroglobulin antibody-positive) was, however, significantly increased after treatment (1 month: 1.27 fold, $p < 0.001$ and 3 months: 1.20 fold, $p = 0.001$). Clinical pregnancy and miscarriage rates in infertile women with Hashimoto's disease were 65.2% (30/46 embryo transfer) and 20.0% (6/30 pregnancies).

Limitations, reasons for caution: The limitation of this study is that it is a retrospective study. Also, although we retrieved oocytes with spontaneous or minimum ovarian stimulation, infertility treatment may have an effect on AMH levels.

Wider implications of the findings: In basic research, thyroid hormone plays a significant role in folliculogenesis. Also, TSH and auto-immune thyroid antibodies have an adverse effect on follicle recruitment, leading to decreasing AMH. In the patients with Hashimoto's disease, LT4 treatment may support follicular development and relieve these adverse effects.
Trial registration number: None.

P-700 AMH levels variations during treatment with GnRh agonist: A prospective observational study

R. Mocciaro[1], R. Venturella[1], D. Lico[1], M. Rocca[1], A. Sacchinelli[1], M. Morelli[1], F. Zullo[1]
[1]*University Magna Graecia, Chair of Obstetrics and Gynecology, Catanzaro, Italy*

Study question: Is Anti-Mullerian Hormone (AMH) a stable and reliable marker of ovarian reserve in women undergoing treatment with GnRH-agonist (GnRH-a)?
Summary answer: Dynamic changes in AMH levels occur up to 6 months after GnRH-a administration, suggesting that AMH is not a reliable marker in this population.
What is known already: AMH is a glycoprotein produced by granulosa cells of antral and preantral ovarian follicles. The AMH levels provide an indication of the size of the growing follicles pool and are commonly used as a surrogate biomarker of ovarian reserve. In young cancer patients, GnRH-a is administered during chemotherapy to preserve fertility, given that studies showed that it reduces the risk of ovarian failure by 57%. AMH levels are relatively stable along the menstrual cycle and during administration of the contraceptive pill, but conflicting data exist about its reliability in women undergoing GnRH-a treatment.
Study design, size, duration: From March 2013 to April 2015 women were enrolled in this observational study. According to a sample size calculation, based on previous studies on AMH levels in premenopausal women undergoing GnRH-a, with 65 participants, yet considering a standard dropout rate of 20%, a 95% study power with an alpha-error of 0.05 would have been achieved. Follow-up evaluation was concluded on November 2015.
Participants/materials, setting, methods: Sixty-nine patients waiting for surgery for uterine myoma, fibromatous uterus and endometriosis received 11.25 mg of GnRH-a. It was administered at 21th day of the menstrual cycle and repeated 3 months later at the University "Magna Graecia`-Catanzaro. At study entry and 1, 3 and 6 months after the administration of the first GnRH-a, serum levels of AMH, FSH, E2 and Antral Follicle Count were measured between first and fourth days of the menstrual cycle.
Main results and the role of chance: The mean (SD) age of participants was 31.9 (5.6) years. Mean body mass index (BMI) was 22.3 (3.5) kg/m^2. None had infertility. Average cycle length was 28 (2) days. At baseline the FSH and E2 mean levels were coherent with the women age. At the basal time the AMH mean (SD) level was 2.3 (0.6) ng/ml; one month later AMH level increased by 39% with a mean level of 3.8 (2.5) ng/ml ($P < 0.01$). At 3 months a significant decline of AMH levels [2 (0.8) ng/ml ($P < 0.01$)] was detected and this reduction became greater at 6 months [1.3 (0.7) ng/ml ($P < 0.01$)]. No significant differences in AFC were demonstrated 1 and 3 months after pituitary downregulation. Only at 6 months a significant AFC reduction was detected ($P < 0.01$). AMH showed a significant positive correlation ($P < 0.01$) with AFC at basal time, 1, 3 and 6 months after treatment. However, considering the significant increase of AMH and the stable number of antral follicles 1 month after pituitary downregulation, the ratio between AMH and AFC (evaluated at basal 1, 3, 6 month) was higher at 1 month after treatment than at the others evaluations. The suppression of FSH and E2 was maintained during the treatment period.
Limitations, reasons for caution: This study provides evidence that dynamic changes in AMH levels occur up to 6 months after GnRH-a administration, suggesting a partial AMH gonadotropin dependence. However, to understand the mechanism by which the GnRh-a acts on AMH clinical trials with longer follow-up and *in vitro* studies are needed.
Wider implications of the findings: In the context of cancer treatment, GnRH-a is often coadministered with chemotherapy with the aim of preserving fertility. To define the interference of GnRH-a on AMH levels is important for allowing the correct counselling in oncologic patients with reproductive desire.
Trial registration number: N/A.

P-701 No evidence for lower serum AMH levels in female BRCA1/2 mutation carriers

A. Bos[1], I. Derks-Smeets[2], T. van Tilborg[1], J. Oosterwijk[3], R. van Golde[4], C. de Die-Smulders[2], L. van der Kolk[5], W. van Zelst-Stams[6], M. Velthuizen[7], A. Hoek[8], M. Eijkemans[9], J. Laven[10], M. Ausems[7], F. Broekmans[1]

Study question: Do *BRCA1/2* mutation carriers have a compromised ovarian reserve compared to proven non-carriers, based on serum anti-Müllerian hormone (AMH) levels?
Summary answer: *BRCA1/2* mutation carriers do not show a lower serum AMH level in comparison to proven non-carriers, after adjustment for potential confounders.
What is known already: It has been suggested that the *BRCA* genes are not only of importance in the prevention of cancer but also play a role in the process of ovarian reserve depletion. Previous studies have shown inconsistent results regarding the association between serum AMH levels and *BRCA* mutation status. Hence, it is yet unclear whether *BRCA1/2* mutation carriers may indeed be at risk of a reduced reproductive lifespan.
Study design, size, and duration: A multi-center, cross-sectional study was performed between January 2012 and February 2015 in 255 women. We needed to include 120 *BRCA1/2* mutation carriers and 120 proven non-carriers to demonstrate a difference in AMH levels of 0.40 μg/L (SD ± 0.12 μg/L, two-sided alpha-error 0.05, power 80%).
Participants/materials, setting, methods: Healthy women aged 18–45 years who were referred to the Clinical Genetics department and applied for predictive *BRCA1/2* testing because of a familial *BRCA1/2* mutation were asked to participate. A cross-sectional assessment was performed by measuring serum AMH levels and filling out a questionnaire. Multivariate linear regression analyses adjusted for age, current smoking, and current hormonal contraceptive use were performed on log-transformed serum AMH levels.
Main results and the role of chance: Out of 823 potentially eligible women, 421 (51.2%) were willing to participate, and of those, 166 (39%) did not meet our inclusion criteria. Two hundred fifty-five women were available for analyses; 124 *BRCA1/2* mutation carriers and 131 proven non-carriers. Carriers were significantly younger at study inclusion compared to non-carriers (median age: 29 [range 20–45] vs. 31 [range 18–44] years, respectively; $P = 0.02$). The median AMH level in carriers was 1.90 μg/L [range 0.11–19.00] compared to 1.80 μg/L [range 0.11–10.00] in non-carriers ($P = 0.34$). Adjusted linear regression analysis revealed no reduction in AMH level in the carriers (relative change = 0.98 (95% CI, 0.77–1.22); $P = 0.76$).
Limitations, reasons for caution: Participants were relatively young and power was insufficient to analyze *BRCA1* and *BRCA2* mutation carriers separately. AMH levels may have been influenced by the use of hormonal contraceptives, though similar proportions of carriers and non-carriers were current users and adjustments were made to correct for potential confounding in our analysis.
Wider implications of the findings: Currently, there seems to be no need to counsel healthy *BRCA1/2* mutation carriers on a jeopardized ovarian reserve condition. Larger, prospective follow-up studies with recurrent AMH measurements may be needed to really unravel a potential association between ovarian reserve and *BRCA* function.
Trial registration number: NTR no. 4324.

P-702 Neurokinin B receptor antagonism suppresses ovarian follicle growth and delays ovulation in healthy women

K. Skorupskaite[1], J.T. George[1], J.D. Veldhuis[2], R.A. Anderson[1]
[1]*The University of Edinburgh, MRC Centre for Reproductive Health, Edinburgh, UK*
[2]*Mayo Clinic, Endocrine Research Unit, Rochester, NY, USA*

Study question: Does pharmacological blockade of hypothalamic neurokinin B (NKB) signalling decrease gonadotropin (LH and FSH) secretion and suppress ovarian function in healthy women?
Summary answer: NKB blockade suppressed follicle growth and estradiol secretion, and delayed ovulation in women. NKB regulates female reproduction likely *via* the modulation of GnRH/LH pulse frequency.
What is known already: Normal follicle development and ovulation requires coordinated interaction between GnRH-driven gonadotropin stimulus to the ovary, and hormonal feedback. Neurokinin B (NKB) is a key modulator of GnRH secretion, as loss-of-function mutations result in hypogonadotropic hypogonadism. When administered throughout the menstrual cycle in women, a neurokinin B receptor antagonist delayed positive estrogen feedback and the LH surge, although no changes in basal LH secretion were seen. We have previously shown that NK3Ra decreased LH pulse frequency in normal women in a model of the mid-cycle LH surge.
Study design, size, and duration: We investigated the role of NKB in the control of follicle development in normal women using pharmacological blockade of NK3R. Six women were administered the NK3Ra, AZD4901, 40 mg orally twice a day for 7 days from cycle day 5–6. All women also had a no treatment control cycle, the order of cycles being randomised.
Participants/materials, setting, methods: Women were healthy with regular menstrual cycles. Serum hormones, leading follicle diameter and endometrial thickness were assessed through the follicular phase of treatment and control cycles until ovulation was confirmed by transvaginal ultrasonography. Urine was collected daily until next menses. Data were compared by ANOVA with Bonferroni multiple comparison post hoc analysis. Ethical approvals and informed consent were obtained.
Main results and the role of chance: Normal follicle development did not occur during NK3Ra treatment, the diameter of the leading follicle being significantly smaller than in controls at the end of treatment, i.e., on cycle day 12–13 (8.9 ± 0.8 vs. 14.5 ± 1.4 mm, $p < 0.02$). Serum estradiol was also lower (122 ± 57 vs. 406 ± 151 pmol/l, $p = 0.05$) and the endometrium was thinner (5.3 ± 0.4 vs. 7.6 ± 0.6 mm, $p < 0.04$) than in control cycles, although no clear differences in serum LH and FSH were observed. After treatment normal follicle development resumed (16.6 ± 1.4 vs. 16.9 ± 1.3 mm on day of LH surge, ns) and estradiol secretion increased (540 ± 105 vs. 608 ± 121 pmol/l, ns) with an LH surge on day 23 ± 2 vs. 15 ± 1 ($p < 0.02$). The delayed ovulation was confirmed by a similarly delayed day of peak urinary progesterone (cycle day 32 ± 2 vs. 22 ± 1, $p < 0.02$) and prolonged cycle length (37 ± 2 vs. 30 ± 2 days, $p < 0.04$); luteal function was unaffected by the NK3Ra (urinary progesterone 80 ± 17 vs. 61 ± 14, pmol/mol creatinine on surge day + 7, ns). To investigate further the mechanistic action of NK3Ra, a second group of women are currently undergoing frequent blood sampling analysis to investigate the effect of NK3Ra on LH pulsatility in the follicular phase.
Limitations, reasons for caution: Subtle changes in gonadotropin secretion were possibly not detected as intensive high-frequency sampling was not carried out. Such analysis is required to elucidate the hypothalamic action of NKB more precisely. One woman appeared to be a non-responder, and only one dose was investigated.
Wider implications of the findings: These findings demonstrate the involvement of NKB signalling in women in the physiological regulation of normal follicle development. Inhibition of NKB signalling has potential translational application in regulating GnRH/LH secretion in a wide range of applications, such as endometriosis, Polycystic Ovary Syndrome and in non-steroidal contraception.
Trial registration number: N/A.

P-703 Do not dismiss the long downregulation protocol for women at risk of ovarian hyperstimulation syndrome (OHSS)

A. Papathanasiou[1], G. Verwoerd[2], P. Snell[2], T. Mathews[2]
[1]*Bourn Hall Clinic, Norwich Clinic, Norwich, UK*
[2]*Bourn Hall Clinic, Cambridge Clinic, Bourn, UK*

Study question: How effective and safe is the long downregulation protocol combined with low-dose gonadotrophin stimulation for women with above-average ovarian reserve?
Summary answer: In women with above-average ovarian reserve, the long downregulation protocol combined with low-dose gonadotrophin stimulation, results in satisfactory live birth and low OHSS rates.
What is known already: For expected "high responders," the use of a long downregulation protocol has been associated with similar live birth rates but higher incidence of OHSS compared to the antagonist protocol (Al-Inany et al., Cochrane Database Syst Rev 2011). As a consequence, current practice is moving away from prescribing the long downregulation protocol for these women.

However, the available randomized trials that compare the two protocols have utilised conventional stimulation doses (≥150 IU FSH daily). We hypothesized that using the long protocol with low starting gonadotrophin doses may constitute a safer but still effective stimulation regime for women at risk.
Study design, size, duration: This is a cohort study based on prospectively collected data from 473 consecutive women with above-average ovarian reserve (AMH ≥ 15 pmol/L), who were treated in a tertiary assisted conception unit from July 2013 to December 2014. During this period, we have been using an AMH-based algorithm for deciding the starting gonadotrophin dose. Women with above-average AMH levels were routinely prescribed the long downregulation protocol with a low starting gonadotrophin dose for their first IVF cycle.
Participants/materials, setting, methods: Women with normal-high (AMH 15–24 pmol/L) and high (AMH ≥25 pmol/L) ovarian reserve undergoing their first IVF/ICSI cycle, were prescribed the long downregulation protocol (from Day 21 of cycle) followed by a starting dose 100 IU–112.5 IU rFSH daily. A "freeze-all embryo" approach was recommended on the day of oocyte collection in the presence of 2 out of 3 risk factors (≥25 oocytes, ≥30 aspirated follicles, oestradiol ≥15,000 pmol/L on day of HCG).
Main results and the role of chance: The average age of women was 31 years old. In the group with normal-high AMH (144 women) a mean of 10 oocytes were retrieved, while in the high AMH group (329 women), a mean of 14 oocytes were retrieved. Suboptimal stimulation (≤3 oocytes) was experienced in only 4% of cases within each group.

The great majority of women (92%) had a single embryo (mainly blastocyst) transfer. The live birth rate was 47.2% (95% CI 38.7%–55.7%) per cycle and 50% (95% CI 41.2%–58.7%) per ET in the normal-high AMH group. In the high AMH group, the live birth rate was 38% (95% CI 32.6%–43.4%) per cycle and 43% (95% CI 37.1%–48.8%) per ET.

One case of severe late-onset OHSS and 3 cases of moderate late-onset OHSS occurred in the high AMH group (1.2% of cases), all eventually resolving and leading to live birth. In 7.9% of cases in the high AMH group, a "freeze-all embryo" approach was implemented. Of these, subsequent frozen embryo replacement achieved a 52% live birth rate.
Limitations, reasons for caution: As this is an observational uncontrolled study, it cannot provide insight to the comparative efficacy and safety of this modified regime against popular protocols for high responders, such as the antagonist protocol.
Wider implications of the findings: Previous research has associated the downregulation protocol with elevated OHSS risk in the context of conventional stimulation. This may not be the case if low gonadotrophin doses are utilised, as evidenced by the absence of significant early-onset OHSS and the infrequent cases of significant late-onset OHSS within our population.
Trial registration number: N/A.

P-704 The mechanism research on hyperhomocysteinemia-associated insulin resistance in polycystic ovary syndrome patients

B. Zhang[1], Y. Pang[1]
[1]*Peking University Third Hospital, Center of Reproductive Medicine, Beijing, China*

Study question: This study is to determine whether the level of homocysteine is associated with monocyte subtype related insulin resistance in women with polycystic ovary syndrome (PCOS).
Summary answer: Our results reveal that there is a positive relationship between homocysteine level and $CD14^{++}CD16^{-}$ inflammatory monocytes or insulin resistance in women with PCOS.
What is known already: The level of homocysteine is significantly higher in Chinese people than European or American people. Hyperhomocysteinemia

(HHcy) induced immune inflammation plays an important role in the pathogenesis of insulin resistance. Moreover, PCOS patients are often accompanied by HHcy, chronic low-grade inflammation and insulin resistance. Monocytes are important inflammatory cell subtype involved in insulin resistance.
Study design, size, duration: A cross-sectional study was carried out from December 2014 to June 2015 in Peking University Third Hospital, enrolling 108 PCOS-diagnosed Chinese women aged 21–35, among whom, 15 HHcy PCOS patients with homocysteine level exceeding 15 mmol/L, 93 PCOS patients with normal homocysteine level. We detected surface markers and related cytokines on the monocytes in peripheral blood samples, collected data of insulin resistance and levels of homocysteine.
Participants/materials, setting, and methods: Based on the Rotterdam PCOS criteria, 108 PCOS-diagnosed Chinese women aged 21–35 have been involved. We detected the monocyte surface markers and related cytokines in the peripheral blood samples by flow cytometry, collected data of insulin resistance and the levels of homocysteine. Confounding factors, including body mass index, blood lipid, and hormone were excluded from the analysis.
Main results and the role of chance: Compared with normal homocysteine group, HHcy patients have more $CD14^{++}CD16^{-}$ inflammatory monocytes and higher levels of IL-1β, IL-6, IL-12p70, and TNFα ($P < 0.05$) in the peripheral blood. Fast insulin and HOMA index, which are major factors reflecting insulin resistance degree, were increased in HHcy PCOS group. The results indicate that homocysteine level has a strong relationship with inflammatory monocytes, inflammatory cytokines, and insulin resistance.
Limitations, reasons for caution: Patient number in HHcy group was small, and sample size would be enlarged in the future study to confirm the conclusion.
Wider implications of the findings: Reducing the level of homocysteine could be one of the possible strategies in treating immune inflammation diseases associated insulin resistance commonly seen in PCOS patients, in order to improve the treating progress and prognosis of PCOS-accompanied insulin resistance.
Trial registration number: Not a clinical trial.

P-705 Low dose human chorionic gonadotropin as an adjuvant to GnRHa for final oocyte maturation rescues the poor outcome of suboptimal responders to GnRHa

Y. Kuang[1], Q. Hong[1], L. Sun[1], Y. Fu[1], A. Ai[1], Q. Lv[1], X. Lu[1]
[1]Shanghai Ninth People's Hospital, Shanghai Jiao Tong University School of Medicine, Department of Assisted Reproduction, Shanghai, China

Study question: How about the pituitary responses to gonadotropin-releasing hormone agonist (GnRHa) trigger in gonadotropin and MPA (Medroxyprogesterone acetate)/progesterone (hMG + MPA/progesterone) treatment IVF/ICSI cycles, and can low dose of human chorionic gonadotropin (hCG) improve the outcome of patients with low pituitary response to GnRHa.
Summary answer: Lower basal LH is a risk factor for suboptimal response to GnRHa trigger. Low dose of hCG could rescue the poor outcome of suboptimal responder.
What is known already: Recently, we found that MPA was an effective oral alternative for the prevention of premature LH surges in woman undergoing controlled ovarian hyperstimulation (COH) for IVF. However, what is the optimal trigger strategy for the hMG+ MPA/progesterone treatment protocols still unknown.
Study design, size, duration: This is a retrospective analysis of a cohort of IVF/ICSI cycles ($n = 8970$) performed in university IVF center during the period from November, 2013 to December, 2015.
Participants/materials, setting, and methods: Eight thousand and ninety two women undergoing 8970 hMG + MPA/progesterone treatment protocol during IVF/ICSI cycles, and triggered with GnRH agonist alone or in combination with hCG (1000 IU, 2000 IU, or 5000 IU).
Main results and the role of chance: In total, 5.17% (464/8970) of patients exhibited a suboptimal response to GnRHa. The suboptimal responders had a significantly lower oocyte retrieval rate (55.83 ± 11.33% vs. 67.97 ± 23.66%, $P = 0.000$) compared with the appropriate responders. Suboptimal responders had significantly lower levels of basal FSH and LH, and FSH and LH levels on the day of trigger. Moreover, basal LH levels served as the single most valuable marker for differentiating the suboptimal responders with an AUC (the areas under the ROC curve) of 0.814. The dual trigger (GnRHa and hCG 1,000 IU), 34–36 h prior to oocyte retrieval, significantly increased oocyte retrieval rates (63.27 ± 24.45 vs. 56.42 ± 25.52, $P = 0.038 < 0.05$), mature oocytes rate (91.29 ± 15.92 vs. 85.09 ± 23.50, $P = 0.015 < 0.05$, and No. of embryos frozen (3.48 ± 2.70 vs.2.72 ± 2.13, $P = 0.039 < 0.05$) in patients with a suboptimal response. No case of OHSS occurred in the dual-trigger (GnRHa + hCG 1,000) group.
Limitations, reasons for caution: This is a retrospective study with its inherent limitations and bias. More sample size with balance in four suboptimal responder groups triggered with GnRH agonist alone or in combination with hCG (1000 IU, 2000 IU, or 5000 IU) is more valuable for analyzing.
Wider implications of the findings: The basal serum LH levels might also be useful predictor of the suboptimal response to the GnRHa trigger. Dual trigger using a low dose of hCG (1,000 IU) as an adjuvant to GnRHa for final oocyte maturation could improve the outcome of suboptimal responder.
Trial registration number: NA.

P-706 Intramuscular versus vaginal progesterone administration in medicated IVF frozen embryo transfer (FET) cycles: a randomised clinical trial

A. Hershko Klement[1], N. Samara[1], A. Weintraub[1], F. Mitri[1], Y. Bentov[1], P. Chang[1], D. Nayot[1], R.F. Casper[1]
[1]TRIO Fertility, Division of Reproductive Sciences, Department of Obstetrics and Gynecology, University of Toronto, Toronto, ON, Canada

Study question: To assess the effect of endometrial preparation with intramuscular progesterone compared to vaginal progesterone on subendometrial contractility in medicated FET cycles.
Summary answer: No difference was observed in subendometrial wave activity between intramuscular progesterone and vaginal progesterone in medicated FET cycles, despite a difference in serum progesterone concentrations.
What is known already: Intramuscular progesterone for luteal support has been popular in the United States, while in Canada and Europe vaginal progesterone is routinely used. Increased frequency of subendometrial contractions in fresh IVF cycles has been associated with lower pregnancy rates and exposure to exogenous progesterone may reduce the frequency of subendometrial contractions. Meta-analyses showed that pregnancy outcomes were similar between intramuscular and vaginal progesterone luteal support in fresh IVF cycles. Less data exists about intramuscular and vaginal progesterone effects on subendometrial contractions and pregnancy rates in frozen embryo transfer cycles. Subendometrial contraction frequency was the primary outcome measure of the present study.
Study design, size, and duration: This was a randomised clinical trial including 34 patients undergoing thawed embryo transfer at the blastocyst stage. Patient allocation to vaginal or intramuscular progesterone was performed by a third party using a computerized randomization table. Sample size calculation based on a difference of 1.8 endometrial waves per minute (variance in Fanchin's original study), assessed by transvaginal ultrasound on the day before the embryo transfer, determined 15 subjects in each arm was required for $P < 0.05$.
Participants/materials, setting, and methods: Patients were treated by the standard medicated FET protocol in our centre, which included oral micronized 17b-estradiol starting on day 3 of the cycle. Once sufficient endometrial proliferation (>7 mm with a triple-line pattern) was achieved, the patient started progesterone. Patients in the vaginal progesterone arm were treated with 200 mg vaginal suppositories 3 times daily. Patients randomized into the intramuscular (IM) progesterone arm were treated with once daily injections of 50 mg progesterone in oil.
Main results and the role of chance: The 17 patients in each study arm were similar in age (35.6 ± 3.7 years in the IM group, 37.1 ± 7.1 years in the vaginal group) and in Day 3 serum estradiol levels (149.1 ± 86.1 pmol/L and 137.0 ± 142.1 pmol/L, respectively, $P = 0.8$). The IM progesterone group had lower day 3 FSH (5.2 IU/l ± 1.5 IU/L) compared to the vaginal group (9.6 IU/l ± 12.1 IU/L, $P < 0.05$). As expected, serum progesterone levels were higher in the IM group compared to the vaginal group on the day of the wave study (85.2 ± 50.1 nmol/L vs. 30.3 ± 11.2 nmol/L, respectively, $P = 0.005$). The number of subendometrial waves counted by ultrasound (blinded examiner) in the IM progesterone group (2.4 ± 4.8 waves/min) was not significantly different from the vaginal progesterone group (1.4 ± 1.1 waves/min; $P = 0.4$). The pregnancy rate was 53% for both groups. In a logistic regression model, both higher FSH levels and higher wave frequency (combining both treatment groups) were significantly correlated with a compromised outcome.

Limitations, reasons for caution: Although this study was adequately powered to test the differences in subendometrial contractility frequency, according to wave frequency parameters related to pregnancy rates chosen from previous work, the number of subjects was still small. A larger study may have shown a difference in contraction frequency between IM and vaginal progesterone.
Wider implications of the findings: The study group consisted of relatively older patients going through a blastocyst transfer and therefore the results should be generalized with caution to cellular stage transfers and younger patients. Higher subendometrial wave frequency appears to be associated with poorer clinical pregnancy outcome as previously shown by other studies.
Trial registration number: ClinicalTrials.gov NCT02078869

P-707 Assessment of endometrial thickness in women with luteinizing hormone deficiency undergoing ovulation induction

E. Burt[1], O. Okewale[1], D. Mavrelos[1], E. Yasmin[1], M. Davies[1], G. Conway[1]
[1]*University College London Hospital, Reproductive Medicine Unit, London, UK*

Study question: Does peak endometrial thickness (ET) impact on pregnancy rates in women with WHO type 1 anovulation undergoing ovulation induction (OI)?
Summary answer: Pregnancy rates are significantly higher in those women with a peak ET greater than 6 mm.
What is known already: Optimal endometrial development is essential for embryo implantation. Folliculogenesis with adequate oestradiol biosynthesis drives endometrial proliferation. It has been widely demonstrated that in women undergoing IVF treatment, ET at the time of embryo transfer can affect clinical pregnancy rates. Less attention has focused on women diagnosed with type 1 anovulation with gonadotrophin deficiency. A challenge in this population, undergoing ovulation induction with exogenous gonadotrophins, is suboptimal endometrial development despite clinical folliculogenesis. This scenario is a feature of inadequate stimulation by Luteinizing Hormone (LH).
Study design, size, duration: This is a single centre retrospective cohort study. Women with a diagnosis of WHO type 1 anovulation attending the Reproductive Medicine Unit at the University College London Hospital between 2006 and 2015 and embarking on OI with human menopausal gonadotrophins (hMG) were included in the study.
Participants/materials, setting, methods: 87 women were included in the study. Demographic, clinical and ultrasonic data at baseline and during OI were obtained by reviewing medical records. A total of 261 treatment cycles were identified of which peak ET was recorded in 225.
Main results and the role of chance: 87 women with type 1 anovulation underwent ovulation induction with hMG. 37 women were diagnosed with Hypothalamic Amenorrhoea (HA), 35 Hypogonadotrophic Hypogonadism (HH) and 15 with Hypopituitarism (HP). There was no difference in baseline characteristic with reference to age ($P = 0.94$) or baseline ET ($P = 0.23$). Women diagnosed with HA had a significantly lower BMI compared with the other diagnostic groups ($P = <0.01$).

Of the 225 cycles, 78 were completed for women with a diagnosis of HA (34.7%), 95 HH (42.2%) and 52 HP (23.1%).

An ET ≥ 6 mm was achieved in 194 cycles (86.2%), whilst an ET <6 mm was demonstrated in 31 cycles (13.8%) and this was equally distributed across diagnostic subgroups. Peak ET was not affected by baseline characteristics.

58/225 (25.8%) cycles resulted in clinical pregnancies, 21/58 (36.2%) were women with a diagnosis of HA, 23/58 (39.7%) HH and 14/58 (24.1%) HP.

56/194 (28.9%) of women who demonstrated a peak ET ≥6 mm achieved clinical pregnancy, compared to 2/31 (6.5%) where the ET was <6 mm ($P = 0.004$). Baseline variables or cycle number did not affect the outcome.
Limitations, reasons for caution: This is a retrospective cohort study and is reliant on the quality and quantity of the data entry at the time of clinical treatment. Furthermore, inter-observer bias needs to be considered, as a single observer did not conduct all the ultrasound examinations.
Wider implications of the findings: Research to date has focused mainly on IVF populations who exhibit supraphysiological oestradiol concentrations during stimulation. In contrast, different mechanisms underpin thin endometrium in women with type 1 anovulation and these women may be at particular risk of thin endometrium depending on the LH content of gonadotrophins used for stimulation.
Trial registration number: The Institutional Review Board of the UCLH was contacted to obtain approval for this study and formal ethics approval was not required.

P-708 Identification of altered microRNAs and mRNAs in cumulus cells of PCOS patients: miRNA-509-3p promote estradiol secretion by targeting MAP3K8

X. Huang[1], H. Cuifang[1], T. Qianqing[1], L. Riming[1], L. Shaoxia[1], Z. Luping[1], Y. Wei[1]
[1]*Yantai Yu Huang Ding Hospital, Reproductive Medicine Centre, Yantai Shandong, China*

Study question: Our aim was to identify the altered miRNA and mRNA expression profiles in cumulus cells of PCOS patients to research their molecular function in the abnormal folliculogenesis of PCOS.
Summary answer: miR-509-3p was up-regulated and MAP3K8 was down-regulated expressed in PCOS cumulus cells. miR-509-3p could improve E_2 secretion by inhibiting the MAP3K8 expression directly.
What is known already: Although the clinical and biochemical signs of PCOS are typically heterogeneous, anovulation which often induced by abnormal folliculogenesis is considered to be a common characteristic of PCOS. The possible mechanisms of anovulation in PCOS have been proposed as follow: high levels of estradiol in PCOS patients could prevent an increase in follicle-stimulating hormone (FSH), which is an essential factor for follicular growth and ovulation induction. The low level of FSH will consequently lead to anovulation. Until now, many genes were identified to elucidate the pathophysiology of abnormal folliculogenesis in PCOS, but how these genes are post-transcriptionally regulated is poorly understood.
Study design, size, duration: miRNA and mRNA expression profiles of the cumulus cells isolated from PCOS and control patients were determined by miRNA and mRNA microarrays. The microarray data were validated by qRT-PCR. The potential target genes of altered miRNAs were predicated by miRWalk 2.0. By compared the list of potential target genes to the list of DEGs in our mRNA microarray, the candidate miRNA and its target genes were chosen for further research in KGN cells.
Participants/materials, setting, methods: A total of 36 participants (18 PCOS and 18 controls) were included in this study. miRNA and mRNA expression profiles of the cumulus cells isolated from 5 PCOS and 5 control patients were determined by miRNA and mRNA microarrays. The cumulus cells isolated from others patients were used in qRT-PCR and western blot analysis. The regulation of candidate miRNA on target genes was studied by luciferase activity assay and transfection tests.
Main results and the role of chance: From the microarrays data, 17 miRNAs and 1263 mRNAs showed significantly different expression in PCOS cumulus cells. The microarrays data were confirmed by qRT-PCR. Compared the list of DEGs isolated from cDNA microarray and the list of predicted miRNA targeted genes, we found that several miRNA targeted genes (i.e., MAP3K8, miR-509-3p target gene; RND3, miR-200b-3p target gene) were also identified by the mRNA microarray. Specially, miR-509-3p was also identified by recently published reports of altered miRNAs in PCOS cumulus cells, with almost the same fold changes as our results. So, miRNA-509-3p and its potential target gene (MAP3K8) were selected for further researched. It showed that miR-509-3p was up-regulated and MAP3K8 was down-regulated expressed in PCOS cumulus cells. The directly interaction between miR-509-3p and MAP3K8 was confirmed by luciferase activity assay in KGN cells. In addition, the miR-509-3p mimics or inhibitor transfection tests in KGN cells further confirmed that miR-509-3p could improve E_2 secretion by inhibiting the MAP3K8 expression. These results will offer new insight into the pathogenesis of anovulation in PCOS, especially the regulation of estradiol production.
Limitations, reasons for caution: We used microarray to identify the altered miRNA in the present study. By using this kind of method, only the miRNAs with its response to probes which included in the microarray could be detected and novel miRNAs could not be found.
Wider implications of the findings: We found that miR-509-3p and its target gene (MAP3K8) showed differentially expressed in PCOS cumulus cells. Further researches in KGN cells confirmed that miR-509-3p could improve E_2 secretion by inhibiting the MAP3K8 expression. These results will offer new insight into the anovulation in PCOS, especially the regulation of estradiol secretion.

Trial registration number: The study belongs to basic research and has no registration number.

P-709 Mechanism of androgen excess inducing neuroendocrine disorders in female rats and dysfunction of GnRH secretion in GT 1-7 cell

C. Yuan[1], G. Jinghui[2], C. Hsiaochang[2], C. Yugui[1], L. Jiayin[1]
[1]*Nanjing Medical University, Center of Clinical Reproductive Medicine, Nanjing City, Jiangsu Province, China*
[2]*Chinese University of Hong Kong, Biomedical Science, Hong Kong, China*

Study question: Neuroendocrine Disorders of Rats with Ovulation dysfunction Induced by Androgen Excess.
Summary answer: Our study has showed that there are neuroendocrine disorders in PCOS models and hyperandrogenism could inhibit the neuropeptide secretion of neuron cell line.
What is known already: Polycystic ovary syndrome (PCOS), which is characterized by ovulatory dysfunction, hyperandrogenism, insulin resistance and neuroendocrine dysfunction, is the most common reproductive endocrine disorder in young women. Although the pathogenesis of neuroendocrine disorder in PCOS is still complex and controversial, a number of relevant studies have emerged to clarify the possible causes. The clinical studies have estimated that inappropriate GnRH secretion with accelerated LH and low FSH level is the typical symptom in PCOS development.
Study design, size, duration: The female rats of 3 weeks aged were used in this study as PCOS animal model. We observed the model from 3 weeks age to 12–15 weeks age and the neuron cell line-GT1-7 cell was including in this study as cell model. Western blot, quantitative PCR, fluorescence staining and Elisa were used.
Participants/materials, setting, methods: The female rats of 3 weeks aged were implanted subcutaneously the silicone tube containing 7.5 mg DHT or nothing as control. Then the serum steroid hormones and estrus cycle were observed pubescent aged and adult aged female rats, and the expression level of endocrine factors in hypothalamus were tested in both groups. Moreover, we observed the effect of DHT and Endoplasmic reticulum stress inducer-TG on GnRH secretion in mice hypothalamus neuroma cell line-GT1-7 cell.
Main results and the role of chance: Comparing to controls, the body weight of DHT rats was significantly higher ($p < 0.01$); and the number of cystic and atretic follicles in DHT rats' ovaries was markedly more than that of controls. Moreover, there was no regular estrus cycle and LH frequency observed in DHT rats that were 8-week-old. Our data showed that the DHT rats of 4–8 weeks of age presented the significant higher expression level of ER stress markers and lower expression level of Kisspeptin in hypothalamus than that of controls ($p < 0.05$), which mean that DHT up-regulated the expression of ER stress signal, and inhibited the Kisspeptin expression. Moreover, in GT1-7 cell line, both of DHT and TG could significantly block the GnRH secretion, which Kisspeptin could up-regulate ($p < 0.05$). All the results suggested that the secretion of GnRH in neuron cell could be inhibited by DHT and ER stress, meanwhile, Kisspeptin could block the effect of DHT and TG.
Limitations, reasons for caution: Only one kind of animal and cell model was used, and the simple of PCOS patients were not including in this study.
Wider implications of the findings: Our data showed that the androgen excess can induce dysfunction in rat models, decrease of Kisspeptin secretion in cell line.
Trial registration number: 2012-SR-048

P-710 The effect of elevated late follicular phase serum progesterone on IVF outcome in good prognosis patients

A. Osman[1,2], S. Pyrianka[1], T. El-Toukhy[1], Y. Khalaf[1]
[1]*Guys and St Thomas NHS Foundation Trust, Assisted Conception Unit, London, UK*
[2]*Cairo University Hospital, Gynecology Department, Cairo, Egypt*

Study question: Does elevated progesterone on the day of HCG affect IVF outcome after accounting for important confounding variables in women with expected good ovarian response?
Summary answer: Elevated serum progesterone level is associated with lower clinical pregnancy rate. However, this result was not reproduced when top quality blastocyst was transferred.
What is known already: Previous studies have reported conflicting results with regard to the effect of high progesterone level in the late follicular phase on IVF outcome. However, there is a wide variation in the population studied, with little evidence available to confirm a detrimental effect of elevated serum progesterone level in the late follicular phase on the clinical pregnancy rate in cycles where a normal or high ovarian response is expected, and particularly after the transfer of high quality blastocysts.
Study design, size, duration: This is a prospective cohort study carried out between May 2014 and December 2015 at a tertiary Assisted Conception Unit in a teaching Hospital. A total of 615 fresh IVF/ICSI cycles were included in the study.
Participants/materials, setting, methods: Women with predicted normal and high ovarian response based on the total AFC (≥10) at baseline scan were recruited.

Exclusion criteria include 1) PGD and oocyte donation, total embryo freezing and when GnRH agonist was used to trigger ovulation. Serum progesterone concentration was measured on the day of HCG administration. Patients were grouped according to their serum progesterone concentration into (high $P \geq 5$ pmol/L) and (normal $P < 5$ pmol/L).
Main results and the role of chance: A total of 615 patients were analysed. 125 (20.3%) had elevated progesterone. There were no statistically significant differences between the 2 groups with regards to age (34.8 ± 4.3 vs. 34.1 ± 4.0, $p = 0.1$); baseline AMH (30.4 ± 26.2 vs. 33.7 ± 25.1, $p = 0.2$); number of embryos transferred (1.56 ± 0.63 vs. 1.51 ± 0.58, $p = 0.5$) and the proportion of top quality blastocysts transferred (65% vs. 61%, $p = 0.3$). Cycles with high Progesterone had significantly higher AFC (17.3 ± 6.9 vs. 18.9 ± 7.5, $p = 0.02$), total FSH dose (2710 ± 1082 vs. 2172 ± 1170, $p < 0.0001$), longer duration of stimulation (13 ± 1.8 vs. 12 ± 2.9, $p = 0.002$), oocyte (15.1 ± 6.3 vs. 13.4 ± 6.1, $p = 0.006$) and 2PN number (9.2 ± 4.5 vs. 7.7 ± 4.2, $p = 0.0007$), A multivariate analysis accounting for important confounding variables (e.g., AFC, oocyte number) showed a significantly lower clinical pregnancy rate CPR (30.4% vs. 43.7%) in the group with elevated progesterone (OR: 0.59, 95% CI: 0.38–0.93, $p = 0.021$). However, a subgroup analysis where at least one top quality blastocyst was transferred showed no difference between the two groups (44% vs. 50%, $p = 0.24$).
Limitations, reasons for caution: Although this is a large prospective study with strict inclusion criteria, it is a single-centre study using baseline AFC to select women with predicted normal or high ovarian response during IVF/ICSI treatment. The results may not apply to other groups of women with different ovarian reserve parameters.
Wider implications of the findings: It is yet to be determined which group of patients with high progesterone is unlikely to achieve a pregnancy. Patients with a top quality blastocyst transfer and high progesterone may achieve comparable results to their peers with normal progesterone concentration.
Trial registration number: None.

P-711 High level of androgen during controlled ovarian stimulation cycle impairs endometrium receptivity in PCOS patients

D.D. Wu[1], H. Wang[2], X.H. Lin[3], P. Zhang[3], H.F. Huang[3]
[1]*International Peace Maternity and Child Health Hospital of China Welfare Institute Hospital, China Welfare Institute, Central Laboratory, Shanghai, China*
[2]*Tong Ren Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai, China, Department of Obstetrics and Gynecology, Shanghai, China*
[3]*The International Peace Maternity and Child Health Hospital, School of Medicine, Shanghai Jiao Tong University, Shanghai, China, Reproductive Centre, Shanghai, China*

Study question: Does High level of androgen during COS cycle impact fresh embryos implantation in PCOS patients?
Summary answer: High level of androgen during COS cycle impaired endometrium receptivity, which contributed to the low fresh embryo implantation rate in PCOS.
What is known already: Hyperandrogenism is the main pathologic characteristic of polycystic ovary syndrome (PCOS). It is generally believed that poor reproductive success in IVF could be achieved in PCOS patients compared with infertile women with tubal factor.
Study design, size, duration: 1357 infertile patients undergoing first IVF cycle treatment were recruited from January, 2014 to June, 2015 in this case control

study. Among these subjects, 177 women were PCOS and 1315 were Controls matched for BMI and age.
Participants/materials, setting, methods: Patients with PCOS were treated with OC before IVF cycle. Standard controlled ovarian stimulation was performed in both of groups. Serum hormone was detected on day 3 and HCG day during the COS cycle. The expression levels of IGFBP-1, EGF, LIF, etc., were screened in endometrium from both groups using real-time PCR. The mRNA and protein expression of IGFBP-1 and LIF were examined in Ishikawa cells treated with different concentrations of testosterone.
Main results and the role of chance: In the total study population, serum LH, E2 and total T levels on day 3 in women with PCOS were comparable with Controls, and no significant differences in the number of oocytes retrieved, fertilization rate, available embryos rate and high quality embryo rate between two groups. While the implantation rate, clinical pregnancy rate, on-going pregnancy rate and live birth rate in PCOS group was obviously decreased compared to the controls. In the subgroup of 154 patients, total T level on hCG day was significantly higher in PCOS (n = 27) than in Controls (n = 127). By endometrium biopsy we found that the mRNA and protein levels of IGFBP-1 and LIF of women with PCOS were significantly lower than in those of controls. In Ishikawa cells, we found high dose of testosterone (more than 10–8 mol/L) significantly reduced the IGFBP-1 and LIF mRNA and protein levels.
Limitations, reasons for caution: The mechanism of how elevated androgen level causes expression of LIF and IGFBP1 reduced hasn't been proved in this study. Further study was needed to clarify it in later study.
Wider implications of the findings: Although endocrine abnormal including hyperandrogenism had been corrected before COS cycle started, higher androgen level was detected on HCG day of COS cycle in PCOS patients, which probably contributed to the decreased fresh embryos implantation rate.
Trial registration number: ChicCTR-OCH-14004536.

P-712 Extensive analysis defines actual differences in absolute and "per-follicle" Anti-Müllerian hormone (AMH) levels obtained by manual and new automated assays

T. Tadros[1], B. Tarasconi[1], J.L. Benhaim[1], J. Taieb[1], J. Nassar[1], R. Fanchin[1]
[1]*Hospital A. Béclère, Department of Reproductive Medicine, Clamart Cedex, France*

Study question: To compare absolute and "per-follicle" AMH levels, as well as the strength of their relationship with antral follicle count (AFC), obtained with 2 automated and 1 manual commercially-available assays.
Summary answer: Although strongly correlated with AFC, AMH levels were lower with automated (−16% and −20%) than with manual assays but higher (5%) with Access than Elecsys.
What is known already: Associated or not to AFC, serum AMH measurements have become the paramount reference in the appraisal of ovarian follicular status. Yet, the observation of non-reproducible and/or aberrant AMH results, often resulting from different calibration, standards, and operator manipulations, discouraged its widespread use. Recently, fully automated AMH assays have become available but extended analysis testing their reliability – in particular taking the relationship between AMH and the number of AMH-producing follicles as reference – remains necessary.
Study design, size, duration: Frozen-thawed serum aliquots obtained between days 2 and 4 of the menstrual cycle in 211 assisted conception candidates aged 24 to 43 years between April 2015 and July 2015 were analyzed. All of them had concomitant, centralized assessment of AFC (follicles measuring 3–10 mm in diameter). "Per-follicle" AMH levels were pragmatically appraised by dividing serum AMH levels by AFC (results expressed in ng/mL/follicle).
Participants/materials, setting, methods: Serum AMH levels were determined using 3 different assays: modified Gen II AMH ELISA (Beckman Coulter, CA, USA), Access AMH (Beckman Coulter, CA, USA), and Elecsys AMH (Roche Diagnostics, Switzerland). AFC was determined using transvaginal ultrasound (5–9 MHz). Differences were assessed 2 × 2 by the Wilcoxon Signed-Rank test, the strength of relationships by the Spearman correlation test, and agreement between assays by the Bland–Altman plots. A $P < 0.05$ was statistically significant.
Main results and the role of chance: Absolute and "per-follicle" AMH levels were, respectively, at 1.97 (0.04–30.66) ng/mL and 0.13 (0.01–0.43) ng/mL/follicle with AMH Gen II ELISA, 1.66 (0.04–30.46) ng/mL and 0.11 (0.01–0.38) ng/mL/follicle with Access AMH, and 1.58 (0.04–26.17) ng/mL and 0.10 (0.01–0.33) ng/mL/follicle with Elecsys AMH. Differences of values between assays were statistically significant ($P < 0.001$). Strengths of correlations between AFC and absolute AMH levels were similar among the 3 assays ($r = 0.83$, $P < 0.001$; $r = 0.83$, $P < 0.001$; and $r = 0.83$, $P < 0.001$, respectively) and Bland–Altman plots revealed adequate agreement between assays.
Limitations, reasons for caution: Our present series was not large enough to determine age-ranked usual values for each assay.
Wider implications of the findings: Automated AMH assays are markedly reliable but show slight yet significant differences (around 5%) in results. Both of them provide results −16% and −20% as low as the manual ELISA assay. Clinicians should be aware of these differences before patient counseling and adaptation of treatments.
Trial registration number: Not Applicable.

P-713 Hormonal parameters before and after withdrawal using vaginal micronized progesterone in anovulatory patients with polycystic ovary syndrome

B. Alvaro[1], C. Dosouto[1], F. Martinez[1], O. Carreras[1], F. Mancini[1], R. Tur[1], P.N. Barri[1], V. Coroleu[1]
[1]*Hospital Universitario Quiron Dexeus, Reproductive Medicine Department, Barcelona, Spain*

Study question: Is the induction of withdrawal bleeding with vaginal micronized progesterone (VMP) necessary for the hormonal evaluation in polycystic ovary syndrome (PCOS).
Summary answer: Induction of withdrawal bleeding with VMP does not significantly alter circulating androgen levels compared to baseline and can be used to assess PCOS patients.
What is known already: One of the diagnostic criteria for PCOS is the baseline increased presence of ovarian androgens. Usually, this assessment is done at the early follicular phase. In amenorrheic patients, it is often done after progesterone withdrawal but it is also performed in amenorrhea. Progesterone administration could suppress ovarian function and androgen synthesis, and it could be a diagnostic bias. Reported data are poor, unclear, with small number of patients assessed and heterogeneous regarding PCOS Rotterdam criteria. In many cases the withdrawal is performed with different kinds of progestins making it hard to compare.
Study design, size, duration: Prospective cohort study including 15 Caucasian reproductive-age patients with PCOS assessed between 2014 and 2015. All subjects fulfilled Rotterdam criteria: chronic ovulatory dysfunction, clinical and/or analytical hyperandrogenemia and polycystic ovaries. Blood sampling was collected at baseline and between the 3rd and the 5th day of withdrawal after administration of VMP 100 mg every 12 h for 7 days.
Participants/materials, setting, methods: Sample 1 (baseline) was obtained the day of the first visit at the clinic for patients with amenorrhea. Sample 2 was obtained between the 3rd and the 5th day of induced withdrawal after 7 days of 100 mg every 12 h vaginal natural micronized P administration. In all subjects, withdrawal bleeding was successful. Blood sample 2 was collected from all patients between 8 and 11 a.m., after an overnight fast.
Main results and the role of chance: 15 patients were included. Two patients presented spontaneous ovulation (confirmed by increased levels of estradiol and P). VMP administration didn't lead to significant modification of hormonal values. There was a trend towards lower levels of gonadotropins during withdrawal bleeding in comparison with baseline values but without significant differences FSH (5.4 ± 1.2 vs. 5.0 ± 1.6, $p = 0.4$) and LH (11.8 ± 7.9 vs. 8.1 ± 4.4 $p = 0.06$).

No significant differences were found between baseline values and values estimated during withdrawal bleeding regarding androgen parameters: free testosterone (5.2 ± 3.2 vs. 4.7 ± 2.7; $p = 0.15$), SHBG (52.3 ± 22.2 vs. 54.3 ± 26.7; $p = 0.50$), DHEAS (2.2 ± 1.9 vs. 2.3 ± 2.1; $p = 0.44$), A4 (2.5 ± 1.0 vs. 2.8 ± 1.3; $p = 0.50$) and 17-OHP (0.6 ± 0.20 vs. 0.7 ± 0.5; $p = 0.86$).

Data from our study indicate that, in women with anovulatory PCOS, the induction of withdrawal bleeding with VMP (7 days of VMP, 100 mg every 12 h) does not significantly modify circulating androgen levels compare to baseline and can be used to time blood sampling in these patients.
Limitations, reasons for caution: Small simple size in this study is a reason of caution. A higher number of patients might have led to different results, although it is hard to find studies with larger sample size about this topic.
Wider implications of the findings: This strategy avoids spontaneous ovulation found in some cases (20% in our group), optimizing schedules and

reaching a diagnosis with the first clinical visit in most of the cases (100% in our group). Therefore it seems to be useful for the assessment of hormonal profile in patients with anovulatory PCOS.
Trial registration number: Non applicable.

P-714 Improved human oocyte *in vitro* maturation in co-culture with cumulus cells from mature oocytes in the same patient: a prospective study

I. Virant-Klun[1], A. Ståhlberg[2], M. Kubista[3], C. Rubio[4], L. Rodrigo[4], T. Skutella[5]
[1]*University Medical Centre Ljubljana, Ljubljana, Slovenia*
[2]*Sahlgrenska Cancer Center, University of Göteborg, Department of Pathology, Göteborg, Sweden*
[3]*TATAA, Biocenter, Göteborg, Sweden*
[4]*Igenomix, Parc Cientific Universitat de València, Valencia, Spain*
[5]*Institute for Anatomy and Cell Biology, Anatomy, Heidelberg, Germany*

Study question: Is *in vitro* maturation of immature oocytes (after ovarian hormonal stimulation) improved by co-culture with cumulus cells from mature oocytes in the same patient ?
Summary answer: The co-culture of germinal vesicle (GV) oocytes with cumulus cells from mature oocytes in the same patient improved the success of *in vitro* maturation.
What is known already: Existing evidence shows that cumulus cell contact during oocyte maturation in mice enhances oocyte developmental competence. The oocyte co-culture with cumulus cells during *in vitro* maturation may compensate the suboptimal maturation medium. The *in vitro* maturation of human GV oocytes in co-culture with cumulus cells of the same oocytes has not been proven to be successful due to potential abnormalities in cumulus cells which may disable the oocyte maturation process. Therefore we matured the oocytes *in vitro* in a co-culture with cumulus cells retrieved from mature oocytes in the same patient.
Study design, size, duration: In this prospective 2-year study 174 immature (GV) oocytes from the *in vitro* fertilization programme (IVF) were matured *in vitro*: 79 oocytes in a maturation medium containing FSH and hCG and co-cultured with cumulus cells from the same patient's mature oocytes and 95 oocytes in a conventional way (in the same medium, without co-culture) to compare the maturation rate, chromosomal status and gene expression profile.
Participants/materials, setting, methods: The subgroups of each group of *in vitro* matured oocytes were analyzed on all chromosomes (aCGH) and gene expression profile (microarrays) in comparison to *in vivo* matured oocytes; each group of oocytes was analyzed in three biological replicates consisted of 10 oocytes. The most interesting genes were further validated by qPCR and evaluated using Principal Component Analysis, Student's *T*-test, and one-way ANOVA to elucidate differences between groups; statistical significance was set at $P < 0.05$.
Main results and the role of chance: In co-culture with cumulus cells a higher proportion of oocytes matured *in vitro* than after conventional *in vitro* maturation without co-culture: 77.2% (61/79) vs. 62.1% (59/95), $P < 0.05$, in spite of approximately the same age of donating women (34.5 ± 4.3 vs. 34.1 ± 4.5 years). In oocytes matured *in vitro* in a co-culture there was a tendency to a higher proportion of oocytes which were normal for all chromosomes than in oocytes matured in a conventional way: 43.1% vs. 9.1%. The transcriptome of oocytes matured *in vitro* in co-culture with cumulus cells was shifted toward the *in vivo* matured oocytes in comparison to oocytes conventionally matured *in vitro*, as revealed by principal component analysis. The co-cultured oocytes expressed a significantly lower number of genes that were up-regulated or down-regulated than conventionally matured oocytes in comparison to *in vivo* matured oocytes, including transcription, epigenetics, embryogenesis, and cell cycle-related genes. In general, our study revealed 15 genes which were differently expressed between *in vitro* and *in vivo* matured oocytes and validated by qPCR, including 7 transcription factors. The most prominent, folliculogenesis specific basic helix-loop-helix (FIGLA), is suggested as a biomarker of human oocyte maturation *in vitro*.
Limitations, reasons for caution: The mature oocytes that did not fertilize *in vitro* were considered to be "*in vivo*" matured oocytes and represented a reference (control) group for other groups of *in vitro* matured oocytes. It is possible that they possess some abnormalities because they did not fertilize *in vitro*.
Wider implications of the findings: The oocyte *in vitro* maturation can be improved by co-culture of GV oocytes with cumulus cells retrieved by denudation of mature oocytes in the same patient, a simple principle, which has not been used until now. It may be beneficial to cancer patients to efficiently cryopreserve their oocytes before oncotherapy.
Trial registration number: The study was approved by the Slovenian Medical Ethical Committee.

P-715 A single dose new long-acting GnRH-antagonist Degarelix effectively downregulates LH in stimulated IVF cycles triggered with agonist for oocyte maturation. A proof of concept study

E. Papanikolaou[1], D. Kyrou[1], L. Kotanidis[1], E. Katsoula[1], E. Timotheou[1], P. Tatsi[1], O. Zafeiratis[1], R. Najdecki[1]
[1]*Assisting Nature, IVF Unit, Thessaloniki, Greece*

Study question: To assess whether a new long-acting antagonist degarelix can efficiently suppress LH without negative impact on the pregnancy outcome.
Summary answer: In stimulated IVF cycles, Degarelix compared to daily antagonist regimen, effectively prevents LH surge, with comparable embryo quality, total embryos produced and pregnancy outcome.
What is known already: The use of daily GnRH-antagonist in IVF protocols is well established. A new long acting degarelix was recently licensed for prostate cancer. There is no data for using them in women undergoing IVF.
Study design, size, duration: This prospective case-control study (within same subjects), performed in a private assisted reproduction centre (January to December 2015), enrolled ten healthy women (aged 22–32 years) undergoing ovarian stimulation for oocyte donation programme. All donors underwent 2 consecutive ovarian stimulations with the antagonist protocol, and oocyte maturation triggered with Agonist and oocyte retrieval followed after 36 h. The primary outcomes were incidence of LH surge (>14 mIU/ml) on the day of triggering, total embryos produced and recipient's clinical pregnancy.
Participants/materials, setting, methods: All oocyte donors underwent first, a donation cycle with the classical fixed day−6 antagonist protocol with daily doses of 0.25 mg of ganirelix and 250 IU of recombinant FSH and agonist triggering. After minimum 4 months, underwent a consecutive donation cycle again with antagonist protocol and 250 IU recombinant FSH. However, this second cycle received a single dose of this new agent, degarelix, on day−6. The dose decided to be according to weight at 0.2 mg/kg subcutaneously.
Main results and the role of chance: No LH surge was observed with any of the protocols. However, LH values were significantly lower on the day of triggering in the degarelix group as compared with the daily antagonist group (0.70 vs. 1.98, $p = 0.04$). Importantly, one donor in the degarelix group with LH = 0.1 mIU/ml on the day of agonist triggering had only 5 oocytes retrieved, which was significantly reduced as compared with the first cycle where 17 oocytes had been retrieved. The mean of MII oocytes (9.25 ± 0.7 vs. 10.85. ± 0.8 respectively; NS) and total embryos produced (5.5 ± 0.6 vs. 6.2 ± 0.6 respectively; NS) were comparable between D6-single-dose Degarelix group and the classical D6-daily-antagonist group. Overall, comparable clinical pregnancy rates per embryo transfer were achieved in both groups (66.6% vs. 50.0%, respectively, $p = 0.4$).
Limitations, reasons for caution: Major drawback of this study is the limited number; however, it is a proof of concept with the same donor as control of herself. We attempted to adjust the single dose according to the weight of the patient first and secondly according LH suppression not lasting more than 6 days.
Wider implications of the findings: Based on our results a single dose of the new long-acting GnRH-antagonist Degarelix at a dose of 0.2 mg/kg can efficiently replace repeated daily doses of the already used antagonists. Patient friendly protocols will make IVF easier for patients.
Trial registration number: Non applicable.

P-716 Role of Karyotyping and FMR gene screening in the anticipation of diagnosis of Premature Ovarian Insufficiency (POI)

M.L. Shenoy[1], A. Deenadayal[2], A.D. Dasari[3]
[1]*Infertility Institute and Research Centre, Department. of Ob/Gyn, Hyderabad, India*
[2]*Infertility Institute and Research Centre, Hyderabad, India*
[3]*Infertility Institute and Research Centre, Reproductive Medicine, Hyderabad, India*

Study question: Are their markers in patients in the stage of Transient ovarian failure (TOF) be that can anticipate POI in the future?
Summary answer: Yes, 14% of patients had an abnormal karyotype, 33% had a family history of either primary amenorrhea or POI and 84% had an AMH < 1 μg/ml.
What is known already: 4–18% of the cases who seek clinical evaluation for secondary amenorrhea have POF. TOI is seen 1–2 years before POI and is characterized by irregular menstrual cycles with a raised FSH. One half of patients saw >3 clinicians before they were diagnosed as POI. The X chromosome abnormalities have been largely implicated in literature. ASRM states than 13% of familial and 5% of sporadic cases have a FMR gene pre-mutation.
Study design, size, duration: A case-control study in 2014–2015 of 97 amenorrheic POI patients below 40 years with an FSH >20 IU/l in comparison with 100 control patients >40 years with normal cycles and FSH.
Participants/materials, setting, methods: The patients were recruited from Infertility Institute and Research Center, Hyderabad, India. A detailed clinical and menstrual history was taken from the patients and control patients followed by karyotyping and FMR1 gene screening at the Center for Cellular and Molecular Biology in Hyderabad.
Main results and the role of chance: Of the 97 patients 50% with primary amenorrhea and 14% with secondary amenorrhea had an abnormal karyotype compared to a normal karyotype in all the controls. 81% of the abnormalities were of the X chromosome. None of the patients had an FMR1 gene pre-mutation. The cases and controls had similar CGG repeats in the FMR1 gene. 59% of the patients with secondary amenorrhea were between 25 and 35 years and most with a history of visiting a gynecologist frequently for irregular periods without the anticipated diagnosis of TOF although they had documented high FSH levels. 85% of the patients were seeking infertility treatment, 70% for more than 3 years with a history of menstrual disturbances before the onset of amenorrhea for which they visited a gynecologist. 17 patients had spontaneous pregnancies. All 4 patients with an abnormal karyotype aborted and 8 out of 13 with a normal karyotype aborted. 33% had a family history of either primary amenorrhea or POF. 84% had an AMH < 1 μg/ml and 16% between 1 and 3 μg/ml.
Limitations, reasons for caution: The study sample was small to make any definitive conclusions.
Wider implications of the findings: The study gives us a reason to believe that a simple concentrated history taking and a inclination towards anticipation of an ovarian insufficiency in the future can give the patient a chance to preserve her oocytes or attempt early pregnancy.
Trial registration number: Not required.

P-717 Metformin decreases bone turnover in polycystic ovary syndrome

S. Lingaiah[1], L. Morin-Papunen[2], J. Tapanainen[2,3], T. Vaskivuo[4]
[1]*University of Oulu, Department of Obstetrics and Gynecology, Oulu University Hospital and Medical Research Centre, Oulu, Finland*
[2]*University of Oulu, Department of Obstetrics and Gynecology, Oulu University Hospital, Medical Research Center and PEDEGO Research Unit Research Unit for Pediatrics, Dermatology, Clinical Genetics, Obstetrics and Gynecology, Oulu, Finland*
[3]*University of Helsinki, Department of Obstetrics and Gynecology, University of Helsinki and Helsinki University Hospital, Helsinki, Finland*
[4]*University of Oulu, Department of Clinical Chemistry, Oulu, Finland*

Study question: To examine the effect of metformin on bone turnover markers in polycystic ovary syndrome (PCOS).
Summary answer: Three months metformin treatment decreased bone turnover in women with PCOS.
What is known already: The available clinical data in diabetics suggest that metformin may be beneficial for bone metabolism, but prospective randomized trials are needed to demonstrate its possible protective role in PCOS. Pioglitazone treatment in premenopausal women with PCOS has shown to decrease bone mineral density (BMD) and markers of bone resorption.
Study design, size, duration: Spin-off study from a recent randomized, double blind, placebo-controlled study. One hundred and fifty women with PCOS randomized to either metformin (n = 75) or placebo (n = 75) for 12 weeks. Metformin or placebo was started at a dose of 500 mg for the first week and subsequently increased in weekly steps by 500 mg up to 1500 mg in non-obese women and 2000 mg in obese women.
Participants/materials, setting, methods: Concentrations of bone formation marker: procollagen type I amino terminal propeptide (PINP) and bone resorption marker: carboxy-terminal telopeptide of type I collagen (CTX) were analysed at the baseline and after 3 months of metformin/placebo by IDS-iSYS Multi-Discipline Automated Analyzer.
Main results and the role of chance: Compared with the baseline measurements, there were significant decreases in the concentrations of PINP (44.3 ± 22.7 vs. 32.3 ± 13.4 ng/ml, $P < 0.001$) and CTX (0.39 ± 0.19 vs. 0.27 ± 0.14 ng/ml, $P < 0.001$) in the metformin group after 3 months, and this was the case in both obese and non-obese subjects. In the placebo group the levels of PINP (47.5 ± 19.8 vs. 48.1 ± 20.5 ng/ml, $P = 0.712$) and CTX (0.41 ± 0.19 vs. 0.38 ± 0.19 ng/ml, $P = 0.079$) remained unchanged.
Limitations, reasons for caution: Short term study and non-assessment of bone mineral density (BMD) are the most important limitations. Long term studies with BMD measurements and clinical fracture rates are required to demonstrate conclusively the underlying mechanisms in bone remodeling during metformin therapy.
Wider implications of the findings: Reduced bone formation and resorption markers indicate that metformin therapy decreased bone turnover in women with PCOS similarly to that seen with bisphosphonates and selective estrogen receptor modulator treatments. Our findings provide insight into bone remodeling effects of metformin in PCOS.
Trial registration number: NCT00994812.

P-718 Mild versus conventional ovarian stimulation for poor responders undergoing IVF/ICSI: a prospective randomized study

C. Siristatidis[1], G. Salamalekis[1], K. Dafopoulos[2], G. Basios[1], P. Vogiatzi[1], N. Papantoniou[3]
[1]*National and Kapodistrian University of Athens, Assisted Reproduction Unit, 3rd Department of Obstetrics and Gynecology, Athens, Greece*
[2]*University of Thessaly, School of Health Sciences, Faculty of Medicine, Assisted Reproduction Unit, Department of Obstetrics and Gynecology, Larissa, Greece*
[3]*National and Kapodistrian University of Athens, 3rd Department of Obstetrics and Gynecology, Athens, Greece*

Study question: Is mild stimulation protocols equal as compared to the conventional GnRH-agonist and antagonist ones in poor responders undergoing IVF/ICSI cycles?
Summary answer: Mild ovarian stimulation is inferior to conventional regimes when applied in poor responders undergoing IVF/ICSI, in numbers of oocytes retrieved, embryos transferred and cancellation rates.
What is known already: Evidence to date indicates that the most efficient approach in managing subfertile poor responders, is the individualization of the treatment protocols, based on antral follicle count (AFC) and anti-Mullerian hormone (AMH) values prior to the IVF cycle, although the success rates remain low. The rationale of the present study lies within the separate benefits of mild stimulation through lower gonadotrophin doses, the lowered cost that accompanies the treatment, together with its suspected equality in terms of effectiveness to the conventionally used protocols for ovarian stimulation.
Study design, size, duration: This RCT was conducted during the period from March 2011 to September 2015. Mild stimulation protocol using clomiphene citrate was compared to the long GnRH-agonist and GnRH antagonist protocols. Randomization was performed by the study coordinator through a phone call to a random non-medical staff belonging to the hospital personnel and by answering to the question "1 or 2" without any further exemplification.
Participants/materials, setting, methods: The study cohort consisted of 58 patients, characterized as "poor responders" according to the Bologna criteria. It was conducted at the Assisted Reproductive Unit of the 3rd Department of Obstetrics and Gynecology, "Attikon" hospital, Medical School, National and Kapodistrian University of Athens.

The primary outcome measure was the number of cumulus oocyte complexes (COCs) retrieved. Secondary outcome measures included duration of stimulation, total dose of gonadotropins administered, clinical pregnancy, miscarriage and live birth per randomised patient.
Main results and the role of chance: Stimulation duration did not differ between groups, as the time of clomiphene citrate use was co-calculated. In contrast, the total gonadotrophin dose was statistically different between groups [1050 (95% CI, 0–2490) vs. 4040 (95% CI, 1800–6795), $p < 0.001$].

A significantly higher number of follicles in the category of 14–15 mm and 18 mm, although not for 16–17 mm, was observed in the control group. Similarly a higher number of COCs and MII oocytes [(1 (95% CI, 0–4) vs. 3 (95% CI, 0–8.4), $p < 0.001$ and 1 (95% CI, 0–4) vs. 2 (95% CI, 0–7.4), $p = 0.001$, respectively], number of fertilized oocytes, cleaved, transferred and frozen embryos (all p values <0.05) was observed in the control group. The endometrial thickness at the day of hCG administration was significantly lower in the study group, compared to the control group [7.8 (95% CI, 4.1–12) vs. 10 (95% CI, 5.1–13.6) mm, $p = 0.015$] and cancellation rates were significantly higher [36.4% (95% CI, 19–53.7) vs. 12% (95% CI, 1.7–25.7), $p = 0.036$].

There was no difference between groups with regards to positive b-hCG [15.2% (95% CI, 2.2–28.1) vs. 20% (95% CI, 3.1–36.9), $p = 0.628$], clinical pregnancy [12.1% (95% CI, 4–23.9) vs. 20% (95% CI, 3.1–36.9), $p = 0.412$], and live birth [9.1% (95% CI, 1.3–19.4) vs. 12% (95% CI, 1.7–25.7), $p = 0.719$] rates, neither to miscarriages [40% (95% CI, 28–100) vs. 40% (95% CI, 28–100), $p = 1.000$].

Limitations, reasons for caution: Limitations of the study would be the lowered clinical value of the results attributed to the reduced cohort size, the existence of two conventional protocols, representing the control group and the difference in terms of oocyte quality and quantity when stimulated between poor responders at a young and advanced age.

Wider implications of the findings: There is a varying discrepancy on the outcomes reported in this study with all four trials published to date, using the same regime and applying it to poor responders. The importance of the reported results lies in the fact that poor responders have an anticipated poor outcome in conventional IVF protocols.

Trial registration number: NCT01319708.

P-719 Anti-Müllerian Hormone (AMH) affects Forkhead box L2 (FOXL2) expression: possible implications in early phases of folliculogenesis

S. Sacchi[1], F. Marinaro[2], T. Marsella[2], D. Tagliasacchi[2], S. Xella[2], S. Giulini[2], A. La Marca[1]

[1]University of Modena and Reggio Emilia and ALM Clinica Eugin Modena, Italy, Mother–Infant Department, Modena, Italy

[2]University of Modena and Reggio Emilia, Mother–Infant Department, Modena, Italy

Study question: The objective was to analyze the inhibitory effect of Anti-Müllerian hormone (AMH) on steroidogenesis through a possible modulating effect on the expression of Forkhead box L2 (FOXL2) transcription factor.

Summary answer: recombinant human AMH (rhAMH) increased the expression of FOXL2 in primary cultures of human granulosa cells (hGCs) *in vitro*.

What is known already: *AMH* and *FOXL2* are two pivotal genes expressed in hGCs, and both exert a similar inhibitory function on activation and follicular growth, in order to preserve the ovarian follicle reserve.

Notably both genes contribute to inhibit steroidogenesis decreasing or preventing the activation of gonadotropin-dependent aromatase *CYP19A1*. Although FOXL2 among others is considered a transcriptional activator of the *AMH* gene, other studies showed that AMH induces *FOXL2* expression in rodent models, suggesting that *FOXL2* is an endogenous downstream target of AMH.

Study design, size, duration: *FOXL2* gene expression elicited by rhAMH was evaluated by dose response (1, 10, 50, 100 ng/ml of rhAMH) and time-course (1, 3, 6, 24 h incubation with rhAMH) studies in hGCs primary cultures. Untreated hGCs were used as control. The expression of *CYP19A1* aromatase and the concentration of intracellular adenosine-3',5'-cyclic monophosphate (cAMP) were evaluated as positive control in order to test the efficiency of rhAMH treatments.

Participants/materials, setting, methods: Primary hGCs cultures were rhAMH treated *in vitro*. Negative controls using corresponding amount of AMH vehicle were performed. Intracellular content of cAMP was measured by immuno-enzymatic reaction. Total RNA or proteins were purified and quantified. The *CYP19A1* and *FOXL2* gene expression, normalized by housekeeping *ribosomal protein subunit 7* (*RpS7*) gene, was evaluated by RT-qPCR. Each reaction was repeated in triplicate. Statistical analysis was performed. Extracted proteins underwent Western-blot analysis with anti-FOXL2 and anti-β-tubulin antibodies.

Main results and the role of chance: rhAMH treatments reduced the content of intracellular cAMP of hGCS as expected. To understand if different concentrations of rhAMH at different time points could affect the *FOXL2* gene expression, samples were analyzed by RT-qPCR. Although the majority of the treatments tested did not produced significant differences in *FOXL2* activation compared to the control, different dosages of rhAMH (10, 50, 100 ng/ml) after 3 h of incubation, increased the *FOXL2* gene expression. However due to statistical analysis, only the 50 ng/ml treatment shows a consistent significant activation of *FOXL2* gene expression. Finally, based on RT-qPCR data previously obtained, the effect of 3 h incubation with 50 ng/ml rhAMH on FOXL2 protein production in hGCs primary cultures was analyzed by Western-blot. The semi-quantified amount of FOXL2 protein normalized by β-tubulin generated by rhAMH treatment is significantly augmented in comparison to untreated controls.

Limitations, reasons for caution: This study was conducted only *in vitro* on primary hGCs culture recovered from patients who had undergone IVF protocol. Even though a general positive effect in the modulation of *FOXL2* by rhAMH is recognizable in most of the treatments tested, a high individual variability, although statistically not significant, was observed.

Wider implications of the findings: This study shows the existence of common pathways between AMH and FOXL2 in hGCs. AMH could be able to regulate folliculogenesis by modulating both gene and protein expression levels of FOXL2. Because FOXL2 induces AMH transcription, these ovarian factors can be finely regulated by a positive feedback loop mechanism.

Trial registration number: NO.

P-720 Luteal phase ovarian stimulation produces competent oocytes in women with diminished ovarian reserve

Z. Liu[1], Z. Merhi[2], M. Yang[1], J. Zhang[1]

[1]New Hope Fertility Center, Reproductive Endocrinology and Infertility, New York, NY, USA

[2]New York University School of Medicine, Obstetrics and Gynecology, New York, NY, USA

Study question: Do oocytes retrieved from follicular phase (FP) and luteal phases (LP) of the same cycle in patients with diminished ovarian reserve (DOR) have similar competency?

Summary answer: Oocytes retrieved from FP and LP in the same IVF cycle have comparable fertilization rate and form embryos with comparable cleavage and blastulation rates.

What is known already: Folliculogenesis occurs in a wave-like fashion indicating that there are multiple follicular recruitment waves in the same menstrual cycle. Patients with DOR often produce poor quality and quantity oocytes by IVF.

Study design, size, duration: In order to increase the number of oocytes collected in the same IVF cycle, double ovarian stimulation in the FP and LP were performed. From July 2013 to December 2014, 60 patients with DOR defined by Bologna criteria, aged between 28 and 48, had 87 IVF cycles.

Participants/materials, setting, methods: Patients were either stimulated with minimal stimulation protocol (MSP) or monitored in natural cycle in FP. If 2 or more small follicles (≤10 mm) were available after oocyte retrieval, they were stimulated with MSP in the LP. In both FP and LP, oocytes were retrieved when the leading follicle reached a size of at least 18 mm. The number of oocytes recovered, number of metaphase II (MII) oocytes, fertilization, cleavage and blastulation rates were assessed.

Main results and the role of chance: Mean age and BMI of the participants were 42.43 ± 3.71 years and 22.75 ± 3.78 kg/m^2, respectively. The average interval of days between oocyte retrieval during FP and LP was 9.44 ± 3.23. Of the 87 IVF cycles studied, 125 follicles in FP and 151 follicles in LP were retrieved. The oocyte retrieval rate was significantly lower in LP (68.21%) compared to that in FP (84%) ($p = 0.002$), but there was no difference in the percentage of MII oocytes (58.94% in LP vs. 62.4% in FP, $p = 0.34$), no difference in fertilization rate (78.67% in LP vs. 86.58% in FP, $p = 0.19$) or blastomere number (7.10 ± 1.90 in LP vs. 7.37 ± 2.19 in FP, $p = 0.47$) on day 3 of culture. 20 of 49 embryos (40.82%) from FP and 24 of 48 embryos (50.00%) from LP reached the blastocyst stage ($p = 0.36$). Of 31 blastocysts that were tested with preimplantation genetic screening, 2 of 13 from FP and 1 of 18 from LP were euploid.

Limitations, reasons for caution: The study may be underpowered to detect statistical significance. The data on comparison of implantation and pregnancy outcomes between FP and LP ovarian stimulation protocols is under collection.

Wider implications of the findings: Oocyte retrieval from both follicular phase and luteal phase by double stimulation in the same cycle provides a new

and safe approach in increasing the amount of oocyte retrieved in the same IVF cycle for the patients with DOR.
Trial registration number: N/A.

P-721 Is there a bridge between diminished ovarian reserve and inflammation? A pilot study

A. Bourdiec[1], C. Le Saint[1], S. Philips[2], I.J. Kadoch[1]
[1]*Clinique Ovo, R&D, Montreal, QC, Canada*
[2]*Clinique Ovo, Embryology, Montreal, QC, Canada*

Study question: Can diminished ovarian reserve (DOR) be linked to immunologic bias?
Summary answer: Immune mediators expressed by cumulus cells are significantly distinct in DOR women vs. control, and specifically correlated with ovarian reserve markers.
What is known already: Diminishment of ovarian reserve (early or not) is recognized as a limiting factor in Assisted Reproductive Technology (ART). Throughout the growth of the ovarian follicle, the oocyte is in close contact with neighboring cells such as cumulus cells (CC), which contribute to the oocyte maturation and quality. Thereby, the oocyte-cumulus dialogue is representative of the quality of the oocyte, which in turn is indicative of the embryo quality and a crucial point in ART. However, the inflammatory environment in which the oocyte evolves is not clearly established, and it remains unclear how ovarian inflammatory background can impact the ovarian reserve.
Study design, size, duration: Retrospective clinical study in which the immune gene expression in CC associated with mature oocytes in DOR and control patients were investigated.
Inclusion criteria: standard IVF and CC from mature oocyte.
Exclusion criteria: Polycystic ovary syndrome, autoimmune diseases.
Participants/materials, setting, methods: 47 CC samples from 8 women (4 DOR, 4 controls) who underwent IVF protocol at Clinique Ovo and provided a written informed consent to participate in a research protocol approved by the ethics committee, were collected. For each sample, mRNA was extracted and subsequently, quantitative real-time PCR was performed. Statistical analyses were performed using Student's *t*-Test and Pearson correlation test.
Main results and the role of chance: In this pilot study, we report that DOR affects the expression of interleukin (IL) 1 members in CC compared with control. Independently of age, mRNA expression of lL1R1 was significantly increased in DOR ($p = 0.0110$). This increase was significantly and negatively associated with AMH (serum level) and antral follicle count (AFC) ($p = 0.0180$ and $p = 0.0001$ respectively). Interestingly, IL1B was significantly and negatively correlated with AMH serum level ($p = 0.0137$). In turn, IL1RN (IL1 antagonist receptor) was significantly increased in DOR ($p = 0.0099$) and negatively correlated with AMH ($p = 0.0182$) and AFC ($p = 0.0001$). Despite IL1RN increase, IL1B/IL1R1 balance was still functional and positively correlated with FSH serum level ($p = 0.0147$ and $p = 0.003$). We observed that, the percentage of circulating neutrophil was significantly increased in DOR and was associated with AMH decrease. Curiously, the major neutrophil chemotactic factor, IL8, was significantly increased in DOR ($p = 0.0001$) and negatively correlated with AMH ($p = 0.0135$) and AFC ($p = 0.0001$). It is important to note that, IL8 and IL1RN mRNA were positively associated with age ($p = 0.0105$ and $p = 0.0001$, respectively). These results indicate that IL1B–IL1R1 axis over expression is correlated with DOR process, and IL8 and IL1RN over expression is correlated with DOR and ovarian ageing process, which can be linked to blood neutrophil count.
Limitations, reasons for caution: We presented a pilot study which needs further investigation. Due to low sample material, only mRNA expression can be assessed.
Wider implications of the findings: Identifying ovarian immune bias as responsible for the DOR would be a new way to manage infertility. To the best of our knowledge, it is the first time that immune mediator expression by CC is linked with DOR, ageing and neutrophil, has been reported.
Trial registration number: NA.

P-722 High AMH doesn't guarantee high pregnancy rate in old patients: AMH should be interpreted with age for outcome prediction of IUI or IVF

Y. Ku[1], J. Jeong[1], K.Y. Moon[1], C.W. Choo[1], S.J. Chae[1], K.S. Lim[1], W.D. Lee[1], J.H. Lim[1]
[1]*Maria Fertility Hospital, OBGY, Seoul, South Korea*

Study question: Is pregnancy rate in old patients who have high AMH levels comparable with that in young patients after IUI or IVF?
Summary answer: AMH should be interpreted with age, because IUI or IVF pregnancy rates in old patients with high AMH are lower than those in young patients.
What is known already: AMH is related with ovarian function. AMH is higher in younger patients and higher levels of AMH corresponded to higher pregnancy rates. However, some young patients have lower AMH levels than average for their age and some old patients have high AMH levels. Whether certain AMH level in old patients can be interpreted the same as the similar AMH level in young patients in is yet to be elucidated.
Study design, size, duration: In this retrospective cross sectional study IUI cycles from January 2014 to July 2015 and IVF cycles from January 2015 to August 2015 were reviewed. Data were collected when their AMH levels were available within a year from IUI or ovum pick-up day.
Participants/materials, setting, methods: 1,044 cycles of IUI and 952 IVF cycles were reviewed. Patients were divided into 2 age groups; 1) young age group (age < 40, $n = 1.549$), 2) old age group (age 40 or more, $n = 447$). AMH percentiles were calculated in each age group and pregnancy rate were estimated depending on age-adjusted AMH percentiles.
Main results and the role of chance: Subgroups were defined depending on AMH percentiles in each age group and AMH cut off values were as follows; 0.73, 0.10 for 5 percentile, 1.20, 0.30 for 10 percentile, 2.27, 0.60 for 25 percentile, 3.91, 1.39 for 50 percentile, 6.56, 2.85 for 75 percentile, 9.79, 5.78 for 90 percentile, 13.41, 8.35 for 95 percentile in young and old age group, respectively. Pregnancy rate of IUI in less than 5 percentile AMH percentile subgroup in young patients was lower (7.1%) than those in other subgroups (23.7%, 16.1%, 12.9%, 17.9%, 19.7%, 27.5% and 26.8% for 10, 25, 50, 75, 90, 95, 95 percentiles or more, respectively). Pregnancy rates of IVF were similar between subgroups in young patients (34.5%, 36.6%, 37.5%, 46.4%, 49.5%, 45.6%, 35.0% and 41.7% in ascending order). In old patients pregnancy rate after IUI were similar between subgroups (0%, 0%, 8.3%, 4.3%, 16.0%, 0%, 0% and 0% in ascending order). While IVF success rates were higher in more than 50 percentile subgroups (18.4%, 18.1%, 20.8%, 29.4% and 66.7% for 50, 75, 90, 95, more than 95 percentile subgroups, respectively) than those in lower AMH percentile subgroups (0%, 0% and 10.9% for 5, 10, 25 percentile subgroups, respectively).
Limitations, reasons for caution: AMH percentile was calculated in study population. Age-adjusted AMH percentile cut off might be changed when investigated in larger group. Further study is necessary to extrapolate this result to general infertile population.
Wider implications of the findings: Pregnancy rate of IUI is low in young patients with low AMH while IVF success rate is maintained. In old patients pregnancy rate of IUI is low regardless of their AMH. Old patients with high AMH level might have benefit from IVF because pregnancy rate is much higher than IUI.
Trial registration number: This is retrospective study.

P-723 Effect of oral contraceptives on change in endocrine and metabolic profiles of women with polycystic ovary syndrome; 1-year follow-up preliminary cohort study

Y.J. Kim[1], S.H. Yoon[2], H.S. Whang[1], K.W. Yi[1], H.T. Park[1], J.H. Shin[1], T. Kim[1], J.Y. Hur[1]
[1]*Korea University Guro Hospital, OB-GYN, Seoul, South Korea*
[2]*Graduate School of Medicine- Dongguk University, OB-GYN, Seoul, South Korea*

Study question: To evaluate the effects of oral contraceptives (OC) on change in endocrine and metabolic profile of women with polycystic ovary syndrome (PCOS) for 1 year.
Summary answer: Long term use of OC could change endocrine and metabolic profile of women with PCOS.
What is known already: PCOS is a common reproductive endocrine disease that is seen among women of reproductive age. OC is commonly used to manage the symptoms of menstrual irregularity and a- or oligo-menorrhea. Although this medication have been beneficial in treating PCOS symptoms, its effect on endocrine and metabolic profile with long time follow-up is still not entirely elucidated.

Study design, size, duration: Fifty-two of women with PCOS diagnosed by Rotterdam criteria were recruited to check endocrine and metabolic profile with annual follow-up in this preliminary cohort study, and there was no attrition.
Participants/materials, setting, methods: Before and after 1-year OC use, endocrine and metabolic profile as the followings were checked in women with PCOS; BMI, basal and PP2 insulin, basal and PP2 glucose, HOMA-IR, cholesterol, triglyceride, HDL, LDL, HbA1c, CRP, estradiol, FSH, LH, AMH, Testosterone, SHBG, free androgen index (FAI), DHEAs, 17-α-OHP, TSH, prolactin. Data were analyzed by Paired *t*-test and McNemar's test where appropriate.
Main results and the role of chance: Among endocrine profiles, basal insulin (10.5 μIU/mL vs. 12.8 μIU/mL, $P = 0.017$), SHBG (63.1 nmol/L vs. 154.9 nmol/L, $P < 0.001$) and DHEAs (185.3 μg/dL vs. 220.5 μg/dL, $P = 0.011$) were increased, and testosterone (1.2 ng/mL vs. 0.7 ng/mL, $P < 0.001$), 17-α-OHP (2.4 ng/mL vs. 1.1 ng/mL, $P = 0.002$) and AMH (15.6 ng/mL vs. 11.6 ng/mL, $P = 0.003$) were decreased after 1-year OC use. In metabolic profiles, triglyceride (83.2 mg/dL vs. 124.0 mg/dL, $P = 0.015$) was increased with 1-year OC use. HOMA-IR was similar although FAI (9.8 vs. 4.7, $P < 0.001$) was decreased by 1-year OC use. Before and after 1-year OC use, women with abnormal HOMA-IR (>2) were 40.0% and 64.4% ($P = 0.901$), and women with abnormal FAI (>4) were 73.3% and 37.8% ($P = 0.487$).
Limitations, reasons for caution: Further study should be necessary with larger sample size and longer follow-up over 5-year.
Wider implications of the findings: One-year OC use could change hormonal status and lipid profiles although it could not change proportion of women with androgen excess significantly. Effect of longer OC use over 1 year should be evaluated in further study.
Trial registration number: 2012-11-0022 (KUGH13147-004).

P-724 Assessment of the Access AMH assay as an automated, high-performance replacement for the AMH Generation II manual ELISA

K. Pearson[1], M. Long[2], J. Prasad[2], Y.Y. Wu[3], M. Bonifacio[4], S. McArthur[5]
[1]*Genea, Biochemistry, Canberra, ACT, Australia*
[2]*Genea, Biochemistry, Sydney, NSW, Australia*
[3]*Genea, Biochemistry, Liverpool, NSW, Australia*
[4]*Genea, Pathology, Sydney, NSW, Australia*
[5]*Genea, Science Commercialisation, Sydney, NSW, Australia*

Study question: To evaluate the performance of the Access Anti Müllerian Hormone (AMH) assay and directly compare it to the modified Generation II (Gen II) ELISA method.
Summary answer: The Access AMH automated assay exhibits high levels of stability and sensitivity, and results correlate with the existing ELISA method and between analyser platforms.
What is known already: A number of AMH immunoassays have been developed in the past; however, a lack of standardisation and technical issues has led to confusion in interpretation of results and scepticism of AMH test reliability. The manual Gen II ELISA method used to measure AMH from Beckman Coulter has recently been superseded by a fully automated AMH immunoassay for both the Access2 and DxI800 instruments. Studies have revealed good correlation between the Gen II and Roche Elecsys AMH assays; however, consensus on correlation between the Gen II ELISA and the new Access AMH assay has not been reached.
Study design, size, duration: The precision, stability, linearity, measurement range and detection limits were established and a correlation study was performed ($n = 142$) to compare the Access AMH assay to the ELISA method using Passing–Bablok and Bland–Altman methods of comparison. A double blinded retrospective observational study was conducted ($n = 492$) to verify that a fertile age-related AMH range previously established using the Gen II ELISA could be used to interpret results from the new automated Access assay.
Participants/materials, setting, methods: The Beckman Coulter Access AMH immunoassay was assessed for use on the Access2 and DxI800 analysers using de-identified patient sera and quality control or calibrator material consisting of human recombinant AMH. The fertile AMH reference range was conducted on 492 pregnant women in their first trimester, aged between 20 and 44 years, who had all conceived spontaneously without the use of ovarian stimulation drugs within 2–3 months of attempted conception.
Main results and the role of chance: The Access AMH assay showed good performance across the measuring range for both intra-assay (CV 1.41–3.30%) and inter-assay (CV 3.04–5.76%) precision and acceptable sample stability. The assay was linear over the range of values recommended by the manufacturer, allowing for accurate reporting within the reported range. The two assay types correlated tightly ($R^2 = 0.9822$ and 0.9832 for Access2 and DxI800), and differences observed between the Access2 and DxI800 analysers were within clinically acceptable ranges, indicating that the methods are interchangeable. Furthermore, we demonstrated that results from a published fertile reference range for the Gen II ELISA correlate with those from the automated Access AMH assay (CV 6.7%).
Limitations, reasons for caution: Samples for the correlation studies required freeze/thawing between testing which may have been a source of sample bias. Limitations of this study include that the reference range is only representative of women with proven fertility and is only applicable to the Beckman Coulter AMH Gen II ELISA and Access assays.
Wider implications of the findings: This study verified the published performance of the Access AMH assay and demonstrates that results from the preceding Gen II ELISA are interchangeable with the new automated Access assay. These findings are an encouraging step towards the necessary establishment of universal cut-off values and the standardisation of AMH assay results.
Trial registration number: None.

P-725 Clomiphene, metformin, letrozole, tamoxifen or combined clomiphene-metformin for polycystic ovary syndrome – a systematic review and individual participant data network meta-analysis

Study question: Which is the most effective pharmacologic ovulation induction therapy for women with polycystic ovary syndrome (PCOS)?
Summary answer: In treatment-naïve women with PCOS, the relative effectiveness of letrozole over other drugs is the highest in women with a high BMI.
What is known already: In women with anovulatory infertility PCOS, Clomiphene has been considered as the first-line pharmacologic therapy for ovulation induction for decades. Clinical decision making based on pairwise meta-analyses does often not reflect the whole picture. A recent network meta-analysis on WHO group II anovulation concluded that letrozole and combined clomiphene–metformin are probably superior to other treatments, including clomiphene alone. However, several included studies in this network meta-analysis also contain women with ovulation induction history.
Study design, size, duration: We performed an individual participant data (IPD) network meta-analysis. We searched MEDLINE, EMBASE and Cochrane Central Register of Controlled Trials databases up to October 2015 without language restrictions and conducted a systematic review and IPD network meta-analysis on relevant randomised controlled trials (RCTs). The primary outcome was clinical pregnancy rate, with live birth, miscarriage, and multiple pregnancy rates as secondary outcomes.
Participants/materials, setting, methods: We included RCTs comparing at least two of following interventions in treatment-naïve women with PCOS: clomiphene, metformin, combined clomiphene–metformin, letrozole and tamoxifen. Studies were excluded if they did not at least partly include treatment-naïve women. First, we performed an aggregate network meta-analysis using a random-effects multiple regression model in STATA. For studies also including treatment-experienced women, only IPD of treatment-naïve women was used. We then performed subgroup analyses using IPD.

Main results and the role of chance: For the aggregate network meta-analysis, we detected 21 trials comprising of 2,500 treatment-naïve women with PCOS across five interventions. Compared to clomiphene, letrozole (odds ratio [OR] 1.79, 95% confidence interval [CI] 1.18–2.70) and combined clomiphene–metformin (OR 1.67, 95% CI 1.03–2.70) resulted in statistically significant higher pregnancy rates. IPD of 1,291 women with PCOS from eight trials in the USA, The Netherlands, New Zealand, India and Italy were provided by authors. Subgroup analyses on body mass index (BMI) showed that only in the highest BMI tertile (BMI > 32.5), letrozole led to higher clinical pregnancy rate than clomiphene (OR 2.88, 95% CI 1.04–7.93) and metformin (OR 14.85, 95% CI 2.47–89.27) alone. In women with a BMI ≤ 32.5, there were no differences between interventions in any of the subgroups.
Limitations, reasons for caution: Only 52% IPD of all participants could be used for this abstract. Since several other authors have agreed to share their IPD, this proportion is expected to increase. Additionally, the included studies are clinically heterogeneous in many aspects including diagnostic criteria, patient characteristics, dosage and duration of the interventions.
Wider implications of the findings: Two major issues limited the application of several major multi-centre RCTs on ovulation induction: 1) not all women were treatment-naïve; 2) not all interventions were compared directly. The current IPD network meta-analysis addressed these problems and updates the current evidence. However, long-term follow-up is still urgent for pharmacologic ovulation induction.
Trial registration number: None.

P-726 Gonadotropin-releasing hormone agonist versus hCG for triggering of final follicular maturation in GnRH antagonist protocol – differential effects on day 3 embryo quality

V. Dinopoulou[1], S. Liarmakopoulou[1], C. Anagnostopoulou[1], M. Fligou[1], A. Siozou[1], T. Moustakarias[1], D. Giannaris[1], E. Makrakis[1]
[1]*Embryo A.R.T., IVF Unit, Athens, Greece*

Study question: Does triggering of final follicular maturation with Gonadotropin-releasing hormone (GnRH) agonist instead of hCG in GnRH antagonist protocol improve the quality of Day 3 embryos?
Summary answer: The percentage of Grade I embryos on Day 3 is significantly higher in patients triggered with GnRH agonist vs. hCG in GnRH antagonist protocol.
What is known already: The introduction of GnRH antagonists in controlled ovarian hyperstimulation protocols has brought a renewed interest in the use of GnRH agonist to trigger final follicular maturation, causing a surge of both endogenous FSH and LH, mimicking the natural cycle surges and therefore considered to be more "physiologic." There is an extensive body of evidence demonstrating that triggering with GnRH agonist (vs. hCG) had no differences in the number of oocytes retrieved, percentage of MII oocytes and fertilization rates, whereas it seems that can almost eliminate ovarian hyperstimulation syndrome (OHSS).
Study design, size, duration: In the present prospective cohort study were included 44 consecutive subjects at risk for OHSS undergoing *in vitro* fertilization (IVF) treatment cycles, between January 2014 and December 2015.
Participants/materials, setting, methods: Controlled ovarian stimulation was applied with GnRH antagonist protocol. The study group (21 women) received for triggering a single bolus of GnRH agonist (0.2 mg) vs. rhCG (250 μg) the control group (23 women). Decision of triggering was based on the estradiol levels and the number of developed follicles. Oocyte retrieval was performed 34–36 h later, followed by simple IVF or ICSI. Embryos were cultured until day 3 and graded according to the established criteria.
Main results and the role of chance: No significant differences were observed between patients triggered by GnRH agonist vs. hCG in terms of age (35.05 ± 4.65 vs. 35.39 ± 4.63, respectively) and FSH levels (6.08 ± 1.41 mIU/mL vs. 5.89 ± 0.88 mIU/mL, respectively). In the group triggered with GnRH agonist, the average estradiol levels on the day of ovulation triggering was significantly higher compared to the group triggered with hCG (6173.86 ± 1513.417 pg/mL vs. 4132.00 ± 1541.18 pg/mL, respectively, $p < 0.01$). No significant differences were seen between the two groups in terms of the number of oocytes retrieved (22.52 ± 8.24 vs. 21.96 ± 3.07, respectively) as well as the number of MII oocytes (18.24 ± 6.94 vs. 17.09 ± 4.13, respectively). Regarding embryo quality on Day 3, percentage of grade I embryos was significantly higher in the study group (GnRH agonist trigger) compared to that in the control group (hCG trigger) (69.48% vs. 56.88%, respectively, $p < 0.01$); percentage of grade II+III embryos was significantly lower in the study group (GnRH agonist trigger) compared to the control group (hCG trigger) (30.15% vs. 42.38%, respectively, $p < 0.01$). Interestingly, no differences in pregnancy rates were seen between the two groups (56% vs. 65%, respectively).
Limitations, reasons for caution: A limitation of our study is its small number of cases. Some caution is also warranted in interpreting the pregnancy rates due to the fact that all the women triggered with GnRH agonist (GnRHa) had frozen–thawed embryo transfer whereas women triggered with hCG had either fresh or frozen–thawed embryo transfer.
Wider implications of the findings: Studies that compared the effect of GnRHa trigger vs. hCG on the number of top-quality embryos concluded that they are either comparable or in favor of GnRHa trigger. Following our observations, in patients at risk to develop OHSS, GnRHa improves embryo quality on Day 3 resulting in improved reproductive outcome.
Trial registration number: Not applicable.

P-727 Follicular flushing in natural cycle IVF neither affects the length of the luteal phase nor the luteal body hormone production – a prospective controlled study

S. Rohner[1], M. Fäh[1], G. Otti[1], A. Kohl Schwartz[1], P. Stute[1], R. Schürch[2], M. von Wolff[1]
[1]*University Women's Hospital, Division of Gynecologic Endocrinology and Reproductive Medicine, Berne, Switzerland*
[2]*CTU Berne, Department of Clinical Research and Institute of Social and Preventive Medicine ISPM University of Berne, Berne, Switzerland*

Study question: Does follicular flushing in Natural Cycle IVF (NC-IVF) affect the length of the luteal phase and the luteal phase concentrations of progesterone and 17beta-estradiol?
Summary answer: Follicular flushing in NC-IVF does affect neither the length of the luteal phase nor the luteal phase concentrations of progesterone and estradiol.
What is known already: In contrast to multifollicular IVF, follicular flushing increases the efficacy of monofollicular IVF such as NC-IVF by higher oocyte yield and higher transfer rates according to two retrospective studies. However, as follicular flushing causes loss of granulosa cells, follicular flushing might negatively affect the formation and endocrine function of the luteal body, requiring luteal phase support with progesterone and possibly also estrogen.
Study design, size, duration: A prospective cohort phase II study was performed with 24 women undergoing NC-IVF in 2013 and 2015. Follicle flushing was expected to reduce luteal phase length (primary outcome) and decrease luteal phase progesterone and estradiol concentrations (secondary outcome). 22 women were required to detect a shortening of the luteal phase due to flushing of the follicles. Data were analysed using a paired Wilcoxon signed rank test with continuity correction for each time point separately.
Participants/materials, setting, methods: Women (age 18–40 years) with regular menstrual cycles (26–32 days) and AMH-concentrations >5 pmol/L were screened at a University based infertility center. Women first underwent a training cycle with HCG induced ovulation, followed by the analysis of the length of luteal phase and concentrations of progesterone and estradiol on day 2–3, 6–7 and 10–11 post ovulation. A second (NC-IVF) flushing cycle was identically performed but follicles were aspirated and flushed 3–5 times.
Main results and the role of chance: 49 women were screened, 46 were enrolled and 24 women finalized the study. The high drop out rate of 52% was due to 11/46 women who became pregnant during the first cycle and 11/46 women who preliminarily stopped the study due to other reasons. Data of luteal phase length was complete in 23/24 women. In 7 of these women luteal phase was shorter (29.2%), in 4 women luteal phase length was equal (16.7%) and in 12 women luteal phase was longer (50.0%) following flushing of the follicles. Overall, the difference in luteal phase length was not significant (median duration [interquartile range] in training cycle: 13 [12; 14.5], flushing cycle: 14 [12.5; 14.5], median difference (95% CI): 0.5 (−0.5 to 1.5); paired Wilcoxon signed rank test: $V = 116.5$, $p = 0.391$). Median progesterone and estradiol concentrations did not differ significantly in the flushing cycle compared to the training cycle (median difference (95% CI) in progesterone [pmol/L], early in cycle: −5.2 (−11.2 to 1.3); mid: 1.1 (−6.6 to 8.7); late: −1.2 (−10.2 to 6.1); median difference (95% CI) in estradiol [pmol/L], early: 65.0 (−3.5 to 172.5); mid: 31.1 (−104.5 to 199.0); late: −17.2 (−135.0 to 85.5); all $p > 0.05$).

Limitations, reasons for caution: The study was not designed to analyse the impact of follicle flushing on pregnancy rates. The conclusion that women might not need luteal phase support in NC-IVF is only based on the study parameters but not on pregnancy rates.
Wider implications of the findings: NC-IVF is favoured by many women due to lower treatment induced psychological stress and lower costs. The result of the study suggest that luteal phase support is not required in NC-IVF, even if the follicles are flushed, thereby allowing further treatment simplification by avoiding uncomfortable luteal phase support.
Trial registration number: KEK-BE 206/12

P-728 Identification of differentially expressed long non-coding RNAs in follicular granulosa cells from polycystic ovary syndrome patients and controls

Z. Yan[1], Y. Kuang[1], L. Wang[2]
[1]*Shanghai Ninth People's Hospital Affiliated to Shanghai Jiao Tong University, Assisted Reproductive Technology, Shanghai, China*
[2]*School of Life Sciences, Fudan University, State Key Laboratory of Genetic Engineering and MOE Key Laboratory of Contemporary Anthropology, Shanghai, China*

Study question: What roles of LncRNAs in pathology of PCOS?
Summary answer: There are some differentially expressed LncRNAs between PCOS patients and controls.
What is known already: Long non-coding RNAs (lncRNAs) are molecules longer than 200 nucleotides with non-protein coding transcripts. Until now, a number of lncRNAs have been identified. Many lncRNAs have significant impact on transcriptional and translational output and many studied have shown that lncRNAs play a key role in regulating diverse cellular processes, which contain intracellular trafficking, chromatin remodeling, transcription and post-transcriptional processing.
Study design, size, duration: PCOS patients in IVF/ICSI were referred from the reproductive medicine center at Ninth Hospital affiliated with Shanghai Jiao Tong University from January 2013 to December 2015.
Participants/materials, setting, methods: The follicular granulosa cells used in this study were obtained from patients and controls. Total RNA was extracted by using the AllPrep DNA/RNA/miRNA Universal kit. The fluorescence labeled cRNA targets for the Agilent Human lncRNA 4 × 180 K. KGN cells were transfected either lncRNA mimics or their controls to KGN cells with HiPerFect transfection reagent. The supernatant was measured for concentrations of estradiol with the UniCel DxI 800 immunoassay system.
Main results and the role of chance: 63,431 lncRNAs were examined in this study. A total of 1,154 lncRNAs and 853 mRNAs were identified to be significantly altered in 3 pairs of PCOS granulosa cells and controls (fold change > 2; $p < 0.05$). Of these differently expression lncRNAs, 305 lncRNAs were up-regulated and 849 were down-regulated. Out of the down-regulated lncRNAs group, lncRNA CUST_12429 has the greatest degree of down-regulation (fold change = 68.27807); and in the up-regulation group, lncRNA CUST_34147 has the greatest degree of up-regulation (fold change = 0.063102). We validated some of differentially expressed lncRNAs. We then transfected lncRNA mimics and corresponding controls into the KGN cell line. We found that lncRNA CUST_12429 regulated estradiol secretion.
Limitations, reasons for caution: Exact mechanism of LncRNAs in PCOS should be explored further in the future. Target genes and pathways should also be explored.
Wider implications of the findings: This study identified a number of LncRNAs in granulosal cells and laid a foundation for investigating roles of LncRNAs in pathology of PCOS.
Trial registration number: Not required.

P-729 Impact of polymorphisms of gonadotropins and their receptors on controlled ovarian stimulation: a prospective observational study

C. Alviggi[1], A. Conforti[1], F. Cariati[2], S. Alfano[1], I. Strina[1], I. Huhtaniemi[3], D. Santi[4], G. De Placido[1], P. Humaidan[5]
[1]*Universita Federico II – University of Naples, Dipartimento di Neuroscienze e Scienze Riproduttive ed Odontostomatologiche, Napoli, Italy*
[2]*Universita Federico II – University of Naples, CEINGE-Biotecnologie Avanzate, Napoli, Italy*
[3]*Faculty of Medicine, Department of Surgery and Cancer, London, UK*
[4]*University of Modena and Reggio Emilia, Unit of Endocrinology, Department of Biomedical, Metabolic and Neural Sciences Center for Genomic Research, Modena, Italy*
[5]*Aarhus University, The Fertility Clinic, Skive Regional Hospital and Faculty of Health, Skive, Denmark*

Study question: Which effect do polymorphisms of gonadotropins and their receptors have on stimulation outcomes in IVF patients co-treated with a GnRHa long down-regulation protocol?
Summary answer: Allele C of FSHR-29, LHCGR-291 and FSHR-680 all resulted in a significantly increased cumulative *r*-FSH dose: total number of oocytes or mature oocytes ratio.
What is known already: Specific polymorphisms might influence controlled ovarian stimulation in women undergoing IVF/ICSI. Data regarding the possible interactions of these polymorphisms are still scanty, especially as regards LHCG-R polymorphisms.
Study design, size, duration: Prospective observational study in 100 normogonadotropic IVF/ICSI patients came from three public IVF Units.
Participants/materials, setting, methods: Normogonadotropic Caucasian women fulfilling the following inclusion criteria were enrolled: age 20–34 years; BMI 20–27 kg/m2; basal FSH ≤ 10 IU/l; functional ovaries. Exclusion criteria were: uterine anomalies; endocrine, genetic or immunological disorders; PCOS; history of impaired ovarian response (≤ 4 oocytes retrieved) in at least one IVF/ICSI cycle. Patients underwent a GnRH long down-regulation protocol with a starting dose of 150 IU of recombinant FSH daily. Six polymorphisms were genotyped.
Main results and the role of chance: The following polymorphisms were analyzed: FSHR-680 (rs6166); FSHR-min29 (rs1394205); LHCGR intronic (rs4073366); LHCGR-291 (rs 12470652); LHCGR-312 (rs2293275); FSHβ-2623 (rs6169).

Basal FSH levels were significantly lower in homozygotic carriers of FSHR-630 (T/T) than in heterozygotic C/T ($p = 0.023$). Lower basal estradiol levels were seen in homozygotic carriers of FSHR-29 promoter C/C compared to heterozygotic C/T ($p = 0.045$). Basal estradiol levels and number of fertilized and mature oocytes were lower in homozygotic carriers of LHCGR-291 (T/T) compared to heterozygotic C/T ($p = 0.035$ and $p = 0.05$ respectively). The presence of allele C on both FSHR-min29 and LHCGR-291 caused an increased ratio between the cumulative r-FSH consumption and the total number of oocytes as well as mature oocytes (RR: 5.47, CI 95%: 3.13–7.81, $p < 0.001$). This observation was also confirmed when polymorphisms of FSHR-680 were included in the analysis. Specifically, the presence of allele C on these three genes was related to an increased ratio between the cumulative FSH consumption and the total number of oocytes or mature oocytes (RR: 5.44, CI 95%: 3.18–7.71, $p < 0.001$).
Limitations, reasons for caution: Although limited by the small size of the population, these findings confirm a possible interaction between multiple polymorphisms in assisted reproductive technology.
Wider implications of the findings: These data support the concept that the ovarian response to exogenous FSH seems to be determined by the interaction of specific genetic traits. Moreover, this study shows an involvement of the LHCGR-291 polymorphism in ovarian response to exogenous gonadotropins.
Trial registration number: Not applicable.

P-730 Outcome after non-hCG triggered serum-free IVM in patients with PCOS: a freeze-or-fresh transfer strategy based on number of available embryos

M. De Vos[1], I. Segers[1], S. Santos-Ribeiro[1], B. Popovic-Todorovic[1], G. Verheyen[1], H. Tournaye[1], J. Smitz[2]
[1]*UZ Brussel, Centre for Reproductive Medicine, Jette, Brussels, Belgium*
[2]*UZ Brussel, Laboratory of Clinical Chemistry and Radioimmunology, Brussels, Belgium*

Study question: What is the outcome of IVM using a strategy of fresh blastocyst transfer or freeze-all d3/frozen embryo transfer (FET), depending on the number of available embryos?
Summary answer: After non-hCG triggered IVM, a strategy of fresh blastocyst transfer or freeze-all d3/FET results in equivalent cumulative ongoing pregnancy rates (OPR).

What is known already: After minimal-stimulation, non-hCG triggered IVM and blastocyst transfer, clinical pregnancy rates of >40% per cycle have been reported in patients with PCOS. However, blastocyst yield after IVM is lower than after IVF. When IVM embryos are transferred freshly at cleavage stage, reported clinical outcomes are dramatically low but they can be significantly improved using a freeze-all strategy, followed by FET in an artificial cycle. The clinical potential of a dual strategy combining high pregnancy rates and low cancellation rates, based on the available number of good-quality d3-embryos after IVM, is currently unknown.
Study design, size, duration: This study is a cohort analysis of retrospective data from the first IVM cycle of 195 Rotterdam-PCOS patients treated at a tertiary university based infertility centre between April 2014 and October 2015.
Participants/materials, setting, methods: Consecutive patients between 20 and 41 years underwent non-hCG triggered IVM (30 h) after a short course of HP-hMG. Patients were planned to undergo fresh blastocyst transfer if ≥ 4 good-quality d3-embryos were available and endometrial thickness was >7 mm at oocyte retrieval. Otherwise, the d3-embryos were vitrified and transferred in an artificial FET cycle. Ongoing pregnancy rates after the first embryo transfer and cumulative ongoing pregnancy rates were calculated.
Main results and the role of chance: The overall oocyte recovery rate per follicle was approx. 50%. Forty-nine patients (25.1%) consented to donate on average 8.6 oocytes for scientific research. The maturation rate adjusted for the loss of oocytes donated for research was 49.2%. On average, 8.7 MII oocytes were available for the patient after IVM. The fertilisation rate was 66.7%. The overall OPR was 41% per cycle (80/195). No embryo was available for transfer or cryopreservation in 25 cycles (12.8%). Seventy patients had fresh transfer of 1.1 ± 0.3 blastocysts, resulting in 28 ongoing pregnancies (40.0%) and 8 clinical miscarriages (11.4%). None of the patients developed OHSS. Of the 96 patients who had a freeze-all policy, 78 did so because <4 embryos were available on day 3 after ICSI. Of these, 75 underwent at least one FET cycle. Seven patients had no FET because no embryo survived after warming. Sixty-eight patients had 1.31 ± 0.46 embryos transferred in their first FET cycle, resulting in 21 ongoing pregnancies (30.9%) and 5 clinical miscarriages (7.3%). Similar cumulative ongoing pregnancy rates were obtained after fresh + vitrified-warmed blastocyst transfers (45.7%) and after freeze all d3 strategy followed by FET (44.1%), $p = 0.85$.
Limitations, reasons for caution: This cohort analysis is based on retrospective data collection, with potential biases related to this design. Divergent treatment strategies are compared between different patient groups, depending on number of available embryos. Randomised trials are needed to demonstrate the true performance of fresh embryo transfer and FET after IVM.
Wider implications of the findings: Embryos generated after IVM have good implantation potential. The cut-off of 4 good-quality d3 embryos to perform fresh blastocyst transfer after IVM combines good clinical outcomes with low cycle cancellation rates. The observation of similar outcomes after cumulative transfer of day 3 embryos compared to blastocysts needs further scrutiny.
Trial registration number: none.

P-731 The opiate antagonist naloxone reduces the release of VEGF from primary granulosa cells of PCOS women

F. Lunger[1], A. Vehmas[2], B. Fürnrohr[3], S. Sopper[4], L. Wildt[1], B. Seeber[1]
[1]*Medical University of Innsbruck, Department for Gynecologic Endocrinology and Reproductive Medicine, Innsbruck, Austria*
[2]*University of Turku, Turku Centre for Biotechnology, Turku, Finland*
[3]*Medical University of Innsbruck, Division of Biological Chemistry, Innsbruck, Austria*
[4]*Medical University of Innsbruck, Department of Internal Medicine V Haematology and Oncology, Innsbruck, Austria*

Study question: How do granulosa cells from PCOS women respond to the opiate antagonist naloxone and is this affected by the presence of insulin?
Summary answer: Exposure of granulosa cells from PCOS women to naloxone induces a decrease in VEGF secretion, even in the presence of insulin.
What is known already: We recently reported for the first time that human primary granulosa cells express OPRM1, the main opiate receptor, on their surface. OPRM1 signaling appears to be functionally coupled to the VEGF signaling pathway. Blockade of OPRM1 by naloxone resulted in a decrease in granulosa cell-derived VEGF release, a phenomenon observed in both cell line (COV434) granulosa cells as well as human primary granulosa luteal cells.
Study design, size, duration: Granulosa cells from PCOS women and controls were challenged *in vitro* with the opiate antagonist naloxone, insulin or both. After 72 h of culture, the concentrations of VEGF in culture supernatant were measured by ELISA. The viable cell number in each well was assessed using a viable cell count assay (CCK-8)
Participants/materials, setting, methods: Primary granulosa cells were isolated from follicular fluid of women undergoing oocyte retrieval for IVF using a density gradient. The study included 12 women with PCOS according to Rotterdam criteria and 12 control women with male factor and/or tubal factor infertility. Granulosa cells were challenged with naloxone, recombinant insulin or both. The concentration of VEGF in culture supernatant was measured using a commercially available immunoassay. Results between groups were compared using a repeated measures ANOVA.
Main results and the role of chance: After 72 h of culture, baseline VEGF levels from PCOS granulosa were significantly higher compared to the control cohort ($p = 0.0268$). When granulosa cells were exposed to naloxone alone (2 ng/ml, 10 ng/ml), a significant reduction in the concentration of VEGF in culture supernatant was observed in both the PCOS ($p = 0.0396$, $p = 0.0003$) as well as the control groups ($p = 0.0010$, $p = 0.0098$). Incubation with insulin alone led to a significant increase in VEGF levels in PCOS granulosa cells ($p = 0.0473$), but not in granulosa cells obtained from controls ($p = 0.387$). The addition of naloxone attenuated the insulin effect, resulting in a decrease in VEGF below baseline levels ($p = 0.0087$).
Limitations, reasons for caution: The study comprised only *in vitro* experiments. Although naloxone is a highly specific OPRM1 antagonist, a low affinity for other opiate receptor subtypes cannot be excluded at the concentrations used in the experimental setup.
Wider implications of the findings: This study adds to the existing new evidence about the role of opioids in regulating granulosa cell function and demonstrates differences between PCOS and non-PCOS cells. The results hold promise for novel therapeutic options in the prevention and/or treatment of OHSS by targeting the opiate signaling system.
Trial registration number: Basic research.

P-732 A review of 300 consecutive new referrals with polycystic ovarian syndrome: presentation and management choices

K. Rathod[1], M. Modarres[1], B. Nusair[1], V. Minns[1], P. Purohit[1], M. Savvas[1], H. Hamoda[1]
[1]*Kings College Hospital, Gynecology, London, UK*

Study question: To review the demographic details, presenting symptoms, biochemical features and management in women with polycystic ovarian syndrome.
Summary answer: A significant proportion of women with amenorrhoea who met the Rotterdam PCOS definition Criteria were hypo-oestrogenic suggesting a superimposed hypothalamic component.
What is known already: Polycystic ovary syndrome (PCOS) is a common heterogeneous endocrine disorder characterized by irregular menses, hyperandrogenism, and polycystic ovaries. The prevalence of PCOS varies depending on which criteria are used to make the diagnosis, but is as high as 15%–20%. Criteria commonly used to define PCOS is that of Rotterdam consensus of 2003. Clinical manifestations include oligomenorrhoea or amenorrhea, hirsutism and frequently infertility.
Study design, size, duration: Retrospective observational study of 300 cases with PCOS referred to the reproductive endocrinology clinic in a tertiary referral hospital from 2008 to 2015.
Participants/materials, setting, methods: Electronic medical records were reviewed to screen cases of PCOS and Microsoft Excel software was used for data collection and analysis.
Main results and the role of chance: The mean (±SD) age was 30 (±6.7) years [range 14–49]. 180 (60%) women were Caucasian, 60 (20%) were Afro-Caribbean, while 60 (20%) were Asian. 226 (75.3%) were nulliparous.

A total of 213 (71%) had oligomenorrhoea, 61 (20.3%) had amenorrhoea, while 26 (8.6%) had regular cycles. 135 (45%) presented with subfertility, while 93 (31%) had hirsutism.

Mean (±SD) FSH and LH were 5.5 IU/L (±2.8) and 17.8 IU/L (±7.9), respectively, while mean (±SD) estradiol level was 253.4 pmol/L (267.1). 27/61 (44.2%) women with amenorrhoea, had low estradiol (<176 pmol/l). Three (1%) women had elevated prolactin levels. Mean (±SD) anti-Mullerian

hormone (AMH) was 44.6 pmol/L (±33.1). 39/45 (87%) had elevated AMH while 6/45 (13%) had normal levels.

Mean (±SD) testosterone level was 2.0 nmol/L (±1.5) and 22 (7.3%) patients had elevated testosterone levels. 20/43 (47% of women assessed) had elevated androstenedione levels. Lipid abnormalities was noted in 13/44 (29.5% of women assessed) and 13/28 (46.4% of women assessed) had raised HbA1C. In a total of six (2%) patients, the ovaries did not appear polycystic.

100/300 (33.3%) women received the combined contraceptive pill, 14/300 (4.6%) had progestogens, while 190/300 (63.3%) had metformin. 48/162 (16%) were referred for fertility treatment with ovulation induction.

Limitations, reasons for caution: This was an observational and retrospective study. This needs to be taken into consideration when interpreting the data.

Wider implications of the findings: The majority of cases presented with oligo amenorrhoea, approximately half of the patients presented with subfertility and there was a high prevalence of elevated adrenal androgens and abnormal lipid profile. A significant proportion of women with amenorrhoea who met the Rotterdam PCOS definition Criteria were hypo-oestrogenic suggesting a superimposed hypothalamic component.

Trial registration number: N/A.

P-733 A novel role for circulating microRNAs in the diagnosis of endometriosis and polycystic ovary syndrome

D. Sakkas[1], E. Faure[2], S. Mahurkar-Joshi[2], W. Neuhausser[1], D. Iliopoulos[2]
[1]*Boston IVF, Waltham, MA, USA*
[2]*UCLA, Center for Systems Biomedicine, David Geffen School of Medicine, Los Angeles, CA, USA*

Study question: Do blood-based circulating microRNAs differ for In Vitro Fertilization (IVF) donors compared to patients identified with endometriosis and Polycystic Ovary Syndrome (PCOS)?

Summary answer: Circulating microRNAs may provide a novel diagnostic and prognostic marker for patients with various forms of infertility diagnosis or being treated by IVF.

What is known already: MicroRNAs are endogenous small RNA molecules which regulate the expression of multiple genes. MicroRNAs have emerged as major players in the complex network of gene regulation and have been implicated in various aspects of human disease. The spectrum of microRNAs expressed in tissues differs between normal and pathologic conditions and specific patterns of microRNAs harbor diagnostic value. In addition, it has been demonstrated that microRNA modulation may have potent therapeutic effects on a plethora of human diseases. These findings have enforced the development of microRNA-based diagnostics and therapeutics in the last few years.

Study design, size, duration: The proposed study investigated differences in microRNA expression in the plasma of women undergoing controlled ovarian hyperstimulation (COH) diagnosed with PCOS [Rotterdam Criteria] and Endometriosis [Patients with laparoscopy-confirmed diagnosis] and compared them to matched Donor oocyte cycles. Samples were collected from 20 patients from each group at the baseline of their cycle (Days 3–5) to initially identify candidate microRNAs for the different etiologies of patients.

Participants/materials, setting, methods: Total RNA was extracted from plasma samples collected on Day 3 to 5 of the cycle. The quality and integrity of the RNA samples was evaluated using the Agilent Bioanalyzer 2100. One hundred nanograms of each RNA sample was used to perform the microRNA high throughput analysis by using the Nanostring nCounter Platform enabling us to evaluate the expression levels of 800 specific microRNAs. A select number of candidate microRNAs were then validated using qPCR.

Main results and the role of chance: The analysis compared Control vs. Endometriosis, Control vs. PCOS and Endometriosis vs. PCOS. Probes were recognized as expressed if there were >25 counts in >25% of samples. We found 353 probes that passed these criteria and were subsequently used for further analyses. *T*-tests were performed to assess significance of differences between expressions. Control vs. Endometriosis and Control vs. PCOS identified 29 and 20 significantly [range $P = 0.003–0.045$] differentially expressed microRNAs, respectively. Endometriosis vs. PCO identified 21 significantly [range $P = 0.001–0.045$] different expressed microRNAs. Further confirmatory analysis initially involved selecting 2 upregulated and 2 downregulated microRNAs from each comparison. All these comparisons confirmed significantly different expression of specific microRNAs, including miR-1249, which was up-regulated in both endometriosis patients (2.2-fold) and PCOS patients (2.7-fold) relative to control samples. Furthermore, miR-555 was found to be increased 2-fold in endometriosis relative to PCOS patients. The identification of differentially expressed microRNAs by the nCounter technology and their further validation by qPCR provides encouragement that these are indeed candidate microRNAs, however further analysis of their particular pathways is needed to rule out misidentification of individual microRNA candidates.

Limitations, reasons for caution: The microRNAs identified in this initial study need to be validated in a larger subset of patients and in a blinded analysis to confidently accept their authenticity. A further limitation is that these results are correlated to our current diagnostic assumptions of both PCOS and endometriosis.

Wider implications of the findings: Improving our ability to non-surgically predict and diagnose various infertility pathologies will significantly impact the practice of IVF. The data can also contribute to improve our understanding of the complex signaling pathways involved in PCOS and endometriosis and assist in developing novel alternatives for treatment.

Trial registration number: Not Applicable.

P-734 The advantage of an immediate frozen embryo transfer following a freeze-all protocol: a retrospective analysis from 2 centres

C. Blockeel[1,2], S. Santos-Ribeiro[1,3], V.T.N. Lan[4], L. Van Landuyt[1], J. Siffain[1], S. Mackens[1], N.P. Polyzos[1,5], H. Tournaye[1]
[1]*UZ Brussel, Centre for Reproductive Medicine, Jette, Brussels, Belgium*
[2]*University of Zagreb, Department of Obstetrics and Gynaecology, School of Medicine, Zagreb, Croatia*
[3]*Santa Maria University Hospital, Department of Obstetrics, Gynaecology and Reproductive Medicine, Lisbon, Portugal*
[4]*University of Medicine and Pharmacy, Department of Obstetrics and Gynaecology, Ho Chi Minh City, Vietnam*
[5]*Faculty of Health University of Aarhus, Department of Clinical Medicine, Aarhus, Denmark*

Study question: Does the timing of the first frozen embryo transfer (FET) after gonadotropin-releasing hormone (GnRH) agonist triggering with the elective cryopreservation of all embryos affect pregnancy outcome?

Summary answer: FETs performed immediately after a freeze-all cycle were associated with higher pregnancy rates.

What is known already: As the interest and use of the freeze-all strategy expand in the field of reproductive medicine, the optimal timing to perform the subsequent FET has become increasingly important. Thus far, all clinical trials evaluating the efficacy of the segmentation strategy opted to electively defer the first FET for at least one menstrual cycle. However, this merely empirical approach may cause unnecessary distress to infertile patients eager to conceive as soon as possible.

Study design, size, duration: This retrospective cohort study included the first FET cycle of all women who underwent a freeze-all protocol between October 2010 and October 2015 in two reproductive medicine centres.

Participants/materials, setting, methods: A total of 344 FET cycles (performed in 335 patients) were included in the analysis. Following the freeze-all cycle, the preparation of the endometrium consisted of the sequential administration of estradiol valerate and micronized vaginal progesterone. The start of the FET was classified as either immediate (≤ 14 days after oocyte retrieval) or delayed (>14 days after oocyte retrieval). Clinical pregnancy rate (CPR) was the main outcome of our study.

Main results and the role of chance: No significant differences were found between the immediate and delayed FET groups regarding female age, number of oocytes retrieved, indication for the freeze-all protocol (specifically, high-risk of ovarian hyperstimulation syndrome, late-follicular progesterone >1.5 ng/mL, late-follicular endometrium <7 mm or other reasons), and the number, developmental stage and quality of the embryos transferred at FET. The CPR was significantly higher in the immediate FET group (54.0% after immediate FET vs. 39.7% after deferred FET, $p = 0.009$), even after accounting for potential confounding with the use of mixed-effects multilevel multivariable logistic regression analysis (adjusted odds ratio 0.54, 95% confidence interval 0.34–0.85, $p < 0.001$).

Limitations, reasons for caution: The results are limited by the retrospective design and the potential for unmeasured confounding. Furthermore, this study only evaluated the effect of FET timing on CPR in artificially-supplemented cycles and, thus, the results should not be extrapolated to live birth rates or natural-cycle FETs.

Wider implications of the findings: This study offers a simple but potentially relevant measure to increase the patient-satisfaction and adherence in couples who seek to become pregnant both safely and as soon as possible.
Trial registration number:/

P-735 Comparing the inter-cycle variation of serum anti-Mullerian hormone and antral follicle count measurements in predicting ovarian response before IVF

H.W.R. Li[1], T.W.Y. Yeung[1], V.C.Y. Lee[1], W.S.B. Yeung[1], P.C. Ho[1], E.H.Y. Ng[1]
[1]Queen Mary Hospital, Department of Obstetrics and Gynaecology, Hong Kong, Hong Kong

Study question: Does serum anti-Mullerian hormone (AMH) have less inter-cycle variation than antral follicle count (AFC) when used as an ovarian response predictor?
Summary answer: Inter-cycle variations were significantly less with serum AMH than AFC measurement, although both have no significant difference in their predictive performance on poor ovarian response.
What is known already: Both AMH and AFC measurements are recognized as the best markers for predicting ovarian response before IVF treatment. There was one report in the European population indicating that AMH (measured using the older ELISA) had less inter-cycle variation than AFC. However, there is no report on this in the Asian population nor using the newer generation ELISA.
Study design, size, duration: This observational study was a secondary analysis using AMH and AFC data from control subjects of another prospective clinical trial on the effect of DHEA pre-treatment. Only control subjects ($n = 45$) in the placebo arm were included in this secondary analysis. AMH and AFC measurements over four consecutive menstrual cycles before they underwent standard IVF treatment using the GnRH antagonist protocol were analysed.
Participants/materials, setting, methods: The subjects underwent IVF treatment in a university-affiliated hospital in Hong Kong. AFC was measured in the early follicular phase (between days 2–5) by transvaginal ultrasonography in four consecutive cycles, and serum was obtained on the same occasions for AMH measurement using the Gen II AMH ELISA (Beckman-Coulter). The intra-class correlation coefficients (ICC) for AFC and AMH across the four study cycles, as well as their predictive performance on poor ovarian response, were compared.
Main results and the role of chance: Subjects were aged between 30 and 40 years. No significant difference was observed in AFC ($p = 0.114$) and AMH ($p = 0.375$) across the four study cycles (Friedman's test). The single-measures ICC of AFC and AMH were 0.597 (95% CI 0.459–0.726) and 0.850 (95% CI 0.778–0.906) respectively. The average-measures ICC of AFC were 0.856 (95% CI 0.773–0.914) and 0.958 (95% CI 0.933–0.975), respectively. Hence, both single-measures and average-measures ICC were significantly higher with AMH than with AFC. The areas under the ROC curve of the four AFC measurements in predicting poor ovarian response (defined as three or less oocytes retrieved) in the subsequent IVF cycle ranged from 0.693 (95% CI 0.536–0.844) to 0.818 (95% CI 0.672–0.918) with no significant difference ($p > 0.05$) between the four cycles, whereas those of the four AMH measurement ranged from 0.785 (95% CI 0.636–0.895) to 0.821 (95% CI 0.676–0.920) with no significant difference ($p > 0.05$) between the four cycles.
Limitations, reasons for caution: This was a secondary analysis on data obtained from another clinical trial; no data on intra-cycle variation of AFC and AMH was available.
Wider implications of the findings: Our study in the Chinese population using the newer generation AMH ELISA concurred with the findings from a previous European study. Although both AFC and AMH are good predictors of ovarian response, AMH is less subjected to inter-cycle variation than AFC, hence allowing pre-IVF assessment at more flexible timing.
Trial registration number: NCT01915186 (www.clincialtrials.org).

P-736 Intracellular oxidative stress in granulose cells impact on ART success in reduced ovarian reserve

M. Santonastaso[1], F. Mottola[2], D. Mele[1], L. Rocco[2], F. Caprio[1], N. Colacurci[1]
[1]Seconda Università degli Studi di Napoli, Department of Woman, Child and General and Special Surgery, Naples, Italy
[2]Seconda Università degli Studi di Napoli, Department of Environmental, Biological and Pharmaceutical Sciences and Technologies, Naples, Italy

Study question: To assess the relationship between intracellular reactive oxygen species (ROS) levels in granulose cells (GCs) and assisted reproductive techniques (ART) outcome parameters in reduced ovarian reserve-ART patients.
Summary answer: High levels of intracellular oxidative stress (OS) in GCs have a negative impact on ovarian reserve and ART outcomes.
What is known already: ROS play physiological roles during folliculogenesis and oocyte maturation but excessive ROS production may create an unsuitable environment for reproduction and be related to pathological conditions. ART outcome is adversely affected if an imbalance exists between ROS and antioxidants in the oocyte microenvironment. In PCOS- ART cases, OS mediated alterations in GCs negatively influences ART success. So, OS might be responsible for reduced ovarian reserve in young women who were admitted to ART treatment. To our knowledge, no study examined the correlation between intracellular ROS levels in GCs and ART outcome parameters in low responder patient.
Study design, size, duration: This prospective study compared ART outcome parameters (oocyte quality, fertilization rate and embryo quality) with intracellular ROS in GCs percentage of 15 patients 35 years, expected low responders (defined as having AMH ≤ 1 ng/L) (A Group) and 15 patient <35 years, expected normal responders (AMH >1 ng/L) (B Group) undergoing ICSI-ET cycles during the period from March to October 2015.
Participants/materials, setting, methods: Exclusion criteria: PCOs, endometriosis, metabolic and endocrinology diseases, severe Oligoasthenoteratozoospermia. GCs samples were isolated by centrifugation from follicular fluid that was obtained on the day of oocyte retrieval. The intracellular ROS levels were assessed by H2DCF-DA (2',7'-dichlorofluorescein diacetate) fluorescent probe. Oocyte quality, fertilization rate and embryo quality outcome were assessed. The data were analyzed using the unpaired Student's *t*-test and considered significant if p-value ≤ 0.05.
Main results and the role of chance: Statistically significant difference between the two groups in intracellular ROS levels in GCs have been observed. In particular, ROS percentage was significantly higher in young women with reduced ovarian reserve compared normal responders ($p \leq 0.05$) (34 ± 5.5 vs. 19 ± 7.8). The B group showed a better oocyte quality associated with a higher percentage of fertilization and embryo development compared to A group ($p \leq 0.05$). In detail, the average percentage of MII oocytes recovered was 75% ± 6.7 and 86% ± 8.4 in poor responder and normal responder patients respectively ($p \leq 0.05$). Among A and B Group, a significant statistical difference was recorded in the average percentage of fertilization (72% ± 6.0 vs. 92% ± 3.0). The average percentage of good quality (grade 1–2) embryos on day 3 in patients with reduced and normal ovarian response was 71% ± 4.2 and 87% ± 5.5 respectively ($p \leq 0.05$). High levels of ROS in GCs were significantly negatively correlated with ART outcome parameters.
Limitations, reasons for caution: Small number of participants. Lifestyle factors (i.e., smoking, diet) are not considered.
Wider implications of the findings: This research showed that increased oxidative stress in GCs is a possible explanation for low ovarian response in young women. The demonstrated excessive ROS production has negative implication in ART fertility outcome. These results could lead to the development of specific antioxidant therapies for women with poor prognosis undergoing ART.
Trial registration number: No. 29 (19/01/2015).

P-737 Reproductive outcomes in patients with polycystic ovaries: does phenotype matter?

S. Pareyn[1], M. De Vos[1], P. Drakopoulos[1], S. Santos-Ribeiro[1,2], N. Polyzos[1,3], H. Tournaye[1], C. Blockeel[1,4]
[1]UZ Brussel, Centre of Reproductive Medicine, Brussels, Belgium
[2]Santa Maria University Hospital, Department of Obstetrics, Gynaecology and Reproductive Medicine, Lisbon, Portugal
[3]University of Aarhus, Faculty of Health, Department of Clinical Medicine, Aarhus, Denmark
[4]University of Zagreb, School of Medicine, Department of Obstetrics and Gynaecology, Zagreb, Croatia

Study question: Do live birth rates vary in women with different Rotterdam PCOS phenotypes who undergo IVF/ICSI treatment with fresh embryo transfer?

Summary answer: Patients with Rotterdam PCOS are a heterogeneous group with divergent outcomes after IVF/ICSI. Hyperandrogenemia seems to be associated with a significantly poorer outcome.
What is known already: There is increasing evidence from reproductive endocrinology research that PCOS patients with Rotterdam criteria constitute a heterogeneous population with distinct risk profiles of metabolic, reproductive and obstetric complications. However, the impact of the PCO/PCOS phenotype on reproductive outcomes after controlled ovarian stimulation on a fresh embryo transfer is currently unknown.
Study design, size, duration: This was a retrospective cohort study using clinical and laboratory data from 330 PCO/PCOS patients with AMH levels above the cut-off for predicted hyperresponse, i.e., > 20 oocytes, undergoing their first IVF/ICSI treatment cycle using a GnRH antagonist protocol in a tertiary reproductive centre. Data were collected between January 2010 and December 2014. Patients with unspecified PCOS phenotype and those requiring either PGD or testicular biopsy were excluded.
Participants/materials, setting, methods: Patients were divided into four phenotype groups: women with isolated increased serum AMH levels (n = 102) without cycle irregularities, mild PCOS presenting with isolated increased serum AMH levels and either oligo/amenorrhoea (PCOS-OA, n = 129) or hyperandrogenemia (PCOS-HA, n = 35), and full-blown severe PCOS with all of three Rotterdam criteria (n = 64). The primary endpoint of the study was live birth rate (LBR). Secondary endpoints included consumption of gonadotropins, duration of stimulation and incidence of OHSS.
Main results and the role of chance: The distinct groups had similar baseline characteristics except for the body-mass index (BMI). The mean BMI (kg/m^2 ± standard deviation) was significantly higher in severe PCOS patients (29.1 ± 5.6; $p < 0.001$) compared to women with isolated increased AMH (24.2 ± 5.1), PCOS-OA (23.6 ± 4.6) and PCOS-HA (27.0 ± 5.6).

The LBR in women with isolated increased AMH, PCOS-HA, PCOS-OA and severe PCOS were 35.3%, 14.3%, 33.3% and 12.5%, respectively (Pearson χ^2, $p < 0.001$). Pairwise comparisons revealed that LBR were significantly lower in women with the severe PCOS phenotype when compared to those with isolated increased AMH ($p = 0.002$) and PCOS-OA ($p = 0.003$). The χ^2 test for trend was significant ($p = 0.02$).

Multivariate logistic regression analysis accounting for the following confounding factors was also performed: BMI, age, fertilisation rate, day of embryo transfer in the fresh cycle and insemination method (IVF, ICSI or IVF/ICSI). In this analysis, PCOS phenotype remained an independent predictive factor ($p < 0.02$) for LBR.

The total consumption of gonadotropins was significantly higher in patients with severe PCOS whereas the duration of stimulation, number of retrieved oocytes and fertilisation rate did not differ significantly among the groups. Seven patients (2.1%) developed OHSS requiring hospital admission: 2 women with isolated elevated AMH, 3 from the PCOS-OA and 2 from the severe PCOS group.
Limitations, reasons for caution: These results should not be extrapolated to PCO/PCOS patients with normal AMH-levels. Furthermore, only biochemical hyperandrogenemia (and not clinical hyperandrogenism) was considered in this study. Another limitation is the retrospective design and the relatively small sample size of the PCOS-HA subgroup. Anyhow, these results warrant confirmation in future studies.
Wider implications of the findings: The lower LBR in patients with severe PCOS, compared to other PCOS phenotypes, is potentially related to the impact of BMI or metabolic profile on oocyte and endometrium quality. These preliminary findings may one day imply the need for a tailored approach when treating PCOS patients with hyperandrogenemia.
Trial registration number:/

P-738 How to implement in real-life settings the results of meta analysis? Example of dydrogesterone as luteal phase support after fresh embryo transfer in IVF procedure

N. Massin[1], C. Pietin-Vialle[1], M. Pasquier[1], G. Heluin[1], B. Haddad[1], H. Bry-Gauillard[1]
[1]*Intercommunal Hospital, University Paris XII, Department of Gynecology, Obstetrics and Reproductive Medicine, Creteil, France*

Study question: The primary objective was to compare in an unselected population the live birth rate after fresh embryo transfer either with oral dydrogesterone or vaginal progesterone for luteal phase support (LPS).
Summary answer: In an unselected population dydrogesterone and vaginal progesterone for LPS after fresh embryo transfer showed similar live birth rates.
What is known already: Randomized controlled trials and meta analysis demonstrate that LPS after ovarian hyperstimulation, oocyte pick up and embryo transfer is mandatory for the best success in IVF cycle and that different routes of progesterone show the same efficacy. However these studies are performed in selected populations and the worlwide application of these findings remains weak, especially for oral progesterone. The most used route remains the vaginal one, despite the discomfort for the women. But changing the routine in a clinical practice is challenging, specifically in ART procedures, which success depends on a large range of factors.
Study design, size, duration: This is a prospective cohort study including all the women undergoing a fresh embryo transfer after autologous IVF procedure, in one public IVF center for 16 months, from December, 2011 to march, 2013. To get real-life data, the size of the cohort was estimated to be at least 500 patients, which represents approximately one year practice in an average setting in our country.
Participants/materials, setting, methods: All the 559 consecutive fresh embryo transfers during the study period were included, no women were excluded, whatever demographic data were. The progesterone supplementation was introduced the day of oocyte pick up. As both treatments were expected to be as effective, women were treated with micronized vaginal progesterone 200 mg twice a day when starting on even day (N = 291) or oral dydrogesterone 10 mg twice a day when starting on uneven day (N = 268).
Main results and the role of chance: The two groups were comparable regarding the demographic data (age, BMI, duration of infertility), stimulation protocols (IVF/ICSI, agonist/antagonist, total dose of FSH) and stimulation outcomes (number of oocytes retrieved, metaphase2 oocytes, total embryos and embryos replaced). However, there was a significative difference in the rank of IVF procedure 1.73 ± 0.96 vs. 1.54 ± 0.80 (p = 0.004) and number of embryos cryopreserved 3.0 ± 2.2 vs. 3.7 ± 3.0 (p = 0.006), in vaginal progesterone and dydrogesterone groups respectively. There were no significant differences in clinical pregnancy, implantation and birth rates between the vaginal and oral groups, 31.3% vs. 27.2% (p = 0.29), 18.6% vs. 17.1% (p = 0.49) and 24.1% vs. 22.4% (p = 0.64) respectively. The miscarriage rate was also similar in both groups 23.1% vs. 17.8% respectively. A subgroup analysis was performed in good prognosis patients (rank 1 or 2 and < 35 years old; N = 274): all the demographic and stimulation data were comparable in both groups. The clinical pregnancy rate and birth rate were similar in vaginal and oral groups, 35.9% vs. 31.7% (p = 0.48) and 26.6% and 30% (p = 0.55) respectively. But miscarriage rate was significantly higher in the vaginal progesterone group 26.1% vs. 5.3% in the oral group (p = 0.01).
Limitations, reasons for caution: This is a real-life setting study with practical randomization, the limitation to the conclusion is bias for studying non comparable groups regarding the demographic data or the protocols used, which is currently the case. This can be addressed with subgroups analysis with sufficient number of patients in different groups.
Wider implications of the findings: Although this is not a registered indication, dydrogesterone was as effective and safe as vaginal progesterone, not only for good prognosis patients. The benefits of oral over vaginal route are observance and tolerance, especially in the group of younger patients, less dedicated to the effort to continued treatment for LPS.
Trial registration number: Not required.

P-739 Defining critical progesterone elevation to estimate effect on pregnancy and live birth rates: influence of selected threshold on exposure frequency, effect size and clinical impact.

M. Caballero[1,2], M.T. Navarro González[2], E. Ceballos García[2], I. Ilic[2], R. Núñez Calonge[3], A. García Enguídanos[1], L. Ortega López[3], P. Caballero Peregrín[1], F. Pérez Milán[2,4]
[1]*Clínica Tambre, Reproductive Medicine Unit, Madrid, Spain*
[2]*Hospital General Universitario Gregorio Marañón, Reproductive Medicine Unit. Obstetrics and Gynaecology Department, Madrid, Spain*
[3]*Clínica Tambre, IVF Laboratory, Madrid, Spain*
[4]*Universidad Complutense de Madrid, Obstetrics and Gynaecology Department, Madrid, Spain*

Study question: To evaluate the influence of defining threshold for progesterone elevation in final clinical impact, in terms of lost clinical pregnancies and live birth rate reduction.

Summary answer: Defining thresholds of progesterone elevation determine an inverse association between elevation frequency and effect size, so final impact on IVF outcomes is discrete.
What is known already: Early progesterone elevation (EPE) has been described as unfavorable side-effect of ovarian stimulation that can disregulate endometrial receptivity and embryo implantation rate in IVF. Controversy about the critical level of progesterone serum level on day of HCG that could be detrimental for IVF outcomes is still remaining. Lack of consensus about this issue has generated an important heterogeneity in defining thresholds of EPE, which has obvious consequences on described frequencies and sizes of effect.
Study design, size, duration: Retrospective cohort study of an opportunity sample of 3729 IVF cycles with fresh embryo transfer, carried out over an 8-year period. Cycles with data about final progesterone serum concentration and pregnancy outcome were included. Attrition rate due to missing data that impeded inclusion of observations in multivariate analysis was quantified.
Participants/materials, setting, methods: We analyzed 3729 IVF cycles from Clínica Tambre, an specialized reproductive centre in Madrid (Spain). After identifying potential progesterone thresholds able to decrease IVF outcomes by interval analysis, we performed univariate estimation of effect size for each one. Multivariate analysis identified independent associations with outcome variables. Crude and adjusted risk differences were used to estimate NNH and final impact of each threshold of elevated progesterone on pregnancy and live birth rate loss.
Main results and the role of chance: Serum progesterone level on HCG day was significantly and proportionally associated with clinical pregnancy and live birth rate within a concentration range, including levels from 1.26 ng/mL to 1.81 ng/mL and from 1.26 ng/mL to 1.65 ng/mL, respectively. Relative risk (RR) for clinical pregnancy declined progressively from lower to upper critical thresholds considered to define early progesterone exposure: estimated RR for clinical pregnancy varied from 0.73 (CI 95%: 0.61–0.88, $p < 0.001$) for progesterone levels >1.26 ng/mL (177 cycles) to 0.52 (CI 95%: 0.35–0.77, $p < 0.001$) for expositions to progesterone >1.65 ng/mL (112 cycles).

Similarly, effect size for live birth decreased from estimated RR of 0.75 (CI 95%: 0.6–0.95, $p = 0.004$) for progesterone >1.26 ng/mL (357 cycles) to 0.48 (CI 95%: 0.27–0.78) for progesterone exposure upper to 1.65 ng/mL. The harmful effects of progesterone elevation remained after adjusting by other independent covariates.

The inverse relation between selected threshold and frequency of progesterone elevation determined a linear and parallel increase of progesterone frequency and number of cycles needed to harm (NNH) for clinical pregnancy (10.6 to 6.5) and for live birth (NNH: 15.6 to 7.2). Anyway, final number of estimated lost clinical pregnancies and live births were low and relatively unchanging.
Limitations, reasons for caution: The retrospective approach of our study could be considered as a limitation. Additionally, multivariate analysis has been used to reduce risk of bias effects, but they can not be absolutely excluded.
Wider implications of the findings: Accordingly with previous studies, endometrial progesterone exposure appears detrimental for IVF effectivity but only above extreme values. Although highest levels of exposure are related to relevant decreases of pregnancy and live birth rates, these exposures affects only a small proportion of cycles, so final impact could be considered low.
Trial registration number: No applicable.

P-740 The most effective starting dose of gonadotropins in the first IVF cycle in patients under 35 years of age – GnRH agonist versus antagonist protocol.

P. Kuğ, P. Laudağski[1], P. Pierzyğski[2], A. Kuczyğska[2], R. Milewski[3], I. Martynowicz[4], K. Łukaszuk[5], W. Kuczyğski[6]

[2]*Medical University of Bialystok, Department of Reproduction and Gynaecological Endocrinology, Centre for Reproductive Medicine Kriobank, Bialystok, Poland*
[3]*Medical University of Bialystok, Department of Statistics and Medical Informatics, BIALYSTOK, Poland*
[4]*Medical University of Bialystok, Centre for Reproductive Medicine Kriobank, Bialystok, Poland*
[5]*INVICTA, Fertility Clinic, Warsaw, Poland*
[6]*Medical University of Bialystok, Department of Gynecology and Gynecological Oncology, Centre for Reproductive Medicine Kriobank, Bialystok, Poland*

Study question: What is the most effective starting dose of gonadotropins in the first IVF cycle in patients under 35 years of age – GnRH agonist vs. GnRH antagonist protocol.
Summary answer: The most effective starting dose of gonadotropin for GnRH agonist protocols is 150 IU in comparison to <150 IU per day in antagonist protocols.
What is known already: A significant number of randomized controlled trials were identified the question of the most effective FSH starting dose in expected normal responders. The most of results suggested a maximum effective dose of recombinant gonadotropin for the first IVF cycle for 300 IU/day, with a starting dose of 150 IU per day.
Study design, size, duration: Retrospective observational study on 3116 fresh embryo transfers, during the decade, in patients in the first IVF cycle. Analysis covers clinical data, embryological data and outcomes of fertility treatments.
Participants/materials, setting, methods: 3116 patients in GnRH agonist or GnRH antagonist protocol with mild male or tubal factor of infertility were included to the study. Only patients with good ovarian reserve were included to the study. The number of fertilized eggs was limited to 8 and single embryo transfer was performed. All cycles were divided according to the starting dose of gonadotropins <150 IU, 150–224 IU, 225–299 IU, >300 IU and type of protocol – GnRH agonist and antagonist.
Main results and the role of chance: The highest clinical pregnancy rate per embryo transfer 60.2% was observed at starting dose of gonadotropins 150–224 IU in long GnRH agonist protocol. In GnRH antagonist protocol the highest clinical pregnancy rate 59.3% were observed at starting dose <150 IU. The lowest clinical pregnancy rate per embryo transfer 37.7% was observed at starting dose of gonadotropins <150 IU in long GnRH agonist protocol. In GnRH antagonist protocol the lowest clinical pregnancy rate 47.7% were observed at starting dose >300 IU. The highest mean consumption of gonadotropins was observed in long GnRH agonist protocol (2946.21 IU) with mean time of stimulation 10.2 days (starting dose >300 IU). The lowest consumption of gonadotropins was observed in GnRH antagonist protocol (1217.21 IU) with mean time of stimulation 9.1 days (starting dose 150–224 IU).
Limitations, reasons for caution: This is only a data presenting clinical pregnancy outcome. The results will be completed when all available live-birth data can be analyzed, as well as miscarriages and preterm deliveries rate.
Wider implications of the findings: The results can be helpful to presents the best compromise between safety and efficacy of treatment for the younger IVF patient with a good prognosis depending on the type of controlled ovarian hyperstimulation protocol.
Trial registration number: N/A.

P-741 Anti-Müllerian hormone (AMH) serum levels enable preoperative estimation of the number of cumulus-oocyte complexes (COC) in female-to-male transgender persons (trans men)

C. De Roo[1], S. Lierman[1], K. Tilleman[1], S. Weyers[2], G. T'Sjoen[3], P. De Sutter[1]
[1]*University Hospital Ghent, Reproductive Medicine, Gent, Belgium*
[2]*University Hospital Ghent, Gynaecology, Gent, Belgium*
[3]*University Hospital Ghent, Endocrinology, Gent, Belgium*

Study question: Can we correlate the number of COC in ovaries of trans men at the time of ovarian tissue cryopreservation to clinical or biochemical markers?
Summary answer: AMH correlates significantly with the number of recovered COC, enabling to determine an average estimated increase of COC by 7.48 per unit AMH.
What is known already: Ovarian cortex cryopreservation is a standard technique for fertility preservation in trans men. During tissue manipulation for ovarian cortex freezing, COC are possibly released from antral follicles. It has been shown, in an oncologic patient cohort, that these immature oocytes can be recovered from the antral follicles and subsequently *in vitro* matured and cryopreserved (Huang et al., 2008; Fasano et al., 2011; Segers et al., 2015). The presence of these immature oocytes nor possible clinical or biochemical markers are thus far confirmed during the processing of ovaries originating from trans men.
Study design, size, duration: From June 2013 to December 2014, 30 trans men (mean age 24 + 6 years, mean duration of testosterone treatment

59.0 + 23.8 weeks) were included after informed consent. Patient characteristics and hormone serum levels were collected. Following ovarian cortex processing for cryopreservation, the manipulation dishes were examined under a stereomicroscope for COC. To validate our findings, from February 2015 to January 2016 we included 9 trans men (mean age 22 + 3 years, mean duration of testosterone treatment 60.4 + 40.3 weeks).

Participants/materials, setting, methods: The hormone levels were determined using a E170 Modular® (Roche Diagnostics, Mannheim, Germany), except for AMH serum levels (A73818, Elisa Immunotech, Beckman Coulter, Woerden, Netherlands). For validation of our finding, AMH serum levels of 9 patients were determined using the AMH Roche E170 (Roche Diagnostics, Mannheim, Germany). Statistical analysis for correlation (Spearman's rank-order correlation test) and linear regression analysis was performed with IBM SPSS Statistics 23.

Main results and the role of chance: In total, 1087 COC were collected from the first patient cohort ($N = 30$). A mean of 36.23 + 35.81 COC per patient were retrieved. AMH serum levels correlated strongly with the amount of COC (Rs 0.787, $p < 0.001$). The number of COC did not correlate with other hormone serum levels nor with duration of testosterone treatment. Next, linear regression analysis showed an equation $y = 0.847 + 7.48x$ (R^2 0.714) with a non-significant intercept (b0 = 0.847; $p = 0.875$; 95% CI −10.44–12.19) but a significant increase of the estimated mean number of COC with 7.48 per unit AMH (µg/L) ($p < 0.001$, 95% CI 5.73–9.23). Validation of the average estimated increase of 7.48 COC (95% CI 5.73–9.23) per unit AMH (µg/L) was confirmed on the second patient cohort. This equation could correctly predict the number of COC in 44.44% (4/9) patients but underestimated the COC yield in 44.44% (4/9) patients. The underestimation ranged from 36.95 estimated vs. 60 retrieved COC to 7.55 estimated vs. 32 retrieved COC. In case of the overestimation, only 22 COC were collected where 49.14 COC were calculated.

Limitations, reasons for caution: The COC yield in this study did not show a correlation with testosterone serum levels nor with the duration of the testosterone therapy. Nevertheless, the influence of hormonal treatment in transgender persons on the ovary is currently not fully understood.

Wider implications of the findings: An estimation of the COC yield in function of AMH could be of importance during the counseling of patients for fertility preservation options. Our results clearly indicate that the average estimated increase is assay specific and should therefore be calculated before use in daily practice based on the available assay.

Trial registration number: UZ Ghent reference: 2012/780 – Belgian registration number: B670201215468.

P-742 Start stop protocol: A preliminary study of a new controlled ovarian stimulation method for Bologna poor responders

B. Yilmaz[1], E.S. Gulec[2], A. Suleyman[3], C. Kose[2], A.Z. Isik[3]
[1]Izmir Katip Celebi University, Department of Obstetrics and Gynecology, Tepecik Education and Research Hospital, IVF Unit, Izmir, Turkey
[2]Tepecik Education and Research Hospital, IVF Unit, Izmir, Turkey
[3]Izmir University, Department of Obstetrics and Gynecology, IVF Unit, Izmir, Turkey

Study question: Is there any clinical importance for follicular improvement of 1 week later control of Bologna poor responder patients unresponsive to initial controlled ovarian stimulation (COS) in IVF/ICSI cycle**.**

Summary answer: Start Stop Protocol is a new and effective alternative method for Bologna poor responders unresponsive to initial 1 week COS in IVF/ICSI cycle.

What is known already: Although many protocols with different doses and types of gonadotropins have been proposed in the literature, to date, there is insufficient evidence to identify the use of any particular intervention to improve treatment outcomes in poor responders.

Study design, size, duration: This retrospective uncontrolled pilot study was conducted in IVF units of two university hospitals. A total of 375 patients fulfilling the Bologna poor responder criteria underwent COS (recFSH plus hphMG) and unresponsive to initial gonadotropins were included in the study between January 2015 and January 2016.

Participants/materials, setting, methods: Forty three of the 375 patients (11.5%) unresponsive to about 1 week initial COS in IVF/ICSI cycle were included in the study. After stopping all gonadotropin medications, the patient was requested for ulrasonography and serum estradiol control. If follicular improvement and/or increase in estradiol level were detected, patient underwent COS using antagonist protocol. Once follicle diameter >17 mm, hCG was administered and the oocyte collected 36th after hCG.

Main results and the role of chance: Baseline demographic and clinical data: Mean age 36.3 ± 5.02 years, body mass index 26.02 ± 4.68 kg/m^2, infertility period 6.47 ± 4.81 years, basal FSH 17.7 ± 12.6 mIU/ml, basal estradiol 32.9 ± 40.6 pg/mL, median number of day 2 antral follicul count 2 (0–6), hCG day follicle >17 mm 1 (0–4), stimulation time until COS stop 8 (4–14) days, stimulation time after COS restart 5 (0–11) days, number of MII oocyte 1 (0–4), number of 2PN embryo 1 (0–4). Nineteen of 43 patients (44.2%) achieved MII oocyte yield and seventeen of 43 patients (39.5%) achieved embryo transfer. Clinical pregnancy rate was 29.4%.

Limitations, reasons for caution: Retrospective design, small sample size and having no control group are major limitations of this study. However, this is a preliminary report of a new treatment strategy for Bologna poor responder patients.

Wider implications of the findings: Further prospective controlled studies are needed to show effectiveness of Start Stop Protocol for Bologna poor responder patients unresponsive to initial COS in IVF/ICSI cycle**.**

Trial registration number: N/A.

P-743 Long-term health of women with FSH resistant ovaries

K. Luiro[1], K. Aittomäki[2], J.S. Tapanainen[1]
[1]Helsinki University Hospital and University of Helsinki, Department of Obstetrics and Gynaecology, Helsinki, Finland
[2]Helsinki University Central Hospital HUCH, Department of Medical Genetics, Helsinki, Finland

Study question: Do inactivating FSH receptor mutation and hypoestrogenism have long-term effects on health and morbidity, and can these be overcome by an adequate hormone therapy (HT)?

Summary answer: All women with FSH resistant ovaries (FSHRO) in this cohort had been on HT and had no major health problems related to the mutation.

What is known already: Autosomal, recessively inherited FSH receptor mutation underlies FSHRO syndrome, a genetic form of primary ovarian insufficiency (POI). FSHRO patients have low endogenous estrogen levels, which has potential effects on health and morbidity. In addition, FSH resistance arrests follicle development at antral stage leading to infertility. The inactivating FSH receptor mutation was discovered 20 years ago, and due to the relatively short follow-up period so far, its long-term effects on health and morbidity, and the effect of HT have not been thoroughly investigated.

Study design, size, duration: A cohort study of 26 women with a confirmed inactivating FSH receptor mutation (A189V). Twenty-two of them (85%) filled and returned a questionnaire.

Participants/materials, setting, methods: Twenty-two women aged 28–70 years participated in this study. The questionnaire included detailed questions regarding the use of HT, infertility treatments and their success, bone density measurements and incidence of osteoporosis, and cardiovascular symptoms and disease. In addition, the patients were asked to report any malignancies, operations, and neurological, psychological, respiratory, gastro-intestinal, cutaneous, or allergy symptoms.

Main results and the role of chance: All women had used and currently 46% were using HT. 14% of the women were also using local vaginal estrogen therapy. The median starting age for the use of HT was 18 years and the median time of use was 20 years. 14 women (63%) had undergone infertility treatments *via* ovum donation, and 10 women had become pregnant, four of them twice. The outcomes were one miscarriage, 11 singleton pregnancies and two twin pregnancies. Overall 15 children have been born. The pregnancies were largely uneventful. A bone density measurement (DXA) had been performed on 16 (73%) of FSHRO patients, and only one person was diagnosed with osteoporosis. Seven women were currently under hypertensive medication, but no coronary heart disease was reported. Four women were using asthma medication, and four were on proton-pump inhibitor medication. No malignancies were reported, and only one woman had been diagnosed with a cervical dysplasia.

Limitations, reasons for caution: The information on health and morbidity was self-reported.

Wider implications of the findings: Early-onset HT seems to be effective in preventing major long-term effects on health and morbidity in a genetic form

of POI. Ovum donation is an effective treatment of infertility in FSH resistant ovary syndrome.
Trial registration number: The Hospital District of Helsinki and Uusimaa Ethics Committee for gynaecology and obstetrics, pediatrics and psychiatry 333/13/03/03/2013.

P-744 Different pregnancy rate with the same results of AMH using 5 different AMH kits including new automated assays

D. Bialobrzeska-Lukaszuk[1], K. Lukaszuk[1,2], M. Kunicki[3], J. Liss[1], P. Ewa[2], G. Jakiel[3,4]
[1]Invicta Sp. z o.o., Reproduction and Fertility Centre, Gdansk, Poland
[2]Medical University of Gdansk, Department of Obstetrics and Gynecological Nursing, Gdansk, Poland
[3]Invicta Sp. z o.o., Reproduction and Fertility Centre, Warsaw, Poland
[4]Medical Centre of Postgraduate Education, Department of Obstetrics and Gynaecology, Warsaw, Poland

Study question: The aim of that retrospective study was to compare embryological and clinical outcome with respect to five different AMH kits.
Summary answer: This study demonstrated that we could expect totally different pregnancy rate with the same results AMH using different AMH kits.
What is known already: Ovarian reserve is an important parameter for assessment of the chances for successful infertility treatment and AMH is important, widely used parameter for its determination. Based on AMH results decisions regarding gonadotropins dosage and pregnancy prediction in IVF for each individual patients are made. Few kits are available on the market for determination of AMH concentration. Some studies presented different AMH values with different kits – but the vast majority was limited to a small number of patients. This is why we decided to compare five kits regarding the pregnancy rate with a large cohort.
Study design, size, duration: The study population consisted of 3693 patients treated by ICSI in our IVF Center between 2007 and 2015. For retrospective analysis, we excluded women that participated in the oocyte donation, enterprise program, e.g., those with frozen–thawed embryo transfers. We divided women according to age and AMH categories.
Participants/materials, setting, methods: In this study, we compared AMH serum concentrations using five tests. All women underwent controlled ovarian stimulation. Embryo transfer was performed on blastocyst stage on day 5. Number of embryos transferred was determined by their availability and quality, and the guidelines of the institution and ASRM. Each patient was tested only once using one kit.
Main results and the role of chance: Immunotech I Gen. RUO (n = 1451), Beckman Coulter II Gen. RUO (n = 652), Beckman Coulter II Gen. IVD (n = 214), Ansh Labs I Gen. IVD (n = 897), Elecsys Roche (n = 479) assays were investigated.

Assays differed significantly in the meaning of pregnancy rate achieved. In women <35 years with AMH concentrations <0.6 ng/ml and above 1.4, and in those >39 years with AMH concentrations between 0.6 and 1.4 and above 1.4, the clinical pregnancy rate differed significantly between AMH kits. In both aforementioned subgroups, the higher rate occurred with the Beckman Coulter II Gen and Ansh Labs. IVD, beside group >39 and >1.4 where the Elecsys Roche group exhibit highest value. The lowest pregnancy rate was seen with the IOT.

When we divided women according to their age category, the highest pregnancy rate was observed in women <35 years. In that case, the higher clinical pregnancy rate was found with the Beckman Coulter II Gen. IVD, while the lowest was found with the IOT.

AMH concentrations also differed significantly between different kits. In groups of women <35 and those in age 35–37, the highest value was found for IOT, and the lowest for Beckman IVD.
Limitations, reasons for caution: Limitation was retrospective nature of study that could be a bias for the achieved results in terms of pregnancy rate. On the other hand our pregnancy rate was quite stable during investigated period.
Wider implications of the findings: In summary, these results could have potential importance for clinical decision making as AMH levels are frequently used to determine gonadotropins dosing in IVF.
Trial registration number: Not applicable.

P-745 Serum Prolactin and Cortisol levels for luteal phase support (LPS) during IVF: subcutaneous vs. intramuscular progesterone

F. Caprio[1], D. Mele[1], L. Vaccarella[1], F. Grauso[1], M.D. D'Eufemia[1], N. Colacurci[1]
[1]Second University of Naples, Department of Woman, Child and General and Special Surgery, Naples, Italy

Study question: Investigate whether LPS with IM and SC progesterone determine changes in the stress hormones (Cortisol and Prolactin), that are known to influence IVF outcomes.
Summary answer: The values of Prolactin and Cortisol were statistically significantly higher in group treated with IM route compared to the group treated with SC route.
What is known already: The stress role in IVF has long been a topic of interest. Questions include whether the treatment is stressful, whether stress or anxiety has an impact on success of fertility treatment and whether interventions to decrease stress are useful.

LPS in IVF is necessary and recommended, because it has been shown that in stimulated cycle there is an abnormal luteal phase, leading to poor endometrial development and an asynchrony of endometrial receptivity.

Recently, it has become available a water-soluble injectable progesterone, that makes possible the subcutaneous (SC) injection for which patients are already familiar for daily treatment with gonadotropins.
Study design, size, duration: This is a prospective study that include 70 women undergoing their first IVF treatment for primary infertility from February to December 2015; they were randomized in two groups with different way of administration of LPS: A group (35 patients) receive 33 mg/day of IM in oil-progesterone starting from pick-up day and than 50 mg/day from embryo transfer (ET) day; B group (35 patients) receive 25 mg of SC water soluble-progesterone from pick-up day.
Participants/materials, setting, methods: Were excluded: acute illness, chronic disorders, PCOs, Endometriosis, organic dysfunction. Patients underwent ovarian stimulation with a long protocol. Blood samples were obtained from all subjects at day + 7 from oocyte retrieval. CORT and PRL serum levels were obtained by Immulite from DPC/Siemens (Princeton, NJ). The outcome was the comparison between patients treated with IM and with SC progesterone. For statistical analysis, t-test, χ^2, log rank analysis, and analysis of variance were used as appropriate.
Main results and the role of chance: All patients completed IVF stimulation, egg retrieval, ET, and resultant pregnancy tests. Group A and B were similar concerning baseline characteristics and stimulation data. All patients have a regular lifestyle during LPS, not experiments bleeding or spotting and any health problem. The values of PRL and CORT were statistically significantly higher in group treated with IM route compared to the group treated with SC route (respectively 27.5 ± 3.3 vs. 21.8 ± 3.3, $p < 0.001$ and 345.5 ± 29.9 vs. 310.5 ± 28.7, $p < 0.001$).
Limitations, reasons for caution: A limit of our study is the small number of patients enrolled. By the way, we want to point out that this experience represents a pilot study, on the basis of which we hope to design a more important study to validate our results.
Wider implications of the findings: Our results show for the first time that treatment with SC progesterone is associated with lower Cortisol and Prolactin levels. This suggests new opportunity in IVF to reduce patients distress and improve quality of life, supporting the development of new research perspectives and new therapeutic strategy for LPS management.
Trial registration number: Protocol N° 63 of 5 February 2015

P-746 Serum vitamin D is not associated with ovarian reserve in infertile patients

B.C. Tarlatzis[1], J. Bosdou[1], C. Venetis[2], G. Mintziori[1], D. Goulis[1], T. Tarlatzi[1], L. Kyriazi[1], N. Konstantinidou[1], D. Savaidou[1], E. Kolibianakis[1]
[1]Aristotle University of Thessaloniki, Unit for Human Reproduction, Medical School, 1st Department of Obstetrics and Gynecology, Thessaloniki, Greece
[2]University of New South Wales, Department of Women's and Children's Health, St George Hospital, School of Women's and Children's Health, Kogarah, NSW, Australia

Study question: Is serum concentration of 25-hydroxyvitamin D [25(OH)D] associated with ovarian reserve in infertile patients?

Summary answer: Serum concentration of 25(OH)D is not associated with ovarian reserve in infertile patients.
What is known already: Vitamin D has been suggested to play an important role in female fertility which might be explained by the widespread distribution of vitamin D receptors in reproductive tissues. Vitamin D deficiency has been associated with significantly lower pregnancy rates in patients undergoing IVF treatment. An age dependent association between serum 25(OH)D and Anti-Müllerian Hormone (AMH) levels has been recently reported using, however, previous generation kits for AMH assessment, the accuracy of which has been criticized.
Study design, size, duration: This is a prospective, observational study, performed between June 2015 and December 2015, in 99 consecutive women, attending the outpatient infertility clinic of a University Hospital. Infertility was either idiopathic or due to female factor, male factor, or combination of both factors. In all patients, ovarian reserve was evaluated by assessment of baseline follicle stimulating hormone (FSH), serum AMH, as well as by ultrasound assessment of antral follicle count (AFC) and mean ovarian volume.
Participants/materials, setting, methods: AMH and 25(OH)D were measured using the automated Elecsys AMH and Elecsys Vitamin-D total assay (Roche-Diagnostics), respectively. The correlation of 25(OH)D with variables reflecting ovarian reserve was evaluated using Pearson's correlation coefficient. Multivariable logistic regression was used to assess the association between 25(OH)D and poor ovarian reserve, defined according to the Bologna criteria. The association of 25(OH)D with AMH, controlling for the effect of age, was assessed by generalized estimating equations (GEE).
Main results and the role of chance: The mean (95% CI) age of patients analysed was 39.0 years (38.1–39.9), with a body mass index of 25.5 (24.3–26.7) and infertility duration of 5.8 years (5.1–6.6). Baseline serum FSH and AMH levels were 10.8 (9.3–12.4) IU/mL and 1.6 (1.3–1.9) ng/mL, respectively. AFC and mean ovarian volume were 12.3 (10.5–14.0) and 6.5 (5.9–7.1) mL, respectively. Serum 25(OH)D levels were 21.4 (19.4–23.5) ng/mL. The proportions (95% CI) of patients with 25(OH)D levels <30 ng/mL and those with <10 ng/mL were 82.8% (73.9–89.7) and 11.1% (5.7–19.0), respectively. Poor ovarian reserve, according to the Bologna criteria, was present in 42.4% (32.5–52.8) of patients included.
No statistically significant correlation was observed between 25(OH)D levels and age (r=–0.037, p = 0.72), baseline FSH (r = –0.082, p = 0.42), AMH (r = 0.035, p = 0.73), AFC (r = 0.108, p = 0.29) or mean ovarian volume (r = –0.071, p = 0.48).
Logistic regression with dependent variable poor ovarian reserve, according to Bologna criteria, and independent variable 25(OH)D, as well as variables that were significantly associated with poor ovarian reserve in univariable logistic regression analysis (gravidity, cause of infertility and number of previous IVF cycles), showed no association of 25(OH)D with poor ovarian reserve (odds ratio: 1.002, 95% CI: 0.96–1.05). GEE analysis showed no association between 25(OH)D and AMH, controlling for the effect of age (p = 0.89).
Limitations, reasons for caution: A large proportion of patients in the current study fulfilled the Bologna criteria and this might have affected the results obtained. Moreover, sample size may have limited the establishment of a significant association between 25(OH)D and ovarian reserve.
Wider implications of the findings: Although vitamin D is considered to be associated with female fertility, this association does not appear to be mediated through ovarian reserve. If the current findings are confirmed, alternative explanations for the role of vitamin D in female fertility need to be explored.
Trial registration number: –

P-747 Recombinant luteinizing hormone (rLH) and recombinant follicle stimulating hormone (rFSH) for controlled ovarian stimulation in IVF/ICSI cycles

N.A. Danhof[1], R.O. Ayeleke[2], F. van der Veen[1], M. van Wely[1], M.H. Mochtar[1]
[1]*Academic Medical Center, Center for Reproductive Medicine, Amsterdam, Netherlands*
[2]*University of Auckland, Department of Obstetrics and Gynaecology, Auckland, New Zealand*

Study question: Does adding recombinant LH (rLH) to recombinant FSH (rFSH) for controlled ovarian hyper stimulation (COS) increases pregnancy chances in women undergoing IVF/ICSI compared to rFSH alone?
Summary answer: Adding rLH to rFSH might increase pregnancy chances in women with poor ovarian response in agonist downregulated IVF/ICSI cycles.
What is known already: In 2006 a Cochrane review summarized studies on adding rLH to rFSH for COS in IVF/ICSI and described no evidence of a higher live birth rate (LBR). Since then more data has become available, in particular with respect to pregnancy-loss and poor ovarian response.
Study design, size, duration: We performed a systematic review and meta-analysis. We searched the following databases and trial registers to May 2015: CINAHL, the Gynaecology and Fertility Group Specialised Register, PsychInfo, CENTRAL, MEDLINE and EMBASE. There were no language restrictions. We included randomized controlled trials (RCTs) comparing rLH and rFSH to rFSH alone in IVF/ISCI cycles using either a GnRH agonist or antagonist for pituitary downregulation. Two review authors independently assessed trial quality and extracted data.
Participants/materials, setting, methods: The primary outcome was the live birth rate (LBR) and the primary safety outcome was the incidence of ovarian hyperstimulation syndrome (OHSS). We combined data to calculate odds ratios (ORs) and 95% confidence intervals (CIs). Statistical heterogeneity was assessed using the I^2 statistic. We assessed the overall quality of the evidence for the main comparison using GRADE methods.
Main results and the role of chance: We included 34 RCTs consisting of 7979 women. We found no difference in LBR between rLH and rFSH (rLH + rFSH) and rFSH alone using GnRH agonists (OR 1.74, 95% CI 0.81–3.77; n = 474; RCTs = 5; I^2 = 53%) nor using GnRH antagonists (OR 0.94, 95% CI 0.48–1.85; n = 240; RCTs = 1) in all women. The ongoing pregnancies (OR 1.27, 95% CI 1.02–1.57; n = 1980; RCTs = 14; I^2 = 17%) and clinical pregnancies (OR 1.21, 95% CI 1.05 to 1.40, RCTs = 19, n = 4189, I^2 = 34%) were significantly higher in women treated with rLH + rFSH compared to rFSH alone using GnRH agonists. We found no difference in ongoing (OR 1.08, 95% CI 0.82–1.43; n = 1149; RCTs = 7; I^2 = 0%) or clinical (OR 0.90, 95% CI 0.65–1.24, RCTs = 4, n = 776, I^2 = 0%) pregnancies between rLH + rFSH in women using GnRH antagonists.

We found lower or respectively no difference in OHSS following COS with rLH + rFSH compared to rFSH alone using GnRH agonists (OR 0.16, 95% CI 0.03–0.88, RCTs = 4, n = 1418, I^2 = 0%) GnRH antagonists (OR 0.80, 95% CI 0.21–3.00, RCTs = 2, n = 760).

In a sub analysis of women with poor ovarian response we found that adding rLH to rFSH in GnRH agonist downregulated IVF/ICSI resulted in higher ongoing pregnancy rate compared to rFSH alone (OR 2.06, 95% CI 1.20–3.53; n = 276; RCT's = 3; I^2 = 0%) but not in women with normal response (OR 1.17, 95% CI 0.91–1.51; n = 1349; RCTs = 7; I^2 = 34%).
Limitations, reasons for caution: The overall quality of the included studies was low due to poor reporting of study methods and lack of precision in the findings for most of the GRADE-specific outcomes.
Wider implications of the findings: The evidence suggests that there might be a beneficial effect of rLH + rFSH in GnRH agonist down regulated IVF/ICSI cycles in poor-responders. The risk of OHSS is not increased by rLH. IPD meta-analysis is required to better estimate the effect of poor response on the effectiveness of rLH + FSH.
Trial registration number: NA.

P-748 The preventive effect of resveratrol in cisplatin-induced ovarian damage

M. Atli[1], Y. Engin-ustun[2], A. Tokmak[3], M. Caydere[4], S. Hucumenoglu[4], C. Topcuoglu[5]
[1]*Zekai Tahir Burak Women's Health Education and Research Hospital, Zekai Tahir Burak Women's Health Education and Research Hospital, Ankara, Turkey*
[2]*Zekai Tahir Burak Women's Health Research and Education Hospital, IVF center, Ankara, Turkey*
[3]*Zekai Tahir Burak Women's Health Research and Education Hospital, Gynecology, Ankara, Turkey*
[4]*Ankara Training and Research Hospital, Pathology, Ankara, Turkey*
[5]*Ankara Numune Education and Research Hospital, Biochemistry, Ankara, Turkey*

Study question: Is there a preventive effect of resveratrol in cisplatin (CP)-induced ovarian damage?
Summary answer: Resveratrol may be effective in maintenance of primordial, primary and tertiary follicle levels in cisplatin-induced ovarian damage.

What is known already: Some cancers develop in women of reproductive age. Every year thousands of women receive chemotherapy for cancer treatment; hence some women are faced with a reduction in fertility from minimal to complete ovarian failure. Therefore, many of these women may be needed fertility preservation options. Resveratrol, a natural biochemical found in red wine and certain foods, that has antioxidant properties. Increased levels of reactive oxygen species may play an important role in the ovarian aging process. In this study we aimed to evaluate whether resveratrol has protective effects on cisplatin-induced ovarian damage.
Study design, size, duration: Experimental study.
Participants/materials, setting, methods: 28 female Wistar–albino rats were divided into 4-equal groups. Group1 was defined as sham group. During 21-day-study period, 5 mg/kg/day resveratrol was given to group2, 25 mg/kg/day resveratrol to group3, 1 ml/kg/day saline to group4. Three blood samples were taken of all groups on basal, 15 and 21 days of treatment, and anti-Mullerian hormone (AMH) levels were measured. All rats were oophorectomized 1 week after the chemotherapeutic agent and ovarian follicles were counted.
Main results and the role of chance: No significant difference was found in AMH levels of groups according to the follow up time after Bonferroni correction ($p > 0.0125$). In group 2 the number of primordial follicles was statistically higher than other groups ($p < 0.05$). The number of primordial follicles in group 3 was statistically lower than group 1 and 2; higher than group 4 ($p < 0.05$). In group 4; number of primordial follicles was statistically lower than the other groups (according to group 1 $p < 0.001$; to group 2 and 3 $p < 0.05$). In group 2; the number of primary follicles was higher than the other groups ($p < 0.05$). In group 3 the number of primary follicles was statistically significantly lower than group 2, higher than group 4 ($p < 0.05$). In group 4; levels of primary follicles were lower than the others (according to group 1 $p < 0.001$; to group 2 and 3 $p < 0.05$). In group 2 and 3; levels of tertiary follicles were higher than group 4, lower than group 1 ($p < 0.05$). Tertiary follicles were the lowest levels in group 4 (according to group 1 $p < 0.001$; to group 2 and 3 $p < 0.05$).
Limitations, reasons for caution: (i) Limited number of subjects, (ii) the implementation of a single dose of cisplatin, (iii) short study period, (iv) lack of knowledge of the optimal dose of resveratrol.
Wider implications of the findings: Resveratrol may be effective in maintenance of primordial, primary and tertiary follicle levels in cisplatin-induced ovarian damage. There is a need for further studies to investigate the effects of resveratrol on human ovaries.
Trial registration number: Ankara Training and Research Hospital Animal Experiments Local Ethics Committee, date and decision number: 04 June 2015/0024.

P-749 The role of PI3-K signalling pathway in insulin actions on testosterone synthesis in peripheral adipose tissue of women with and without polycystic ovarian syndrome

S. Amer[1], N. Alzanati[1], R. Khan[1]
[1]*University of Nottingham, Obstetrics and Gynaecology, Derby, UK*

Study question: Is there a role for PI3-K signalling pathway in insulin regulation of testosterone synthesis in peripheral adipose tissue of women with and without polycystic ovarian syndrome (PCOS)?
Summary answer: PI3-K signalling pathway does not seem to be involved in insulin regulation of testosterone synthesis in peripheral adipose tissue of women with or without PCOS.
What is known already: The positive correlation between the level of circulating androgens, insulin resistance and central obesity is well established. In addition, recent *in vitro* studies have provided evidence of excess androgen synthesis in peripheral adipose tissue of women with PCOS, which could be a potential source of hyperandrogenism. Further research showed insulin to up-regulate the expression of androgen synthesis enzymes (CYP 17 and AKR1C3) as well as testosterone synthesis in peripheral adipocytes of normal but not PCOS women. The underlying mechanisms and the exact signalling pathway involved in the insulin actions on steroidogenesis in adipose tissue of normal women remains to be determined.
Study design, size, duration: This was a laboratory based study involving an *in vitro* differentiated serum free monolayer cell culture of adipocytes harvested from subcutaneous adipose tissue obtained during gynaecological surgery from women with ($n = 5$) and without ($n = 5$) PCOS. All participants were of reproductive age (20–45) with a BMI of 20–35 kg/m^2.
Participants/materials, setting, methods: Pre-adipocytes were isolated from the adipose tissue samples and differentiated to mature adipocytes, which were cultured in FCS-free medium. Recombinant insulin ± LH ± PI3-k inhibitor (LY294002) was added to the cell culture at different concentrations. The supernatant was collected for testosterone measurement before and after treatment with insulin ± LH ± LY294002 using enzyme-linked immunosorbent assay (ELISA).
Main results and the role of chance: Testosterone concentration in the supernatant of untreated cultured PCOS adipocytes (mean ± sem, 129.3 ± 2.5 pg/ml) was significantly ($P < 0.0001$) higher than that (33.7 ± 4.6 pg/ml) of non-PCOS adipocytes. Insulin addition in different concentrations (1 nM/l, 10 nM/l, 100 nM/l) caused a significant increase of testosterone concentrations (94.1 ± 7.1; 118.2 ± 18.2, 200.0 ± 7.3 pg/ml respectively) in the supernatant of cultured non-PCOS adipocytes but not the PCOS adipocytes (118.1 ± 1.8, 90.5 ± 6.4, 89.3 ± 7.6 pg/ml respectively). The increase of testosterone levels in the non-PCOS adipocyte culture supernatant followed a dose dependant fashion. The magnitude of increase in testosterone concentrations in non-PCOS adipocyte culture supernatant was markedly increased when LH was added to insulin. Adding PI3-K inhibitor (LY294002, 1010 ng/ml) to insulin did not change the magnitude of insulin stimulatory effects on testosterone concentrations in non-PCOS adipocyte culture supernatant (Insulin 1 nM/l + LY, testosterone 91.8 ± 2.6; Insulin 10 nM/l + LY, testosterone 119.6 ± 19.4 pg/ml; Insulin 100 nM/l + LY, testosterone 175.1 ± 15.4 pg/l).
Limitations, reasons for caution: The number of biopsies was relatively small in this study and the results will therefore need to be verified by further larger studies.
Wider implications of the findings: Peripheral adipose tissue testosterone levels seem markedly elevated in PCOS women. This supports the hypothesis that excess adipose tissue androgen synthesis plays an important role in PCOS pathogenesis. Insulin±LH seem to play a role in the increased androgen synthesis in adipose tissue, but not through the PI3-K signalling pathway.
Trial registration number: N/A.

P-750 Recombinant vs. urinary human chorionic gonadotrophin (hCG) for triggering final oocyte maturation in patients at risk for ovarian hyperstimulation syndrome OHSS: a randomized clinical trial

G. Lainas[1], T. Lainas[2], C. Venetis[3], I. Sfontouris[2], I. Zorzovilis[2], G. Petsas[2], J. Bosdou[4], B. Tarlatzis[4], E. Kolibianakis[4]
[1]*Barts and The London Centre for Reproductive Medicine, Reproductive Medicine, London, UK*
[2]*Eugonia, IVF Unit, Athens, Greece*
[3]*University of New South Wales, School of Women's and Children's Health UNSW Medicine, Sydney, NSW, Australia*
[4]*Aristotle University of Thessaloniki Medical School, Unit for Human Reproduction, 1st Department of Obstetrics and Gynecology, Thessaloniki, Greece*

Study question: Is the number of metaphase-II (MII) oocytes associated with the type of hCG used for triggering final oocyte maturation in patients at risk for OHSS?
Summary answer: The number of MII oocytes is not associated with the type of hCG used for triggering final oocyte maturation in patients at risk for OHSS.
What is known already: Urinary hCG (u-hCG) and recombinant hCG (rec-hCG) are widely used for triggering final oocyte maturation in patients undergoing ovarian stimulation for *in vitro* fertilization (IVF). Previous studies comparing various doses of u-hCG and rec-hCG have been conducted in normal responders, undergoing long down-regulation protocols. The meta-analysis of these studies suggests that the number of oocytes retrieved, severe OHSS and ongoing/live birth rates are similar between the u-hCG and rec-hCG groups. However, information on the efficacy and safety, of rec-hCG and u-hCG in patients at risk for ovarian hyperstimulation syndrome (OHSS), using GnRH antagonist and recombinant FSH (rec-FSH) is currently not available.
Study design, size, duration: One-hundred patients, undergoing ICSI between 11/2013 and 11/2015 in a single ART center, were randomized to receive either rec-hCG or u-hCG, provided that ≥14 and <24 follicles >11 mm were present at ultrasound on the day of triggering final oocyte maturation. On that day, a study nurse performed random allocation, using a computer-generated randomization list. Based on previously published data, the study was powered to detect a difference of 2.3 MII oocytes between groups at $a = 0.05$ and $b = 0.20$.

Participants/materials, setting, methods: Patients (aged 18–39) underwent ovarian stimulation with recFSH and gonadotrophin releasing hormone (GnRH) antagonists. Following randomization to rec-hCG or u-hCG and oocyte retrieval, fertilization was performed by intracytoplasmic sperm injection (ICSI). The primary outcome measure was the number of MII-oocytes, assessed by an embryologist blinded to the type of the triggering signal. Secondary outcome measures included number of oocytes retrieved, number of 2PN oocytes, ongoing pregnancy rates and incidence of severe early or late OHSS.

Main results and the role of chance: No significant differences were observed between the rec-hCG and u-hCG groups regarding female age (years) (33.7, 95% CI: 32.6–34.8 vs. 33.6, 95% CI: 32.6–34.6, respectively; $p = 0.916$), BMI (Kg/m^2) (23.1, 95% CI: 21.9–24.4 vs. 24.6, 95% CI: 23.3–25.9, respectively; $p = 0.102$), or basal FSH (IU/L) (7.3, 95% CI: 6.87.8 vs. 6.9, 95% CI: 6.5–7.4, respectively; $p = 0.324$). Moreover, no significant differences were observed regarding duration of stimulation (days) (10.2, 95% CI: 9.8–10.6 vs. 9.8, 95% CI: 9.4–10.2, respectively; $p = 0.141$) and total units of gonadotrophins required (1742, 95% CI: 1644–1841 vs. 1708, 95% CI: 1579–1837, respectively; $p = 0.669$).

The mean number of MII-oocytes, was not different between the rec-hCG and the u-hCG groups (12.3, 95% CI: 11.4–13.2 vs. 13.5, 95% CI: 12.6–14.3, respectively; $p = 0.056$).

In addition, rec-hCG and u-hCG groups did not differ in the proportion (%) of mature oocytes retrieved (76.4, 95% CI: 72.3–80.6 vs. 80.2, 95% CI: 76.1–84.3, respectively; $p = 0.205$), in the number of oocytes retrieved (16.1, 95% CI: 15.4–16.8 vs. 16.8, 95% CI: 16.1–17.5, respectively; $p = 0.188$) and in the number of 2PN oocytes (9.1, 95% CI: 8.1–10.0 vs. 9.6, 95% CI: 8.6–10.5, respectively; $p = 0.449$). Finally, the two groups did not differ in ongoing pregnancy rates (23/50 = 46%, 95% CI: 32.1%–60.5% vs. 30/50 = 60%, 95% CI: 45.2%–73.3% respectively; $p = 0.229$). No cases of severe early or late OHSS were observed in either group (95% CI: 0–7.1%).

Limitations, reasons for caution: The patients included in the current study opted to undergo fresh embryo transfer despite extensive counseling regarding the associated risk of severe OHSS and the availability of alternative methods to trigger final oocyte maturation, such as the use of GnRH agonist triggering combined with embryo cryopreservation.

Wider implications of the findings: Both rec-hCG or u-hCG, used for triggering final oocyte maturation, in patients at risk for OHSS appear to have a similar reproductive outcome and OHSS incidence. However, the ease of use, the higher degree of purity and specificity characterizing rec-hCG should be weighted against the lower cost of u-hCG.

Trial registration number: NCT00415766.

P-751 Interventions to improve ART outcome in PCOS patients: a systematic review and meta-analysis

M. Kollmann[1], W.P. Martins[2], M.L. Lima[2], L. Craciunas[3], C. Nastri[2], A. Richardson[3], N. Raine-Fenning[3]
[1]*Medical University Graz, Department of Obstetrics and Gynecology, GRAZ, Austria*
[2]*Ribeirao Preto Medical School, University of Sao Paulo, Department of Obstetrics and Gynaecology, Ribeirao Preto, Brazil*
[3]*School of Medicine, University of Nottingham, Division of Child Health, Obstetrics and Gynaecology, Nottingham, UK*

Study question: Are there any effective interventions which improve ART treatment in women with polycystic ovary syndrome (PCOS)?

Summary answer**:** Low quality evidence suggests benefit of antagonist protocols and metformin Supplementation. Ovulation induction and estradiol is equally effective for endometrial preparation before FET.

What is known already: Recent developments have seen the introduction of various measures to reduce the risks of OHSS and cycle cancellation and to improve oocyte quality. It remains unclear, how all these new approaches have impacted on ART outcomes in PCOS women.

Study design, size, duration: We performed a systematic review and meta-analysis. A comprehensive literature search of the standard medical databases was performed. The last electronic search was run in July 2015.

Participants/materials, setting, methods: Randomized controlled trials evaluating interventions aiming to improve the effectiveness or to reduce complications of ART in women diagnosed with PCOS were included. Data from the included studies was extracted independently by two authors using a predefined pro-forma. Statistical analysis was performed using RevMan version 5.3 (The Nordic Cochrane Centre, Copenhagen, Denmark) and MedCalc version 12.7 (MedCalc Software bvba, Ostend, Belgium).

Main results and the role of chance: We screened 1,021, completely assessed 173 records, and finally included 66 studies in the quantitative analysis. Many different interventions were assessed, however overall quality of studies was low. We observed moderate quality evidence that there is no clinically relevant difference on live birth/ongoing pregnancy, or clinical pregnancy when comparing antagonist and agonist protocols for controlled ovarian stimulation. Additionally, we found low quality evidence that metformin improves live birth/ongoing pregnancy and clinical pregnancy rates. We further found low quality evidence that there is no clinically relevant difference on live birth/ongoing pregnancy and clinical pregnancy when comparing human menopausal gonadotropin (hMG) for inducing ovulation and artificial preparation with estradiol valerate for endometrial preparation for frozen embryo transfer. Low quality evidence suggests that mannitol and antagonist protocols reduce ovarian hyperstimulation syndrome (OHSS).

Limitations, reasons for caution: Limitations included methodological quality, marginal variability of investigated interventions and outcomes.

Wider implications of the findings: Further investigation is recommended. To facilitate metaanalysis, future research should be done using outcome measures consistent with those in the studies included here.

Trial registration number: PROSPERO – CRD42014007304

P-752 Are polyfluoroalkyl chemicals associated with raised levels of serum testosterone in women with and without Polycystic Ovary Syndrome, undergoing controlled ovarian hyperstimulation IVF cycle

T. Cunningham[1], D. Drage[2], V. Allgar[3], E. Kilpatrick[4], S. Maguiness[1], J. Mueller[2], S. Atkin[5], T. Sathyapalan[6]
[1]*The Hull IVF Unit, Hull, UK*

[3]*Hull York Medical School, Statistical Department, Hull, UK*
[4]*Sidra Medical and Research Centre, Sidra Medical and Research Centre, Doha, Qatar*
[5]*Weill Cornell Medicine, Research, Doha, Qatar*
[6]*Hull York Medical School, Centre for Cardiovascular and Metabolic Research, Hull, UK*

Study question: Could Polyfluoroalkyl agents(PFAAs) be an environmental trigger for abnormal testosterone production in women with and without Polycystic Ovary Syndrome?

Summary answer: PFAAs have significant correlation with serum testosterone levels in both women with and without PCOS.

What is known already: PFAAs are formed by degradation of polyfluorinated compounds used in many consumer products such as in the paper and textile industry. The three most abundant PFAAs are perfluoro octanoic acid (PFOA), perfluorooctane sulfonic acid (PFOS), and perfluorohexane sulfonic acid (PFHxS), with half-lives to be 3.8, 5.4, and 8.5 years, respectively.

There is minimal literature on PFAAs, but animal studies have demonstrated that exposure to PFOS and PFOA may affect the integrate balance of sex hormones and pregnancy loss in animals. Exposure of male rats to PFOA can reduce testosterone levels, resulting in hyperplasia of the Leydig cells within the testis.

Study design, size, duration: This prospective cohort study was undertaken over a 6-month period in the Hull IVF Unit, UK. PCOS women were selected using the revised 2003 criteria from the Rotterdam ESHRE/ASRM sponsored PCOS consensus workshop group. No patients were lost to follow-up. Statistical analysis was performed to assess for potential associations with the levels of serum contamination of these endocrine disrupting agents (EDAs), pregnancy rates and endocrine profiles of the subjects.

Participants/materials, setting, methods: Fasting serum samples were collected from 59 (29 PCOS and 30 controls) women undergoing IVF/ICSI. The serum samples were analysed using Liquid chromatography-tandem mass spectrometry to measure the concentration of the polyfluoroalkyl congeners. Testosterone is measured by stable isotope dilution chromatography-tandem mass spectrometry. All patients underwent a standard IVF antagonist protocol, embryo transfers were performed on day 3 or ideally at day 5 (blastocyst) to give the best chance for implantation.

Main results and the role of chance: In this present study PFOS, PFOA, PFHxS and perfluorononanoic acid (PFNA) were detected in 100% of the serum samples and perfluorononanoic acid (PFDA) was detected in 76% of samples. PFOS was the PFAA detected in the highest concentration in both the PCOS and control groups, 4.11 ± 1.62ng/ml and 3.33 ± 1.05ng/ml respectively. PFOS concentration was significantly higher in the PCOS group compared to the controls, $p = 0.03$. The levels of PFOS in this study were significantly lower than recent literature, confirming that levels of EDCs continue to decline following the ban of these chemicals. The PFAAs had significant positive correlations with testosterone in the overall patient population and in both the control and PCOS subgroups. In the 59 patients overall, PFOS and PFDA had very significant positive correlations with testosterone ($r = 0.411$, $p = 0.001$, and $r = 0.393$, $p = 0.002$ respectively), with PFHxS, PFOA and PFNA having significant positive correlations at the $p = 0.05$ level. In the control group PFOS and PFOA maintained a significant positive correlation ($p = 0.02$ and $p = 0.04$ respectively) and in the PCOS group PFOS and PFDA maintained a significant positive correlation ($p = 0.03$ and $P = 0.02$ respectively). There was no correlation between the levels of EDAs and pregnancy rates in either the PCOS and control groups.
Limitations, reasons for caution: Studies have demonstrated associations with EDAs and adverse reproductive effects, however no standard validated test can assess potential exposure to EDAs and possible adverse reproductive outcomes. This small study has demonstrated a possible endocrine disrupting effect of PFAAs and testosterone but larger studies are needed to support these findings.
Wider implications of the findings: PFAAs may effect the androgen pathway in both women with and without PCOS, but the higher levels of PFOS in the PCOS group may demonstrate that this population of women may be more prone to the effects of this group of EDAs.
Trial registration number: Not applicable

P-753 Altered expression of Wnt/beta-catenin signaling pathway in endometrium of women with polycystic ovarian syndrome (PCOS)

W. Palomino[1], M. Fajardo[1], F. Argandoña[1], P. Kohen[1], L. Devoto[1]
[1]University of Chile, Institute for Maternal and Child Research, Santiago-RM, Chile

Study question: Is Wnt/beta-catenin signaling pathway abnormally expressed in the endometrium of women with polycystic ovarian syndrome (PCOS)?
Summary answer: The endometrium of women with PCOS exhibit altered beta-catenin expression compared to fertile cycling women
What is known already: The Wnt/beta-catenin signaling contributes to normal endometrial proliferation and secretory transformation driven by ovarian steroids during menstrual cycle. Unopposed estrogen action may lead to constitutive Wnt/beta-catenin activation triggering endometrial hyperplasia and cancer. Risk factors for endometrial hyperplasia and cancer includes PCOS.
Study design, size, duration: Retrospective observational study was designed to compare the expression of beta-catenin in endometrial samples of 32 fertile women with regular menses and infertile women with PCOS diagnosed according to Rotterdam criteria obtained during 2012–2014 at university affiliated institution in Santiago Chile.
Participants/materials, setting, methods: Endometrial biopsy was obtained during proliferative phase. Institutional Ethics Board approved the protocol. Beta-catenin was localized by immunohistochemistry. Histologic score (Hscore) was assigned for immunostaining. Protein abundance and mRNA levels was determined by western blot and qRT-PCR in endometrial epithelial cells harvested by laser capture microdissection (LCM). Non parametric Mann–Whitney test was employed for comparison of numerical variables.
Main results and the role of chance: Cytoplasmic and nuclear beta-catenin was localized in endometrial cells. According to Hscore high beta-catenin expression was found in proliferative endometrium from women with PCOS compared to fertile cycling women 3.6 ± 0.2 vs. 2.1 ± 0.2 respectively. Western blot for beta-catenin corroborated high protein abundance in PCOS samples. The mRNA levels in epithelial cells dissected by LCM confirmed high beta-catenin expression in PCOS samples 2.7 ± 0.1 vs. 1.4 ± 0.1 respectively.
Limitations, reasons for caution: This is a retrospective study including limited number of samples.
Wider implications of the findings: The altered Wnt/beta-catenin pathway found in this study may represent the early molecular changes of endometrial abnormalities associated with PCOS.
Trial registration number: No required

P-754 Alcohol consumption and live birth among fertility patients: a nationwide register-based cohort study

I. Madsen[1], G. Lindved Petersen[1], M. Kamper-Jørgensen[1], A. Pinborg[2], S. Lone[1]
[1]Department of Public Health, Section of Social Medicine, Copenhagen, Denmark
[2]Copenhagen University Hospital Hvidovre, The Fertility Clinic, Copenhagen, Denmark

Study question: Does preconceptional female and male alcohol consumption influence the probability of achieving a live birth after assisted reproductive technology (ART) treatment?
Summary answer: Male alcohol consumption seems to negatively affect probability of a live birth after ART. Female alcohol consumption was not associated with odds of live birth.
What is known already: Previous studies have shown inconsistent results. One study found no association between female alcohol consumption and live birth, while another found that women consuming at least 4 drinks/week, had 16% lower odds of achieving a live birth compared to women consuming less. An increase in paternal alcohol consumption of one drink/day increased the risk of not achieving a live birth by 3.14 times, while, in another study, no significant effect of male intake was seen. Odds of live birth were 21% lower among couples where both partners consumed at least 4 drinks/week, compared to couples where both spouses consumed less.
Study design, size, duration: A Danish national, register-based prospective cohort study; A total of 29,834 treatment cycles performed on 12,981 women undergoing fertility treatment in the period from January 1, 2006 to September 30, 2010, were included in the study. Collection of outcome was continued till June 30, 2011.
Participants/materials, setting, methods: All Danish women undergoing at least one treatment cycle with autologous oocytes in the study period were eligible for this study. Information on preconceptional alcohol consumption was extracted from the *in vitro* fertilization (IVF) register and linked to registries containing information on all births and abortions. We performed multilevel logistic regression analyses to estimate odds of live birth after ART under consideration of the non-equal rate of success between two different individuals.
Main results and the role of chance: In total, 12,981 women and their partners went through 29,834 treatment cycles. For female abstainers and heavy consumers (>7 drinks/week) the live birth rate was 22.4% and 20.4%, respectively. Concerning men, 22.6% of cycles led to a live birth, when the man was abstinent, compared to 20.2% of cycles in male heavy consumers (>14 drinks/week). Overall, results from statistical analyses did not reach significance, but interesting tendencies were seen. For men, a tendency of decreasing odds with increasing alcohol consumption was observed (OR 0.97 95% CI 0.73–1.30, 0.89 95% CI 0.68–1.15 and 0.74 95% CI 0.44–1.25 for light (1–2 drinks/week), moderate (3–14 drinks/week) and heavy consumers respectively), when comparing to male abstainers. From the trend analysis, a decrease of one percent (OR for trend 0.99; 95% CI 0.97–1.01) was observed with every one-unit increase in weekly alcohol consumption. Female alcohol consumption did not seem to affect odds of achieving a live birth (OR for trend 1.00; 95% CI 0.99–1.01). Combined results on couples were inconclusive.
Limitations, reasons for caution: Alcohol consumption was self-reported, which can cause misclassification due to information bias. However, applying different sensitivity levels did not change our estimates markedly. We excluded 11,205 cycles (24.7% of baseline) due to missing information on female alcohol consumption, but we do not expect non-response to be related to alcohol consumption.
Wider implications of the findings: In accordance with previous findings, our results suggest that preconceptional male alcohol consumption is negatively associated with the ability to achieve a live birth after ART treatment. More focus on both partners' alcohol consumption may be beneficial in the preconceptional care of couples seeking fertility treatment.
Trial registration number: n/a

P-755 World trends in Assisted Reproductive Technology (ART) 2004–2013

V.A. Kushnir[1,2], D. Barad[1,3], D. Albertini[1,4], S. Darmon[1], N. Gleicher[1,5]
[1]*The Center for Human Reproduction, N/A, New York, NY, USA*
[2]*Wake Forest School of Medicine, Obstetrics and Gynecology, Winston-Salem, NC, USA*
[3]*Albert Einstein College of Medicine, Obstetrics and Gynecology, Bronx, NY, USA*
[4]*University of Kansas Medical Center, Molecular and Integrative Physiology, Kansas City, KS, USA*
[5]*Rockefeller University, Laboratory of Stem Cell Biology and Molecular Embryology, New York, NY, USA*

Study question: How have ART outcomes evolved around the world over the last decade?
Summary answer: International ART practices are characterized by highly significant outcome differences between regions.
What is known already: ART has undergone considerable changes over the last decade, with different regions of the world at times going in different directions.
Study design, size, duration: Based on data retrieved from national ART registries, we report how changes in clinical practice between 2004 and 2013 have impacted outcomes in Australia and New Zealand, Canada, Continental Europe, the UK, Japan, Latin America, and the United States (US).
Participants/materials, setting, methods: The data reflect 6,589,581 total ART cycles utilizing both fresh and previously cryopreserved embryos from autologous oocytes that resulted in 1,335,615 live births.
Main results and the role of chance: We observed a worldwide increase in the utilization of single embryo transfer (SET) and of previously frozen embryos. In 2012–2013, fresh cycle live birth rates were highest in the U.S. (29%) and the lowest in Japan (5%). While gradual improvements in live birth rates were observed in most regions, some regions exhibited either no change or even declines. A significant decline in fresh ART live birth rates were most apparent in Japan and Canada. Declining fresh cycle live birth rates in Japan were partially offset by improved rates with frozen cycles. This shift coincided with introduction of mild ovarian stimulation ("mini IVF"), embryo banking and blastocyst stage elective SET protocols. Concomitantly, fresh ART cycle starts in Japan tripled. Declining fresh cycle live birth rates in Canada coincided with implementation of an SET policy in Quebec.
Limitations, reasons for caution: National data sets vary greatly in data collection and quality. They, therefore, are not necessarily comparable. Observed associations with changes in regional IVF practice do not necessarily denote causations.
Wider implications of the findings: Trends suggest that some newly introduced ART practices may have negatively affected outcomes. New ART practices should be introduced to general clinical practice more cautiously. An international consensus on the definition of ART success may be required before attempts to resolve discrepancies in worldwide ART outcomes can be fully realized.
Trial registration number: N/A

P-756 Credibility test in meta-analysis: a support for clinical decision

J.G. Franco Jr.[1,2], C.G. Petersen[1,2], A.L. Mauri[1,2], L.D. Vagnini[2], A. Renzi[2], G.R. Oliveira-Pelegrin[2], A. Nicoletti[1], M. Cavagna[1,2,3], F. Dieamant[1,2], R.L.R. Baruffi[1,2], J.B.A. Oliveira[1,2]
[1]*Centre for Human Reproduction Prof. Franco Jr, Research, Ribeirao Preto, Brazil*
[2]*Paulista Center for Diagnosis Research and Training, Research, Ribeirao Preto, Brazil*
[3]*Women's Health Reference Center, Perola Byington Hospital, Research, Sao Paulo, Brazil*

Study question: This study proposes a simple test to analyse the strength of meta-analysis results.
Summary answer: The credibility test is an important tool for quality control of the results of a meta-analysis.
What is known already: Evidence-based medicine has elevated meta-analyses to the status of key parameters in medical decisions. Every year, over 6,000 meta-analyses are published in medical journals and submitted to the appreciation of physicians, who then must analyse their conclusions and use them to support medical decisions. ART does not escape this rule, and meta-analyses concerning topics with controversy (PGS, GnRH agonists vs. GnRH antagonists, etc.) are frequently published. However, some meta-analyses reach conclusions that periodically change with the addition of new prospective randomized trials.
Study design, size, duration: Two meta-analyses were chosen for the application of the credibility test.

1. Anticoagulant prophylaxis (Dentali et al., 2007) for the prevention of pulmonary embolism; results are in favour of the use of anticoagulants.
2. Endometrial injury (Nastry et al., 2015). An analysis of clinical pregnancy in women with ≥2 previous embryo transfers; results are in favour of the use of endometrial injury.

Participants/materials, setting, methods: Performing the credibility test consists of removing at least 1 study from a meta-analysis and observing whether the original results remain. Interpretation: Credibility Present: the removal of one or more articles does not affect the conclusion of the meta-analysis. Credibility Absent: the removal of one article affected the conclusion of the meta-analysis. Data were analysed using StatsDirect. Data were expressed as in the original meta-analysis. Heterogeneity was evaluated using Cochran's Q and I^2 tests.
Main results and the role of chance: Meta-analysis I: credibility is present. Even after the random removal of two trials, the result continued to significantly favour the use of anticoagulants for the prevention of pulmonary thromboembolism. The result has credibility for clinical application. Meta-analysis II: credibility is absent. The result has no credibility for clinical application. After the random removal of only one trial, the result changed and was no longer statistically significant.

P-757 The association between Hepatitis B virus infection and the underlying cause of infertility – A study in an endemic region

S.M.J. Mak[1], T.T.H. Lao[1], T.C. Li[1]
[1]*The Chinese University of Hong Kong, Obstetrics & Gynaecology, Shatin, New Territories, Hong Kong*

Study question: Is hepatitis B virus infection associated with a specific underlying cause of infertility?
Summary answer: Hepatitis B virus infection was associated with secondary infertility due to tubal and uterine factors.
What is known already: Screening for hepatitis B virus infection is performed routinely in the workup investigation in infertile couples. Positive screening in the male partner has been associated with poor sperm quality. There are conflicting reports on the impact of infection in either partner on the outcome of in-vitro fertilization treatment. However, it is unknown whether infection in either partner is associated with a specific underlying cause of infertility. In this study, we explored the relationship between infection in either partner and the underlying cause of infertility in Hong Kong, where the infection is endemic with reported prevalence of 10% in obstetric population.
Study design, size, duration: This is a retrospective observational study conducted among consecutive infertility couples managed in the Assisted Reproductive Unit, the tertiary referral centre affiliated with the Department of Obstetrics and Gynecology, The Chinese University of Hong Kong, during the period January to October 2015.
Participants/materials, setting, methods: There were 739 couples managed during the study period. The causes of infertility were classified into tubal factor, pelvic adhesion, endometriosis, uterine factor, male, anovulation, polycystic ovarian syndrome, hyperprolactinaema, immunological, coital and unexplained factors. The hepatitis B viral serostatus for the couple were checked upon referral and within 2 years of the treatment cycles.
Main results and the role of chance: Husband of female hepatitis B carrier is 3.15 times risk of being hepatitis B carrier (18.4% vs. 6.7% [$P = 0.003$; OR 3.15, CI 1.440–6.889]). In the female subjects, hepatitis B carriage was more likely to be associated with secondary infertility (63.0% vs. 45.2% [$P = 0.014$; OR 0.479, CI 0.263–0.873]); and with tubal factor (71.4% vs. 42.8% [$P < 0.000$; OR 3.347, CI 1.769–6.335]) and uterine factor (14.6% vs. 3.0% in non-hepatitis carriers [$P < 0.000$; OR 5.431, CI 2.182–13.515]), but was less likely to have unexplained infertility (2.0% vs. 13.8% [$P = 0.018$; OR 0.130, CI 0.018–0.957]). There was no significant association with the other causes that included pelvic adhesion, endometriosis, anovulation, polycystic

ovarian syndrome, hyperprolactinaema, immunological, coital dysfunction, or male factor. In the male subjects, hepatitis B carriage was also associated with tubal factor in female partners (60.0% vs. 43.4% [$P = 0.017$; OR 1.955, CI 1.116–3.423]), but there was no significant association with the other factors, including male factor or coital dysfunction.

Limitations, reasons for caution: Hepatitis B virus could have served as surrogate for other infections in its association with tubal factors of infertility. Although sexually transmitted diseases were screened routinely by culture of endocervical swab, infections such as chlamydial infection could be missed due to the low yield of this method.

Wider implications of the findings: Hepatitis B carriage in infertile women increased the likelihood of tubal and uterine factors but not other infertility factors. The exact underlying reason is unclear but it may alter the immunological response to tubal-peritoneal infections. A positive screening result should be an indication to vigilantly rule out any sexually-transmitted infections.

Trial registration number: Nil

P-758 Does rationing fertility treatment lead to better success rates? A population-based comparative analysis of Australian and New Zealand assisted reproductive technology cycles

C.M. Farquhar[1], W. Gillett[2], L. Rombauts[3], A. Macaldowie[4], G. Chambers[5]
[1]*University of Auckland, Auckland, New Zealand*

Study question: Are the differences in the success rates of assisted reproductive technology (ART) cycles between Australia and New Zealand explained by different funding approaches?

Summary answer: Different funding approaches may have resulted in healthier women undergoing treatment and may explain the improved pregnancy outcomes in New Zealand couples having fertility treatments.

What is known already: The difference in funding arrangements of ART procedures between Australia and New Zealand has meant that Australian women had greater access to treatment compared to women in New Zealand. In 2010, we first reported on the impact of the different funding arrangements on access and outcomes in Australia and New Zealand from the years 2004 to 2007. In that report, the rates of live delivery following fresh ART cycles were significantly higher in New Zealand than in Australia in all age groups, in spite of higher proportions of single embryo transfer (SET) in New Zealand.

Study design, size, duration: A comparative analysis of the treatment, pregnancy and perinatal outcomes of autologous ART cycles in Australia and New Zealand from 2010 to 2013 in the context of policy where New Zealand has specified criteria in order to access public funded fertility treatment and Australia does not.

Participants/materials, setting, methods: 162,952 autologous fresh cycles and 93,376 autologous thaw cycles from Australian and New Zealand Assisted Reproduction Database (ANZARD). ANZARD data are collected annually, in de-identified format, from all fertility centres in Australia and New Zealand. ANZARD includes information about the demographic characteristics of patients undergoing treatment, the types of ART procedures performed, and information on pregnancy and birth outcomes.

Main results and the role of chance: For all age groups, the live birth rates following fresh embryo transfer cycles were significantly higher in New Zealand (23.7%) than in Australia (16.5%) a difference of 8.2% ($p < 0.01$). The crude rate of live delivery per initiated fresh cycles for all women was 1.43 times higher in New Zealand than in Australia (RR 1.43, 95% CI 1.38–1.48). These differences in outcomes persisted in all age groups. The difference in live delivery between New Zealand and Australia was also present in all age groups in thaw cycles although the difference was smaller (23.3% vs. 19.8%, $p < 0.01$). Overall rates of single embryo transfer (SET) are similar between Australia and New Zealand, but significant differences are seen within age categories, with New Zealand utilizing more SET in women aged <35 (90.7% vs. 82.5%, $p < 0.01$) and less SET in women aged >40 compared to Australia (33.8% vs. 53.3%, $p < 0.01$). In agreement with the SET rates, for women aged less than 35 years, there were increased rates of singletons in New Zealand compared with Australia (95.4% vs. 93.3%, $p < 0.01$). Blastocyst transfer rates were also higher in Australia (53.3%) than New Zealand (39.1%, $p < 0.01$) as was intracytoplasmic sperm injection rates (65.3% and 56.7% $p < 0.01$).

Limitations, reasons for caution: Data was not available on length of infertility, body mass index or number of treatment cycles. There was no data on how each cycle is funded in New Zealand. 13.5% of Australian data did not report a cause of infertility. There was a higher proportion with unexplained infertility in Australia.

Wider implications of the findings: Restricting access to treatment may limit utilization but may also select an infertile but healthier population (not obese, non smokers). The purpose of the New Zealand criteria is to treat women with a low likelihood of natural pregnancy and also avoid pregnancies in women at risk of poor perinatal outcomes.

Trial registration number: Not required

P-759 Lethal consequences of infertility on lives of poor women surviving in developing countries like Pakistan

S. Shah Nawaz[1]
[1]*Andrology Institute of Pakistan STAR ICSI, Obstetrics and Gynecology, Sargodha, Punjab, Pakistan*

Study question: Questionnaire was given, where age, duration of infertility, socioeconomic status, known previous ailment (medical or psychological), permanent contact numbers, social and personal status of couple and agreement for future liaison.

Summary answer: Females belonging to poor to average socioeconomic status with age between 33 and 38 years were selected in this study group.

What is known already: Being infertile in developing countries like Pakistan is social crime for women, leading to medical, psychiatric and sometimes surgical problems. Severity is directly related to duration of infertility, extent of poverty and mean age of women. In this study we aimed to investigate that what are the ultimate consequences of infertility on these poor helpless dependent women of Pakistan. Since women of Pakistan are already bearing the crises of male dominating society, so they are prone to be victimized easily resulting in severe medical and psychological distress.

Study design, size, duration: RCT conducted on 252 female patients in Andrology institute of Pakistan (STAR ICSI), between 1st August 2010 and 31st July 2012. A questionnaire was given to gather information about sociodermographic characteristics, and was completed by the individual. Later on follow up was done during 1st January 2014 to 31st December 2015, to see further consequences on infertile women.

Participants/materials, setting, methods: Total 252 females belonging to poor to average socioeconomical status were selected in this study group. Mean age of females was between 33 and 38 years. Duration of infertility was between 5 and 10 years. Patients with known medical disorders were excluded in this group. A bond of agreement was signed by patients, where they agreed to provide future informations about their personal marital lives.

Main results and the role of chance: Among 252 females, 73.41% of them were having primary infertility. During the follow up of consecutive 2 years, 69 patients conceived. It means 27.3% became pregnant. Among remaining 183 Infertile patients, 22 females experienced severe social disaster resulting in the form of divorce. It means 12.2% of females were divorced just because of their inability to conceive. 47 patients are still living separately from their husbands just because of this allegation that they cannot procreate. It means 25.6% of patients suffered from severe social crises. 73 patients suffered from some psychiatric problems for which they have to seek advise and medication from psychiatrist. It means 39.8% of infertile patients underwent some psychiatric problems just because of their stigma of infertility. 27 patients experienced disastrous medical and surgical complications due to maltreatment by dais and quakes. It means 14.7% of patients underwent serious complications of maltreatment. 4 patients died during these 2 years. According to some people of their premises they have

committed suicide (no legal record). 10 patients are still seeking medical help and ready to go for ART. It means 5.4% of patients are still on right pathway and not loosing their hopes.
Limitations, reasons for caution: Developing country like Pakistan who is unable to cope with stigma of population explosion, cannot offer any help to poor infertile dependent female, who is unable to handle this issues alone in this male dominating society, resulting in bad medical and psychological impacts in their lives.
Wider implications of the findings: Although this study has limitations regarding sample size and duration but still this small study may help to create a revolution in the field of infertility, for poor masses in developing countries and may create light in the dark tunnel of disappointment for haunted poor females.
Trial registration number: Applied for registration number. It will be provided at time of presentation.

P-760 Racial differences in birth outcomes in women undergoing ovulation induction (OI)

R. Makhijani[1], V. Mensah[2], I. Iko[3], C. Lam[3], P. Has[4], K. Pagidas[5]
[1]*Brown University, Women and Infants Hospital, Obstetrics and Gynecology, Providence, RI, USA*
[2]*Brown University, Women and Infants Hospital, Reproductive Endocrinology and Infertility, Providence, RI, USA*
[3]*Brown Alpert Medical School, Medical School, Providence, RI, USA*
[4]*Brown University, Women and Infants Hospital, Epidemiology and Biostatistics, Providence, RI, USA*
[5]*University of Louisville, Reproductive Endocrinology and Infertility, Louisville, KY, USA*

Study question: Do reproductive outcomes differ between non-white and white women undergoing OI followed by intrauterine insemination (IUI)?
Summary answer: White women undergoing OI/IUI had a significantly higher clinical pregnancy rate (CPR) and a higher likelihood of achieving clinical pregnancy compared to non-white women.
What is known already: Women of three minority groups in the United States – Black, Asian and Hispanic – have lower birth rates with *in vitro* fertilization (IVF) compared to white women.
Study design, size, duration: This was a retrospective case control using medical records collected in a database of patients who underwent OI/IUI at an academic fertility center. The cohort consisted of 235 white and 166 non-white women between ages 25 and 45 who underwent OI with clomid citrate, letrozole or recombinant FSH followed by IUI between 12/2013 and 4/2014.
Participants/materials, setting, methods: Subjects were matched by age and day 3 FSH and categorized as white or non-white based on self-reporting of race/ethnicity. There was 2:1 matching of white patients to non-white patients. Main outcomes were odds ratios for clinical and biochemical pregnancy as well as CPR and biochemical pregnancy rate (BPR). Data was analyzed using chi-square or Fischer's exact test for categorical variables and *t*-test or Wilcoxon rank-sum for continuous variables.
Main results and the role of chance: Mean duration of infertility for both groups was 21 years. There was a significantly greater prevalence of tubal factor ($n = 6$, 3.6%) and fibroids ($n = 10$, 6.0%) in the non-white group versus the white group ($p < 0.05$). Twenty-five percent of non-white women used donor sperm compared to 12.8% of white women ($p < 0.01$). There were no significant differences between groups in the agent used for OI ($p > 0.05$). CPR was significant higher in white patients ($n = 34$, 14.9%) compared to non-whites ($n = 10$, 6.2%) ($p < 0.05$). BPR was not significantly different (white = 10, 4.4%, non-white = 3, 1.9%, $p > 0.05$). White patients were 2.68 times more likely to achieve clinical pregnancy than non-white patients (CI 95%, 1.28–5.59). White patients were also 2.44 times more likely to achieve biochemical pregnancy compared to non-white patients, but this association was not statistically significant (0.66–9.02).
Limitations, reasons for caution: Due to the retrospective nature of this study, we relied on the accuracy of the electronic record. Furthermore, while this was a case-control and the subjects were matched by age and day 3 FSH, there may have been other confounding factors that we were unable to account for.
Wider implications of the findings: These findings suggest that racial disparities in reproductive outcomes in non-white women are not limited to IVF and extend to OI/IUI cycles. This disparity warrants further investigation into what genetic or biological mechanisms may underlie this inequality.
Trial registration number: Not applicable.

P-761 IVF success rate does not linearly increase with number of collected oocytes when limiting number of fertilised oocytes

P. Pierzynski[1], P. Laudanski[2], P. Kuc[3], A. Kuczynska[1], K. Lukaszuk[4], W. Kuczynski[5]
[1]*Medical University of Bialystok, Department of Reproduction and Gynaecological Endocrinology, BIALYSTOK, Poland*
[2]*Medical University of Bialystok, Department of Perinatology, Bialystok, Poland*
[3]*Medical University of Bialystok, Department of Gynaecology and Gyanecological Oncology, Bialystok, Poland*
[4]*Invicta Fertility Clinic, Gdansk, Gdanski, Poland*
[5]*Medical University of Bialystok, Department of Gynaecology and Oncological Gynaecology, Bialystok, Poland*

Study question: Does fresh IVF cycle allowing collection of up to 9 oocytes offers similar chances for pregnancy as compared to cycles producing more than 10 oocytes.
Summary answer: In fresh IVF following the fertilisation of up to six MII oocytes. cycles producing 7–9 MII oocytes provided the highest chance for pregnancy
What is known already: Results describing the association between the number of oocytes retrieved and IVF outcomes after fresh embryo transfer are conflicting in the literature. Reasonable limiting of number of fertilised oocytes is claimed to decrease the numbers of frozen embryos while maintaining good overall success rates.

In 2013 Polish government introduced public funding of IVF in which, due to ethical/political reasons the number of fertilised oocytes was limited to six and single embryo transfer was obligatory. In this presentation we review the effect of that in the unselected population of women under 35 years treated by IVF.
Study design, size, duration: The data on 12 011 fresh IVF cycles conducted over a period of 2 years (1st of July 2013 to 1st of July 2015) were collected retrospectively. Stratified analysis was used to evaluate the relationships between the number of retrieved oocytes, quality of embryos and the chances for successful outcome of the treatment.
Participants/materials, setting, methods: Participants: Women younger than 35 years of age treated in IVF programme due to infertility related to endometriosis and male, ovarian, tubal or unknown factors of infertility. Setting: 30 accredited fertility centres in Poland. Methods: retrospective analysis covering clinical data, embryological data and outcomes of fertility treatments.
Main results and the role of chance: The study presents unique clinical material of more than 12 thousand fresh IVF cycles with obligatory limitation of number of fertilised oocytes and obligatory single embryo transfer. In 12 011 fresh IVF cycles conducted on women younger than 35 years of age, oocyte retrieval procedure producing 7–9 oocytes offered best chances for pregnancy following the IVF (2 484 fresh embryo transfers (ETs)/37.04% of clinical pregnancies). When reaching 6 or less oocytes, the clinical pregnancy rates were of 32,19% (of 6 894 fresh ETs). Increased numbers of collected oocytes did not offer improvement of chances for clinical pregnancy – when collecting 10–12 oocytes, 13–15 oocytes and 16 and more oocytes, the clinical pregnancy rates reached 35.09% (1553 ETs); 36.68% (668 ETs) and 34.95% (412 ETs), respectively. Relatively high pregnancy rates might indicate on the need for re-evaluation of current approach of fertilizing all collected and mature oocytes. High numbers of analysed cycles limit the impact of chance in the presented material.
Limitations, reasons for caution: It is a preliminary report covering a period of 24 months of health programme originally scheduled for 3 years, ending in June 2016. Comprehensive analysis will follow after the completion of the programme.
Wider implications of the findings: Study provides data on the impact of limitation of number of fertilised oocytes and requirement for single embryo transfer on success rates of IVF cycles. In spite of apparently limiting factors, the

success rates remained relatively high which brings up the question of optimal number of fertilised oocytes in IVF.
Trial registration number: N/A

P-762 Cultural aspects of oocyte freezing: a pilot survey on knowledge and attitudes in a Swiss female academic population

D. Wirthner[1], M. Emery[2], N. El Ghaziri[3], L. De Jonckheere[4], D. Wunder[1], J. Darwiche[3]
[1]Centre for Medically Assisted Procreation CPMA, Reproductive Medicine, Gynecology and Obstetrics, Lausanne, Switzerland
[2]Centre for Medically Assisted Procreation CPMA, Psychosomatic and Psychosocial Medicine, Lausanne, Switzerland
[3]University of Lausanne, Institute of Psychology, Faculty of Social and Political Sciences, Lausanne, Switzerland
[4]Centre for Medically Assisted Procreation CPMA, Sexual and Reproductive Health, Lausanne, Switzerland

Study question: What do young female academics know about fertility preservation through oocyte freezing, what are their opinions and which attitudes do they envisage for themselves?
Summary answer: Most participants knew about oocyte freezing, which was rated more positively if used for medical reasons than for lack of a partner or career choices.
What is known already: In Switzerland, the mean age for women at the birth of their first child rises continually, reaching 31.7 in 2014. Statistics show that 30% of women in their fifties with a university degree are childless and that those with children had less than the number they wished for. Recent studies on fertility awareness and attitudes towards parenthood in academic populations note considerable risks for future involuntary childlessness. The use of oocyte freezing for social reasons is increasing, mostly in the highly educated female population, but generally at ages over 35, which offer lower chances of reaching optimal live birth rates.
Study design, size, duration: This cross sectional exploratory survey aimed to retrieve data from about 100 female academics in a period presumably preceding their wish to start a family, but close enough so that reflecting on childbearing options could be of interest to them. The questionnaire was developed by clinical specialists in ART and research psychologists.
Participants/materials, setting, methods: All female students in a master's class in psychology were invited to fill out the questionnaire in the same sitting, on a voluntary and anonymous basis. Data on previous knowledge of oocyte freezing, as well as the participants' general opinions and personal attitudes towards childbearing, age limits and oocyte freezing for medical or social reasons, were collected. The 95 participants (100% response rate) were aged 21 to 30 (M 23.6; SD 1.98) and were childfree.
Main results and the role of chance: Of the 95 participants, 78.9% knew about the possibility to freeze oocytes. While 9.5% did not wish to have children, the rest indicated the ideal age for themselves as 29 (M = 29.3; SD = 2.4, range 25–39), and the superior limit as 39 (M = 39.0; SD = 3.6, range 31.5–49). The majority (57.9%) noted oocyte freezing as a positive technical advancement, though 2.1% viewed it negatively. While 84.2% saw no religious problem, 34.7% perceived ethical problems such as the high financial cost (69.4%) and the necessity to pose an age limit for childbearing (77.7%). This age limit was noted at 46 years (SD 5.7, range 35–70). Participants were generally favourable towards oocyte freezing in case of chemotherapy (93.7%) or premature ovarian failure (87.4%), but less so if one hadn't found a partner (47.4%), or for career choices (28.4%). Possible personal use of oocyte freezing was rejected by 22.1%, while 77.9% would envisage it for medical reasons, 25.2% for lack of a partner and 9.5% to choose the ideal moment for a pregnancy. Most participants (80%) wished to develop their career before childbearing, 70% had chosen psychology studies in order to balance career and family and for 56.9% oocyte freezing wasn't a good option for attaining this.
Limitations, reasons for caution: The results of this pilot study reflect the attitudes of a sample of highly educated young women, who represent the main population of women using oocyte freezing. Their specialisation in psychology probably indicates heightened interest in socio-cultural issues, and these are perhaps not representative of the general population.
Wider implications of the findings: Young female academics are largely favourable to oocyte freezing for medical reasons, whereas social reasons raise certain ethical questions. Comprehensive information and debating about these issues are important to clarify the influence of socio-cultural factors such as higher education, age and the choice of a partner on future reproductive choices.
Trial registration number: None

P-763 Awareness and attitude of potential Italian oocyte donors towards fertility issues, gamete donation and social freezing: a survey

S. Sgargi[1], A.G. Aiello[1], P. Battistini[1], M.C. Magli[1], A.P. Ferraretti[1], L. Gianaroli[1]
[1]S.I.S.M.E.R. s.r.l., Reproductive Medicine Unit, Bologna, Italy

Study question: What is the attitude of young Italian women towards fertility issues, gamete donation and social freezing?
Summary answer: Almost half of the responders were not informed or did not have an opinion about fertility issues, gamete donation and social freezing.
What is known already: Gamete donation was routinely performed in Italy until Law 40/2004 on Medically Assisted Reproduction (MAR) prohibited this kind of treatment. In 2014, the Italian Constitutional Court ruled that the ban on gamete donation was unconstitutional, thus restoring the possibility of performing this procedure in those cases where infertility cannot be treated in a different way. At present, gamete donation in Italy is a voluntary act and compensation/reimbursement for donors are not allowed. While finding male donors is quite simple, recruiting female donors appears to be a lot more difficult, also due to the complexity of the procurement procedure.
Study design, size, duration: A survey was elaborated by a working group composed of a MAR specialist, two psychologists, a person working in the field of communication and a statistician. The questionnaire was administered to a sample of 200 women aged between 18 and 34 between December 2014 and February 2015.
Participants/materials, setting, methods: The survey was anonymous and it was composed of 20 questions: 13 were multiple-choice questions, while 7 were open questions. Questions aimed at assessing awareness of responders with reference to issues related to infertility and its treatment and to analyse their attitudes towards these techniques. The survey was administered by a dedicated person at the Bologna University Library.
Main results and the role of chance: The average age was 24.4 ± 4.3. A large majority of responders (90%) declared to know MAR techniques, 10% of them did not. When investigating awareness regarding causes of infertility, the sample split in halves with only 53% of women affirming to know them. A smaller percentage of responders declared to know gamete donation procedures (73.5%). Perception of donors is generally positive, although 42.5% of responders did not know how to answer or are indifferent. This partition of responders will recur also in all questions regarding gamete donation and social freezing. When asked whether they would donate oocytes, the majority of responders (44%) did not know how to answer, while only 19.5% would refuse to do so. In general, those who would be available to donate would also be available to receive gametes. Only 61% of women knew about social freezing and when asked whether they would undergo this procedure, once again a large majority (37.5%) does not know how to answer. Only 44% of patients in favour of social freezing would be available to donate a quota of their oocytes in return for a free freezing procedure.
Limitations, reasons for caution: The results of the survey might be influenced by the size and composition of the specific population analysed. Results might have also been affected by the lack of information on these issues between 2004 and 2014 when the ban on gamete donation was in place.
Wider implications of the findings: Although gamete donation is now legal in Italy, putting it into practice is difficult due to the shortage of donors (especially women) compared to the increasing demand for treatments. The survey shows

that a large share of potential Italian donors appear to be uninterested in or unaware of these issues.
Trial registration number: Not applicable

P-764 Competing risk survival techniques provide accurate estimates of long term outcome in Assisted Reproduction and prognostic factors. A first study in France

I. Parneix[1], P. Arvis[2], S. Paillet[3], P. Lehnert[4], C. Avril[5], F. Lesourd[6]
[1]*Clinique Jean Villar, Department of Assisted Reproductive Technology, Bruges, France*
[2]*Clinique mutualiste La Sagesse, Department of Assisted Reproductive Technology, Rennes, France*
[3]*France Merck, Fertility Department, Lyon, France*
[4]*University of Melbourne, Faculty of Medicine, Melbourne, VIC, Australia*
[5]*Clinique Mathilde, Department of Assisted Reproductive Technology, Rouen, France*
[6]*Hospital Paule de Viguier, Department of Assisted Reproductive Technology, Toulouse, France*

Study question: Estimate the probability and prognostic factors of CLBR, spontaneous birth (SBR) and dropout rates (DOR) for couples undertaking IVF. Appropriate methodology illustrated on French data.
Summary answer: CLBR, SBR and DOR were estimated to 65.4%[60.8, 69.7], 4.2%[2.9–5.3] and 28.1%[24.3–32.3] respectively, all affected by age, number of retrieved oocytes and parity.
What is known already: Cumulative Live Birth Rate (CLBR) probably constitutes the main endpoint of IVF, however its estimation is difficult due to missing values further switch between centers, high variability such as country, time, women age, center effect, and heterogeneity of definitions. Our international meta-analytical calculation provided evidence of a very heterogeneous estimate CLBR of 41.6% [24.3–75.6]. Important difference was suspected among countries, centers, and IVF technique. Substantial number of censored values and need to modeling time to LB necessitates survival techniques. However, CLBR, SBR and DOR constitute three competing risks and cannot be treated by elementary techniques.
Study design, size, duration: We conducted a longitudinal observational national multicenter study on retrospective data of 3 years follow-up, beginning in 2010. Single Stage Cluster Sampling combined with sequential recruitment of patients in each cluster constituted our statistical sampling design. To provide a maximum error of 5% on this sampling plan and assuming intra-class correlation of.08, we planned a representative selection of 40 centers with a balanced recruitment of 100 patients per center.
Participants/materials, setting, methods: In each recruited center, couples starting IVF in the center were sequentially selected, and every cycle was documented. Patients lost to follow-up or switching to other centers were followed by direct contact. CLBR, SBR and DOR were considered as three competing events and studied by a Competing Risk (CR) survival technique. For prognostic models, a multivariate CR technique was based on a backward strategy based on a list of prognostic factors previously reported in literature.
Main results and the role of chance: Out of 58 selected IVF centers, 41 IVF centers accepted to participate, gave full data and recruited 3,806 couples (First Cycle in the studied center Selection). We assessed possible biases further existence of non-participating centers. Our sample was characterized by a median age of 33 years (IQR = 7), mean BMI of 23.4 ± 4.7 and 18% smokers, 74.9% of these couples were childless and a median duration of subfertility of 3 years (IQR = 3). We estimated LB rate to 47.2% at the last news in the centers, 18.9% of cancel due to medical decision or other reasons, and 30.9% lost to follow-up including switching to other centers. These patients were followed by telephone and questionnaire. Patients for which follow up exceeded 3 years were censored. The univariate competing survival model estimated the proportions of CLBR to 65.4% [60.8, 69.7], SBR to 4.2% [2.9–5.3] and DOR to 28.1% [24.3–32.3]. The multivariate Competing survival technique provided evidence of three highly significant ($p < 0.001$) main prognostic factors of LB: women age (OR = 0.94 [0.93, 0.95]), number of previous live birth (OR = 1.32 [1.23, 1.41]), and Number of retrieved oocytes (OR = 1.03 [1.02, 1.03]).
Limitations, reasons for caution: Our estimates and prognosis model remain subject to the center effect which necessitates further analysis. Our first investigation was limited to France, results cannot be generalizable to other countries and require a specific investigation.
Wider implications of the findings: This study based on a standard definition of outcome and use of retrospective data analyzed by competing survival technique provides an accurate frame to investigate and compare long term outcome with other countries. Results highlight that CLBR observed in France is similar to CLBR calculated from the international meta-analysis.
Trial registration number: not applicable

P-765 Lead levels and IVF outcome: the case of "Land of fires" (Campania, South Italy)

M.D. d' Eufemia[1], M. Guadagno[1], P. De Franciscis[1], R. Ianniello[1], R. Cicatiello[1], N. Colacurci[1]
[1]*2nd University of Napoli, Dipartimento della donna, del bambino e di chirurgia generale e specialistica, Napoli, Italy*

Study question: To evaluate the correlation between lead levels in biological fluids and fertility in women undergoing *in vitro* fertilization procedures (IVF) residents in the "Land of fires".
Summary answer: High intrafollicular lead levels are correlated to reduced ovarian reserve and lower pregnancy rate in the land of fire.
What is known already: Three decades of illegal practices of waste dumping and consequent environmental abuse have made specific areas of Campania (Southern Italy), currently defined as "land of fires", a unique case in the context of waste-related health outcomes. Scientific evidence is mounting in support of a significant increase in cancer mortality and malformation occurrence, but reproductive health has never been investigated. To date, literature provide few data on the possible relationships between heavy metal exhibition and female reproductive potential. Some evidence indicates a higher incidence of infertility and miscarriages among women occupationally exposed to heavy metals.
Study design, size, duration: In this prospective study 99 women undergoing IVF cycles were enrolled from September 2014 to August 2015. The study group (A Group) included 53 women resident in "land of fires"; the control group (B group) included 46 women resident far from polluted areas. Lead level were evaluated in biological fluids.
Participants/materials, setting, methods: Exclusion criteria: lead occupational exposure; smoke and alcohol abuse. Urine, blood and follicular fluid samples were collected. Lead levels were determined by atomic absorption spectrometry with graphite furnace in dual beam. Ovarian reserve was defined by antral follicular count (AFC) and AMH determination. Pregnancy rates were evaluated as indicator of fertility health. Data were analyzed using the unpaired Student's *t*-test (p-value ≤ 0.05).
Main results and the role of chance: Patients living in areas included in the "Land of fires" have intrafollicular lead levels higher compared to the control group, 1.78 ± 1.45 μg/L and 0.73 ± 0.57 μg/L respectively ($p \leq 0.05$). Not statistically significant differences were found in blood lead levels and piomburia between two groups. The pregnancy rate is 17% in A group and 28% in B group, reaching a statistical significance ($p \leq 0.05$). Among A group patients, pregnant patients showed lower intrafollicular lead level compared with non pregnant patients ($p \leq 0.05$). High intrafollicular lead levels were associated with reduced ovarian reserve. The discrepancy between lead intrafollicular concentrations and blood and urine concentration may underlie a mechanism of intraovarian accumulation of lead due to impaired clearance or a high follicular membrane permeability. The correlation between the higher intrafollicular leads concentrations, reduced ovarian reserve and lower pregnancy rate observed in the study group lead to hypothesize that chronic exposure to lead and its transit through the follicular membrane may results in an intraovarian toxic accumulation of the metal. In this contest lead could act as endocrine disruptor for direct damage on the granulosa cells. The result is reduced ovarian reserve and impaired fertility.
Limitations, reasons for caution: Small sample size. Environmental lead concentration not evaluated.

Wider implications **of the findings:** This is the first research that evaluates lead effects on IVF outcome in the "land of fires". Impaired fertility in the "Land of fires" confirm the need to start investigations for the assessment of individual exposure and the resulting reproductive risk thought an analysis of the environmental contamination.
Trial registration number: Not requested

P-766 The Polish state-funded program – infertility treatment with *in vitro* fertilization for years 2013–2016. results after the first 2 years

Study question: What are the preliminary results of the Polish state-funded programme for infertility treatment with *in vitro* fertilization (IVF) achieved between 2013 and 2015?
Summary answer: Despite significant limitations in the number of fertilized eggs (only six) the results are generally in agreement with data obtained from European registers by ESHRE.
What is known already: It is for the first time that Polish government introduced public funding of *In Vitro* Fertilization (IVF). The programme is exceptional in a way that due to ethical/political reasons the number of fertilized oocytes was limited to six and single embryo transfer was obligatory. In this presentation we summarize the preliminary results of the first 2 years of the programme which will end in June 2016.
Study design, size, duration: The IVF programme approved 3 IVF procedures for women under 40 years of age. For women under 35 years the number of fertilised eggs was limited to 6 and implemented obligatory SET (single embryo transfer). For women over 35 years there were no limitations on the number of eggs fertilised and DET (double embryo transfer) was approved. The presented results were achieved between 2013 and 2015.
Participants/materials, setting, methods: Participants: A total of 19 345 initiated ovarian stimulation cycles in various protocols have been registered in the 2 years period. Setting: The IVF program was conducted in 31 clinics subjected to inspections and required the clinics to report results within 2 weeks of finalizing a procedure. Methods: retrospective analysis covering clinical data, embryological data and outcomes of fertility treatments.
Main results and the role of chance: Clinical pregnancy rates per cycle and embryo transfer were 29.9% and 32.9%, respectively. In FET (Frozen Embryo Transfer) cycles, the pregnancy rate per thawing was 28.32% and per SET and DET were 26.7% and 37.5%, respectively. Treatment cycles reported from all over the country resulted in the cumulative pregnancy rate per cycle of 41.37%. Clinical pregnancy rate per fresh embryo transfer in the group of women under 35 years was 33.9% and multiple pregnancy rate was 4.8%. In the group of women between 35 and 40 years the pregnancy rate per fresh embryo transfer was 30.9% and multiple pregnancy rate was 12.6%. Miscarriage rate was 15.22% and single pregnancy rate was 95.2%. OHSS (Ovarian Hyperstimulation Syndrome) rate was 2.07%. High numbers of analyzed cycles limit the impact of chance in the presented material.
Limitations, reasons for caution: This is only a preliminary data obtained after two initial years. The results will be complete when all available live-birth data can be analysed.
Wider implications of the findings: The success rates of the programme remained relatively high, despite limiting factors, which may have a significant implications for future plans of public-funded IVF programmes.
Trial registration number: N/A

P-767 Effects of laboratory procedures on intrauterine insemination success

L. Lemmens[1], C. Beijer[2], S. Kos[3], W. Nelen[1], A. Wetzels[1]
[1]*Radboud University Medical Center Nijmegen, Department of Obstetrics and Gynaecology, Nijmegen, Netherlands*
[2]*Atal-Medial Medical Diagnostic Centre, Department of Clinical Chemistry, Amsterdam, Netherlands*
[3]*Maasstad Hospital Rotterdam, Department of Clinical Chemistry, Rotterdam, Netherlands*

Study question: What is known about the laboratory procedures of IUI, including the pre- and post-analytical conditions, and how do they relate to the pregnancy rates?
Summary answer: Few laboratory procedures were associated with the pregnancy rates of IUI, but most other procedures were characterized as inconclusive.
What is known already: Several variables were reported to influence the outcome of IUI. Most of these variables are related to patient characteristics or stimulation protocols. The study of the association between laboratory procedures and pregnancy rates, however, is neglected. Despite the protocol described in the laboratory manual of the World Health Organization (WHO, 2010), most laboratories still use their own procedures. The aim of this study is to identify the association of the laboratory procedures and the gaps of knowledge, which could be used for the development of international clinical guidelines.
Study design, size, duration: A systematic review focusing on the influences of semen collection (i.e., ejaculatory abstinence, ejaculatory frequency, collection place), semen processing (i.e., separation method, temperature during centrifugation/storage), insemination (i.e., timing of IUI, bed rest after IUI) and the used devices on pregnancy outcomes. The literature search was based on specific key words in different databases. The levels of evidence of the main conclusions are reported, according to the National Institute for Health and Clinical Excellence (NICE, 2013).
Participants/materials, setting, methods: The literature search was performed in Medline and the Cochrane library. The references and related citations of suitable studies were reviewed as well. When there were no studies studying the association between the laboratory procedures and the pregnancy rates of IUI, we reviewed the association with sperm parameters. When sufficient literature was available, we based our conclusion on the studies with the highest level of evidence according to the NICE guideline.
Main results and the role of chance: The review of literature is for most variables characterized by a low level of evidence, a limited number of studies or an inadequate outcome measure (i.e., sperm parameters instead of pregnancy rates). The comparison of several laboratory procedures revealed that they did not influence the IUI outcome. The pregnancy rates were not related to the different options of the place where the semen sample was collected, the temperature during centrifugation, the method used for the timing of IUI, the time interval between ovulation and IUI, and the insemination catheter. A positive correlation was found between the pregnancy rates of IUI and an ejaculatory abstinence period of up to 2–3 days and bed rest of 10–15 min after insemination (compared to longer periods of abstinence and direct mobilization, respectively), although a limited number of studies was performed on these subjects. The reported influences of the different separation techniques and the time intervals between semen collection, semen processing and IUI revealed no consensus in study results, leading to the inability to select a superior method or time interval.
Limitations, reasons for caution: The review of studies on reproductive medicine often reveals a lack of standardization in inclusion criteria and methodologies in these studies. Study results can differ among these determinants, which makes it sometimes impossible to draw strict conclusions based on previous studies.
Wider implications of the findings: Based on the literature, it is impossible to develop an optimal IUI treatment protocol. This review emphasizes, once again, the need for standardization in assisted reproductive studies technologies. In this way, it will be possible to identify -and to bridge the knowledge gap, in order to improve the protocol.
Trial registration number: Not applicable

P-768 Preconceptual health and fertility treatment – an evidence based approach

E. Chronopoulou[1], S. Seshadri[2]
[1]*University College Hospital, Institute for Women' Health, London, UK*
[2]*The Centre for Reproductive and Genetic Health, CRGH, London, UK*

Study question: What is the existing evidence around preconceptual health and reproductive outcomes for couples who are seeking fertility treatment?
Summary answer: Positive lifestyle modification and the optimization of the preconceptual period for both men and women can influence the outcome of assisted reproductive technology.
What is known already: A large percentage of couples attending a fertility clinic face multiple lifestyle issues but do not always receive appropriate preconcepual advice (Anderson et al., 2010). There is accumulating evidence demonstrating that positive lifestyle modification and the optimization of the preconceptual period for both men and women can influence the couple's reproductive potential (Clark et al., 1995; Klonoff-Cohen, 2005; Dondorp et al., 2010; Sharma et al., 2013).
Study design, size, duration: A thorough electronic search was conducted in PubMed, Embase, Medline and Cohrane databases and references of relevant studies were cross-checked in order to include all relevant human studies from 1946 until December 2015 linking preconceptual behaviors with the outcome of fertility treatment. The computerized search explored the importance of numerous factors such as smoking, caffeine and alcohol consumption, obesity, physical exercise, stress, recreational drug use, diet (including vitamins, micronutrients, antioxidants, minerals), alternative medicine, environmental factors and pollutants.
Participants/materials, setting, methods: The Mesh terms included caffeine (coffee, tea, soft drinks), smoking, BMI/obesity, alcohol, recreational drugs (cocaine, cannabis, opioids, methadone, heroine, anabolic steroids), exercise, diet (Vitamins A, C, D, E, multivitamin supplements, selenium, zinc, coenzyme q10, L arginine, iron, copper, antioxidants, folate, melatonin, carnitines, isoflavones), genetic conditions, acupuncture, environment (perfluorinated chemicals. pesticides, herbicides, mercury, lead, solvents, cell phone, laptop, phthalates, phenols, cosmetics), stress "AND" fertility/IVF (*in vitro* fertilization) for men and women.
Main results and the role of chance: A total of 398 relevant studies were identified. Negative parental lifestyle behaviors can affect the outcome of fertility treatment and could even have transgenerational effect on the fertility of the offspring as demonstrated by human and animal studies (Lutterodt et al., 2009; Anderson et al., 2014; Fowler et al., 2014; Sobinoff et al., 2014). The evidence is stronger for some of the factors examined such as smoking, physical exercise, balanced diet and body mass index whilst more research is needed around other factors such as a variety of diet supplements, environmental exposures, stress reducing techniques and even caffeine intake before they are incorporated in the counseling for subfertile couples.
Limitations, reasons for caution: Large epidemiological studies and randomized controlled trials are needed for solid conclusions to be drawn in order to offer clear advice to infertile couples as a big part of the existing evidence is retrospective in nature.
Wider implications of the findings: Proper preconceptual care and counseling for couples undergoing fertility treatment can improve success rates and also prevent pregnancy complications. Adequate preconceptual counseling incorporating this evidence is essential.
Trial registration number: Not applicable

P-769 Are non-phthalate substitute plasticizers safe? The association of urinary di-isononyl cyclohexane-1,2-dicarboxylate (DINCH) metabolites with *in vitro* fertilization (IVF) outcomes: results from the EARTH study

I. Souter[1,2], L. Minguez-Alarcon[3], P.L. Williams[4], R. Hauser[2,3]
[1]*Massachusetts General Hospital, Reproductive Endocrinology and Infertility, Boston, MA, USA*
[2]*Harvard Medical School, Obstetrics, Gynecology and Reproductive Biology, Boston, MA, USA*
[3]*Harvard T.H. Chan School of Public Health, Environmental Health, Boston, MA, USA*
[4]*Harvard T.H. Chan School of Public Health, Biostatistics, Boston, MA, USA*

Study question: Are concentrations of urinary DINCH (Ur-DINCH) metabolites [MHiNCH and MCOCH, cyclohexane-1,2-dicarboxylic acid-mono(hydroxy-isononyl) ester and cyclohexane-1,2-dicarboxylic acid-mono(carboxy-isooctyl) ester, respectively] associated with IVF outcomes among women attending an academic fertility center?
Summary answer: There was a suggestion of an inverse association between urinary MHiNCH (Ur-MHiNCH) concentrations and number of retrieved and mature oocytes.
What is known already: Over the last decade, non-phthalate plasticizers (such as DINCH) are increasingly used as "safer" alternatives to ortho-phthalate esters in food packaging and in the manufacturing of toys, building materials and medical devices. Since 2002, DINCH metabolites have been increasingly detected in urine samples collected from children and adults in both Europe and the US. Due to its increased use in the manufacture of various products, higher and more widespread human exposure to DINCH is expected in the future. To our knowledge, there are no data on the potential human health effects of DINCH.
Study design, size, duration: Prospective cohort of 118 women undergoing 160 fresh IVF cycles at the Massachusetts General Hospital in Boston, MA, USA (06/2011–06/2015). All women participated in the Environment and Reproductive Health (EARTH) study and provided up to two urine samples prior to oocyte retrieval (285 urine samples).
Participants/materials, setting, methods: We quantified the urine specific-gravity adjusted concentrations of Ur-DINCH metabolites (MHiNCH and MCOCH, Ur-MHiNCH and Ur-MCOCH, respectively) by isotope dilution tandem mass spectrometry. Intermediate and clinical endpoints of IVF treatments were abstracted from electronic medical records. We used generalized linear mixed models to evaluate the association between Ur-DINCH metabolites concentrations and IVF outcomes, with random effects to account for multiple IVF cycles, and adjusting for age, year of treatment and infertility diagnosis.
Main results and the role of chance: For MHiNCH and MCOCH, 49.3% and 32.3% were above the limit of detection, and urine specific-gravity adjusted concentrations ranged up to 42.8 and 16.0 µg/L, respectively. For statistical analysis we defined three groups for MHiNCH (low/medium/high) and two groups for MCOCH (low/high). The groups did not differ significantly by participant baseline characteristics. Increased specific-gravity adjusted Ur-MHiNCH concentrations were associated with a decreased yield of retrieved and mature oocytes, with adjusted means (95% CI) for low, medium and high Ur-MHiNCH concentrations of 13.0 (11.7–14.6), 12.2 (10.6–14.2), and 10.9 (9.2–13.0)] for number of retrieved oocytes; and 10.5 (9.4–11.8), 9.7 (8.3–11.3), and 9.0 (7.6–10.7), for number of mature oocytes, respectively. Women in the highest group of specific-gravity adjusted Ur-MHiNCH concentrations had a 16.2% and 14.3% decrease in the number of retrieved and mature oocytes, respectively, compared with women in the lower group (p-trend = 0.08 and p-trend = 0.10, respectively). Specific-gravity adjusted Ur-MHiNCH concentrations were not associated with other IVF outcomes (proportion of best embryos, p-trend: 0.66; rates of fertilization, p-trend: 0.61; implantation, p-trend: 0.96; clinical pregnancy, p-trend: 0.77; and live-birth, p-trend: 0.49). For MCOCH, there were no associations between specific-gravity adjusted urinary concentrations and any of the IVF outcomes measured.
Limitations, reasons for caution: DINCH metabolites were measured in urine samples collected during the IVF cycle and reflect only short-term exposure. Measured urinary concentrations might not accurately represent long-term exposure and its contribution to the observed early IVF outcomes. Results may not be generalizable to women conceiving naturally.
Wider implications of the findings: Higher Ur-MHiNCH concentrations were associated with lower yield of retrieved and mature oocytes among women undergoing IVF, suggesting that exposure to certain non-phthalate plasticizers might affect fertility. However, further studies are required, since this is the first human study evaluating potential adverse effects of non-phthalate plasticizers on reproductive health.
Trial registration number: None.

The above findings/conclusions are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention (CDC).

P-770 Population based Northern Finland Birth Cohort 1966 study shows serum lipids and metabolic syndrome to have association with an increased risk of uterine fibroids

O. Uimari[1,2], J. Auvinen[3], J. Jokelainen[3], K. Puukka[4], A. Ruokonen[4], M.R. Järvelin[3], T. Piltonen[2], S. Keinänen-Kiukaanniemi[3], K. Zondervan[1], I. Järvelä[2], M. Ryynänen[2], H. Martikainen[2]
[1]*University of Oxford, Nuffield Department of Obstetrics and Gynaecology, Oxford, UK*

[2]University of Oulu, Department of Obstetrics and Gynaecology, Oulu, Finland
[3]University of Oulu, Centre for Life Course Health Research, Oulu, Finland
[4]University of Oulu, Department of Clinical Chemistry, Oulu, Finland

Study question: Are uterine fibroids associated with increased cardiovascular risk?
Summary answer: We herein report of an association between increased serum lipids and metabolic syndrome with increased risk of uterine fibroids.
What is known already: Uterine fibroids are the most common tumour in females. Recent studies suggest similarities in biological disease mechanisms for fibroids and atherosclerosis. Similar risk factors have been associated with both conditions: obesity, hypertension, and abnormal serum lipids. These findings are awaiting confirmation that a population based follow-up study could offer with extensive health examination data collection linked with a national hospital discharge register.
Study design, size, duration: The Northern Finland Birth Cohort (NFBC1966) is a population-based prospective study including all children born in 1966 in the Northern Finland area. The data were collected from national registries, postal questionnaires and clinical health examinations. All females included in the NFBC 1966 who underwent an extensive clinical health examination at age 46 years (n = 3,268) comprised the study population for this study.
Participants/materials, setting, methods: All females included in the NFBC1966 who were alive and traceable (n = 5,118) were invited for the 46-year follow-up study; 3,268 (63.9%) responded, returned the postal questionnaire and attended the clinical examination. Uterine fibroid cases were identified through the national hospital discharge register that has data on disease diagnoses based on WHO ICD-codes. Uterine fibroid codes, ICD-9: 218 and ICD-10: D25 were used for case identification. Self-reported fibroid cases were identified through the postal questionnaire.
Main results and the role of chance: A total of 729 fibroid cases were identified through WHO ICD disease codes for fibroids and self-report. With logistic regression analysis, the odds ratio of risk of uterine fibroids (all cases, and ICD code identified cases) according to serum lipid profile, metabolic syndrome by the International Diabetes Federation (IDF) definition and body composition was estimated. With adjustment for parity, education and BMI, the risk of fibroids rose significantly for every 1 mmol/l increase in LDL and triglycerides, (OR = 1.14 95% CI 1.02, 1.26 vs. OR = 1.27 95% CI 1.09, 1.48). The risks were higher for hospital discharge-defined (ICD code based) fibroid diagnosis (OR = 1.22 95% CI 1.05, 1.42 vs. 1.37 95% CI 1.10, 1.68). With the same adjustment model, IDF-defined metabolic syndrome raised the risk of hospital discharge-based fibroid diagnosis significantly (OR = 1.50 95% CI 1.10, 2.03). Additionally every 1 cm increase in waist circumference increased the risk of fibroids (all fibroids: OR = 1.02 95% CI 1.00, 1.04; hospital discharge-based fibroid diagnosis: OR = 1.03 95% CI 1.01, 1.06).
Limitations, reasons for caution: The majority of fibroid cases were identified by self-report only. There was likely an under-identification of cases and misclassification of some cases as controls; this would have diluted the effects of reported associations. The data analysed were cross-sectional and therefore cause and effect for the associations observed cannot be distinguished.
Wider implications of the findings: Increased serum lipids and metabolic syndrome are associated with increased risk of uterine fibroids. Along with central obesity these findings add to an increased risk for cardiovascular disease among women with fibroids. These observations might also suggest that metabolic factors could have roles in underlying biological mechanism in fibroid development.
Trial registration number: *

P-771 Oocyte donation in India – characterisation of donors

P. Rana Arora[1], I. Mukherjee[1], A. Madhavan[1], N. Mahajan[1], P. Sharwan[1]
[1]Nova IVI Fertility, Reproductive Medicine, New Delhi, India

Study question: The primary objective of the study was to identify the factors which motivate women to donate oocytes.
Summary answer: All donors were from a low socio-economic background and the primary motivation for oocyte donation was financial gain.
What is known already: Advancements in assisted reproductive technology in the form of oocyte donation has given hope to achieving parenthood in women who do not have healthy oocytes. There are two main kinds of oocyte donors – family/friends and anonymous (generally referred to as altruistic donors). In India, all donors are anonymous as family/friends are not permitted.
Study design, size, duration: A cross-sectional survey was administered to 20 consecutive women who registered for anonymous oocyte donation over a 6-month period from July 2015 to December 2015 at a specialised tertiary infertility clinic in North India.
Participants/materials, setting, methods: A professionally trained psychologist with experience in counseling, administered the questionnaire to the oocyte donors after taking their consent. The questionnaire had two main domains – (1) basic demographic and socio-economic information (2) factors motivating for oocyte donation.
Main results and the role of chance: The age range of the 20 respondents was 21–28 years. 20% had had no formal schooling; 30% had attended primary school and the remaining 50% had attended/completed secondary school. No respondent had done graduation or post-graduation. A third of the respondents were not formally employed and the remaining two thirds were mainly employed as unskilled workers. The primary factor motivating the respondents was financial gain (95%) and altruism (5%). However, 60% of the respondents did derive satisfaction at being able to assist couples desiring parenthood. 40% of respondents would consider repeat donation for further financial benefit. Importantly, prior to the counselling, 20% of respondents had not completely understood the implications of being an oocyte donor.
Limitations, reasons for caution: Small sample size and use of a questionnaire. Further exploration by qualitative interview techniques assessing the motivation to donate oocytes as well as the impact following oocyte donation on the physical and psychological well-being of the donor will be helpful.
Wider implications of the findings: The knowledge that the primary motivating factor for individuals to donate oocytes is financial gain, would necessitate development of policy which safeguards the interest of the donors as well as the recipients. Such a policy is currently lacking in India.
Trial registration number: Not applicable

P-772 Impact of geographical origin on IVF results: a monocentric French retrospective observational cohort study evaluating three populations originating from Europe and North or Sub-Saharan Africa

M. Peigné[1], A. Benammar[2], E. Devouche[3], S. Gricourt[1], C. Gauché-Cazalis[1], D. Luton[1], C. Patrat[2], S. Epelboin[1]
[1]Bichat-Claude Bernard Hospital, APHP, Paris7-Diderot University,, Department of Gynecology Obstetrics and Reproductive Medicine, Paris, France
[2]Bichat-Claude Bernard Hospital, APHP, Paris7-Diderot University, Department of Reproductive Biology, Paris, France
[3]Paris Descartes University, Laboratory of psychopathology and health process, Paris, France

Study question: Is geographical origin an independent factor impacting ovarian response to IVF stimulation and IVF outcomes?
Summary answer: After adjusting for confounding factors, no difference was found in IVF outcomes according to geographical origin, except for the estradiol peak, higher in sub-Saharan women.
What is known already: First American studies described an association between ethnicity and poorer IVF outcomes in African-American and Asian minorities. In these studies, socio-economic, as well as environmental and genetic factors were incriminated. Despite the recent migration context, different from the situation of African-Americans, a recent UK study showed that African or Asian ethnicity was an independent risk factor for worse IVF outcomes, even after adjusting for several biases. Ovarian response to stimulation was less studied than IVF outcomes. Differences were sometimes noticed, in particular a higher estradiol (E2) level on the day of hCG triggering and a increased number of oocytes retrieved.
Study design, size, duration: A monocentric French retrospective observational cohort study in a public academic infertility unit characterized by a wide variety of patient's geographical origins was conducted. The three main groups were almost equally originating from Europe, Sub-Saharan Africa (SSA) and North-Africa (NA)(Maghreb). Data from January 2013 to June 2015 were analysed involving a total of 812 first IVF cycles. Main outcome measures were stimulation data and clinical pregnancy rates per oocytes retrieval and embryo transfer.
Participants/materials, setting, methods: Data for all women undergoing their first IVF cycle during the study period were analysed for ovarian stimulation and IVF outcomes according to their geographical origin. Data were retrospectively collected in the global IVF attempts database: *IVF Medifirst*

software. Stimulation protocol choice, oocyte retrieval timing and fertilization technique were based on identical criteria for the three groups. General linear models including ANOVA and multiple regressions were used for statistical comparison and adjustments.
Main results and the role of chance: Eight hundred and twelve women were included: 286 from Europe, 292 from SSA and 234 from NA. All women were comparable for age and ovarian reserve parameters. SSA and NA women had higher BMIs, were less nulliparous, less often smokers, and received more agonist protocols than Europeans. SSA women were more likely to be infected by HIV or HBV than Europeans (22.9% vs. 2.8% for HIV). Duration of stimulation, number of oocytes retrieved, mature oocytes and embryos were similar in the three groups but total dose of gonadotropins, peak of E2 and cancellation rate were increased in SSA women compared to Europeans. After adjusting for age, BMI, primary infertility, protocol, smoking status, viral infection and fertilization technique, only the peak of E2 (1,698 ± 867 pg/ml vs. 1,454 ± 681) and the cancellation rate (28.8% vs. 19.6%) remained significantly higher in SSA women. Compared to Europeans, without adjustment, SSA women had poorer IVF outcomes despite the same number of embryo transferred (clinical pregnancy rate per transfer 20.1% vs. 31.4%). After adjustment, this difference did not reach significance. Nevertheless, after adjusting for the same parameters except HIV, pregnancy rates were significantly poorer in SSA women. Concerning NA women, no difference with Europeans was noticed in IVF stimulation or results.
Limitations, reasons for caution: Although the study size was important, adjusting for many factors to avoid confounding bias decreased the strength of the study. It generated no difference in IVF results without any lesson to be drawn in daily practice. A case-control study, considering ethical issues, could be a better approach for future studies.
Wider implications of the findings: Many confounders can conceal the independent impact of geographical origin. Based on our results, no specific adaptation of gonadotropin dose or embryo transfer policy depending on geographical origin seems needed. Only the usual criteria should be used such as age, BMI or HIV infection status for our everyday clinical practice.
Trial registration number: N/A

POSTER VIEWING SESSION

REPRODUCTIVE SURGERY

P-773 Hysteroscopic septum resection versus expectant management for women with a septate uterus

J.F.W. Rikken[1], C.R. Kowalik[2], M.H. Emanuel[3], B.W.J. Mol[4], F. van der Veen[1], M. van Wely[1], M. Goddijn[1]
[1]Academic Medical Center, Center for Reproductive Medicine, Amsterdam, Netherlands
[2]Academic Medical Center, Gynaecology, Amsterdam, Netherlands
[3]Spaarne Gasthuis, Gynaecology, Hoofddorp, Netherlands
[4]University of Adelaide, Gynaecology, Adelaide, SA, Australia

Study question: Does hysteroscopic septum resection improve reproductive outcome in women with a septate uterus?
Summary answer: Septum resection is not superior to expectant management in improving reproductive outcome in women with a septate uterus, but good quality data is missing.
What is known already: Women with a septate uterus are at increased risk for miscarriage, subfertility and preterm birth. Resection of the septum could improve reproductive outcome in these women and is considered to be the standard of care in many countries. However, data on the effectiveness of this surgical procedure are scarce.
Study design, size, duration: We systematically reviewed the literature for studies that assessed the effect of hysteroscopic septum resection in women with a septate uterus.
Participants/materials, setting, methods: The Cochrane Menstrual Disorders and Subfertility Group searched their specialized Register, the Cochrane Central Register of Controlled Trials (CENTRAL), MEDLINE, EMBASE and PSYCHINFO (inception to September 2015), one reviewer searched other registers for unpublished dissertations and theses. In this search, only randomised controlled trials (RCTs) were eligible for inclusion. In addition we searched the abovementioned databases for retrospective and prospective comparative studies.
Main results and the role of chance: We did not identify randomised controlled trials on the topic. There were nine comparative non-randomised studies, three of which were prospective and six were retrospective studies. Three studies included women with recurrent miscarriage, three studies women with subfertility and three studies included both. The chances of a live birth were significantly lower in the septum resection group than in the expectant management group (7 comparative studies, n = 338 vs. n = 296, OR 0.4, 95% CI 0.2–0.6, I^2 for heterogeneity = 18%). Clinical pregnancy rates were not different (9 comparative studies, n = 518 vs. n = 451, OR 1.6, 95% CI 0.5–5.4), I^2 for heterogeneity = 75%).
Limitations, reasons for caution**:** There was a high risk of bias as none of the studies was randomised, all but one study were single-centre studies and only 3 studies were prospective studies. Also, heterogeneity was considerable, especially for clinical pregnancy.
Wider implications of the findings: This systematic review shows there is no sound evidence that septum resection is superior to expectant management in women with a septate uterus. This procedure should not be performed, unless as part of a randomised controlled trial. Such a trial is urgently needed, and currently halfway (TRUST study, NTR 1676).
Trial registration number: Not applicable

P-774 Proinflammatory cytokines TNF-α and IL-1 in pelvic peritoneal adhesions of various etiology at reproductive age women

A. Sulima[1], A. Davydova[2], V. Litvinov[3]
[1]Crimean Medical Academy named after S. I. Georgievskyi, Department of Obstetrics, Gynaecology and Perinatology, Simferopol, Russia CIS
[2]Crimean Medical Academy named after S. I. Georgievskyi, Department of Pathological Anatomy with Sectional Course, Simferopol, Russia CIS
[3]"Altra Vita" IVF Clinic, Department of IVF, Moscow, Russia CIS

Study question: To study the expression of TNF-α and IL-1 in the tissue of the pelvic peritoneal adhesions of various origins in women of reproductive age.
Summary answer: Morphological examination and immunohistochemical study of the pelvic peritoneal adhesions revealed differences in the expression of cytokines IL-1 and TNF-α depending on the genesis.
What is known already: One of the reason identifies the high frequency of adhesion formation is the presence of inflammation in the abdominal cavity with different severity and origin. Activation of intercellular relationships in the peritoneum becomes promoter of further adhesions when inflammation. It is known that TNF-α and IL-1 are among the most important pro-inflammatory cytokine that effect cells and tissues both by means of paracrine and endocrine mechanism. Data on expression of TNF-α and IL-1 in the pelvic peritoneal adhesions in connection with their prescription, localization and origin is absent at accessible literature.
Study design, size, duration: One hundred infertile women (aged 19–49 years) with pelvic peritoneal adhesions, who were underwent operative laparoscopy. 38 patients with a history of chronic inflammatory diseases of pelvic organs; 32 patients with endometrial disease (12 patients with endometrioma and 20 patients with external peritoneal endometriosis) and 30 patients who had undergone previous surgery for pelvic and abdominal cavity took part in this study.
Participants/materials, setting, methods: The material for this study was the fragments of surgical material (adhesions and their parts) n = 100, taken from the women of reproductive age who suffered with infertility during operative laparoscopy. The morphological and immunohistochemical study of adhesions were carried out by standard techniques using paraffin blocks, reagents of Dako and monoclonal antibodies to TNF-α (Anti-TNF alpha antibody (ab6671)) and IL-1 (Anti-IL-1alpha antibody [as5] (ab17281)) of Abcam with automatic coloring Dako Cytomation.
Main results and the role of chance: Immunohistochemical study of tissue adhesions obtained from the women who underwent surgeries on the pelvic organs, the expression of TNF-α was extremely low and was equal to 19 ± 0.3 points. Only a few positively stained macrophages were found in a limited number of observations. Also in this material IL-1 was characterized by an extremely low level of expression and was equal to 13 ± 0.4 points, in some observations there was no expression of this marker. During the immunohistochemical study

of adhesions in women with a history of inflammatory diseases of the pelvic organs, there was a mild TNF-α, i.e., it was 35 ± 0.2 points. Positive staining was detected mainly in the mesotheliocytes' cytoplasm covering the adhesions, at least in lymphoid-macrophage clusters. IL-1 is also detected in meager quantities, mainly in the cytoplasm of mesothelial cells was 17 ± 0.1 points. Immunohistochemical study of the material obtained adhesions in patients with external genital endometriosis carried out in the first phase of the cycle was characterized by a moderate expression of TNF-α and IL-1 in the mesothelial cells, lymphocytic-macrophage aggregates and endometriosis. Expression of TNF-α was 151 ± 0.5 points and IL-1 – 148 ± 0.2 points.
Limitations, reasons for caution: Age limitation, only women aged 19–49 yrs took part in this study. Exclusion criteria were the following for the groups: acute gynecological diseases, malignant diseases of female genitalia and ovarian tumors.
Wider implications of the findings: The extremely low level of TNF-α and IL-1 expression was found in postoperative and inflammatory adhesions. The highest degree of these cytokines was detected in patients with external genital endometriosis. Thus, in case of endometriosis, the adhesion's tissue by itself is the site of the induction of inflammation in the pelvis.
Trial registration number: Case control study.

P-775 The experience of absorbable knotless wound closure device used in laparoscopic myomectomy

C.C. Chan[1], C.Y. Lee[1]
[1]Taipei City Hospital, Department of Obstetrics and Gynaecology, Taipei, Taiwan ROC

Study question: The laparoscopic surgery has more several advantages than traditional explore laparotomy. Comparison with handiwork, operating by slender instrument is more imprecision to sew and tie.
Summary answer: Absorbable Knotless Wound Closure Device is a device with the efficient barb and welded loop design. It help surgeon close wound stabilized and tie rapidly.
What is known already: Many surgeries are accomplished by virtue of it nowadays. Hemostatic handing, suturing, and renovating of leiomyoma are the most important procedures and they will be operated by slender instruments with stitch suture and tie. Comparison with handiwork, operating by slender instrument is more imprecision to sew and tie. So that it may bring on following situations such as joints between tissue not rigid enough or difficulties for stypsis on suture and cross-cut. We apply the device in laparoscopic myomectomy and hope to use it can diminish surgery time, blood loss, complication but better to uterus recovery.
Study design, size, duration:
Materials and methods: this prospective study evaluated data on the efficacy of treatment in the 62 women who underwent laparoscopic myomectomy at Taipei City Hospital Zhongxiao Branch from January 2010 through August 2012. The patients were randomly assigned to Absorbable Knotless Wound Closure Devicegroup and 2–0 vicryl suture group.
Participants/materials, setting, methods: We applied this device to laparoscopic myomectomy with the aim of diminishing surgery time, reducing blood loss and reducing the number of complication; such improvement ought to result in better uterus recovery.
Main results and the role of chance:
Result: The two groups were similar in terms of age, body weight, delivery number, hemoglobin and hematocrit before surgery. After surgery, blood loss, operation time, change in hemoglobin, change in hematocrit and the presence of uterus defects among the Absorbable Knotless Wound Closure Device group were significant less than among the vicryl group. There are 26 patients pregnant after accepted surgery within 2 years. 12 of them are classified as Absorbable Knotless Wound Closure Device and the others are 2-O Vicryl. Among these 26 pregnant patients, 1 patient classified as 2-O Vicryl has received Hysterectomy cause of uterine rupture on the timing of the 24 week during her pregnancy, and the others have taken Cesarean Section successfully for childbirth.
Limitations, reasons for caution: This is one hospital experience and less cases (62 cases) study. The more experience were need.
Wider implications of the findings:
Conclusion: The Absorbable Knotless Wound Closure Device allows the surgeon to stably close any wound rapidly without having to tie-off separately. The wound margin is held firmly together. In conclusion, the Absorbable Knotless Wound Closure Device brings a lot of benefits when used for laparoscopic myomectomy.
Trial registration number: TCHIRB-10402105-E

P-776 Risk factors for parasitic myoma after use of morcellator in laparoscopic myomectomy: multicenter experience and literature review

E. Bratila[1], P. Bratila[2], D.E. Comandasu[1], C. Berceanu[3], C. Mehedintu[4]
[1]"Saint Pantelimon" Clinical Emergency Hospital, Obstetrics-Gynecology, Bucharest, Romania
[2]"Euroclinic" Minimally Invasive and Reconstructive Hospital, Obstetrics-Gynecology, Bucharest, Romania
[3]University of Medicine and Pharmacy of Craiova, Obstetrics-Gynecology, Craiova, Romania
[4]"Nicolae Malaxa" Clinical Emergency Hospital, Obstetrics-Gynecology, Bucharest, Romania

Study question: What are the risk factors involved in the appearance of the parasitic myoma after laparoscopic myomectomy using morcellation?
Summary answer: The type of morcellator used in laparoscopic myomectomy is an important risk factor in the appearance of the parasitic myoma.
What is known already: The most important risk factor involved in the appearance of the parasitic myoma described in the studies published until present in the literature is leaving fragments of the uterus or myoma tissue in the abdominal cavity after morcellation.
Study design, size, duration: Multicenter retrospective study realized on 720 cases of laparoscopic myomectomy divided in two groups. The first group of patients were operated between 2006 and 2010 and we used Sawalhe super cut II Karl Storz for morcellation, while the second group of patients was operated during 2010–2016 and we used RotoCut G1 Karl Storz.
Participants/materials, setting, methods: From the first lot of patients (320 cases) we diagnosed 2 cases of abdominal polifibromatosis at 13, respectively 18 months postmyomectomy. The diagnosis was established clinically and imagistically (ultrasound, MRI) in both cases. The myoma nodules were excised by laparotomy (we excised totally 6, respectively 12 nodules).
Main results and the role of chance:
Limitations, reasons for caution: Using a right sheath morcellator increases the risk of excessive fragmentation of the myoma during morcellation. The morcellators with a 45 degrees angle sheath favor the peeling effect, decreasing thus the risk of appearance of small fragments which can disseminate in the abdominal cavity.
Wider implications of the findings: Using a right sheath morcellator increases the risk of excessive fragmentation of the myoma during morcellation. The morcellators with a 45 degrees angle sheath favor the peeling effect, decreasing thus the risk of appearance of small fragments which can disseminate in the abdominal cavity.
Trial registration number:

P-777 Copper intrauterine device improves pregnancy outcome in women with repeated implantation failure

X. Mao[1], S. Zhang[1], J. Zhang[1], Y. Kuang[1]
[1]Shanghai 9th People's Hospital, Assisted Reproduction Department, Shanghai, China

Study question: Does clinical pregnancy rate increase in sterility women with repeated implantation failure by placing copper intrauterine device (Cu-IUD)?
Summary answer: Cu-IUD effectively improve clinical pregnancy rate for patients with repeated implantation failures.
What is known already: Repeated implantation failure (RIF) is still a problem for many patients and their physicians. Some interventions have been practiced to overcome this problem, including utilization of adjuvant to enhance oocyte number and quality, endometrial injury to improve poor endometrial response, assisted hatching and preimplantation genetic screening to correct embryonic factors, as well as Chinese herbal medicine and acupuncture. Although previous studies have shown that hysteroscopy improved pregnancy outcomes in women

with or without intrauterine abnormalities, the effect of hysteroscopy and Cu-IUD on pregnancy rate is unclear.

Study design, size, duration: A retrospective cohort study was conducted involving 440 sterility women with RIF at our center during 2014. RIF is considered to exist in women who do not achieve clinical pregnancy after two or more transfers with at least one good-quality embryo. Of the 440 patients, 382 were in Cu-IUD group, and 58 were in non-IUD group. The pregnancy outcomes were followed up to 6 months after hysteroscopy.

Participants/materials, setting, methods: Women with RIF aged 18 to 45 were recruited. Patients with congenital uterine malformation were excluded. All patients were examined with hysteroscopy. If endometrial polyps, or slight intrauterine adhesions were found, pruning was conducted. Cu-IUD was inserted immediately after hysteroscopy in Cu-IUD group and removed after two menstrual periods. For non-IUD group, embryo was implanted the next month after hysteroscopy. Clinical pregnancy and Implantation data were collected up to 6 months after hysteroscopy.

Main results and the role of chance: Patients'characteristics such as age, BMI, infertility duration, cause of infertility were comparable among the two groups. The most common abnormalities in women with RIF included endometrial polyps or polypoid endometrium, chronic endometritis and intrauterine adhesions. Clinical pregnancy rates in Cu-IUD group were significantly higher than in the non-IUD group (43.96% vs. 33.56%, respectively, $P < 0.05$). Following the office hysteroscopy and Cu-IUD administration, a significant increase was observed in the implantation rate of women with RIF (28.96% vs. 20.37%, respectively, $P < 0.05$) compared to non-IUD group. There were no significant differences in early abortion, ectopic pregnancy, and late abortion rate between Cu-IUD group and non-IUD group. Removal of endometrial polyps, polypoid endometrium, and slight intrauterine adhesions with hysteroscopy improves the pregnancy rate. In addition, the mechanical endometrial injury caused by hysteroscopy may have a positive prognostic value for achieving a subsequent pregnancy. Although the mechanism that insertion of Cu-IUD before embryo transfer increase implantation rate is not clear, it is possible that Cu-IUD stimulates endometrial inflammation and the change of inflammatory factors favours embryo implantation.

Limitations, reasons for caution: The current findings support a possible role of hysteroscopy and Cu-IUD in treating women with RIF. Further large randomized controlled trials are required to investigate the efficacy of this intervention. The mechanism need to be investigated further.

Wider implications of the findings: Pregnancy outcomes are improved in women with repeated implantation failure (RIF) by office hysteroscopy and placing copper intrauterine device (Cu-IUD). This means may be a good alternative approach for RIF.

Trial registration number: NO

P-778 Clinical efficacy of modified adenomyomectomy in infertile women with adenomyosis

S.H. Yoon[1], K.R. Hwang[2], Y.J. Kim[3]
[1]*Dongguk University ILSAN Hospital, Obstetrics and Gynecology, Goyang city, Gyeong Gi Do, South Korea*
[2]*Seoul National University Boramae Medical Center, Obstetrics and Gynecology, Seoul, South Korea*
[3]*College of Medicine, Korea University, Obstetrics and Gynaecology, Seoul, South Korea*

Study question: Does surgical removal of adenomyosis have clinical efficacy in infertile women?

Summary answer: Modified adenomyomectomy as a uterus-sparing surgery could be an effective method for increasing pregnancy rate and conservation of fertility potential in infertile women with adenomyosis.

What is known already: The relation between infertility and uterine adenomyosis is controversial, but it appears to affect endometrial receptivity and increase abortion rate. In infertility where uterine conservation is paramount, the treatment of adenomyosis is often complicated, that is to say, medical treatment is often transient and hysterectomy for eradication could not preserve their fertility. At this stage, there is no agreement on the most appropriate therapeutic methods on fertility outcome in infertility patients with adenomyosis. Regarding surgical removal of adenomyosis, including laparoscopic reduction, uterus-sparing surgery appears to be satisfactory and reduced the need for hysterectomy, but needs well designed prospective study.

Study design, size, duration: Prospective clinical trial was conducted. The subjects consisted of 41 infertile patients with adenomyosis and were enrolled after the failure of *in vitro* Fertilization (IVF) for pregnancy from December 2007 to August 2015.

Participants/materials, setting, methods: All cases were classified as having unexplained infertility, adenomyosis with severe periodic dysmenorrhea and occasional menorrhagia. This newly designed operative procedure included pediatric foley insertion into the uterine cavity, injection of diluted vasopressin along the uterine incision, T- or transverse H-incision on the adenomyotic wall, careful excision of adenomyosis tissue using argon laser under intra-operative ultrasonography. After reduction surgery, patients underwent follow up examination for symptom relief, reduction of adenomyosis by MRI and pregnancy rate.

Main results and the role of chance: The mean age and the duration of infertility were 35.07 ± 3.07 years and 57.12 ± 49.93 months, respectively. The mean volume of excised specimens of adenomyosis was $94.40 \pm 61.79g$. The relief of dysmenorrhea was observed clearly in all patients at 6 months after operation (NRS; 7.07 ± 2.50 vs. 1.07 ± 0.83, $p < 0.001$). The amount of menstrual blood was also significantly decreased (137.50 ± 97.56 vs. 72.75 ± 67.32, $p = 0.023$). The CA 125 level was significantly decreased at the time of 6 months after operation (187.75 ± 229.52 vs. 20.36 ± 19.19, $p = 0.026$). Post-operational complication occurred in four patients (hematoma, ureter fistula, shrinkage of uterus and primary ovarian insufficiency). Six patients were lost in the follow-up. Of 28 patients who attempted pregnancy, 16 patients conceived by IVF-ET or T-ET after the operation (16 of 28; 57.1%). However, miscarriage occurred in four patients, ectopic pregnancy in three patient, preterm delivery in one patient and eight patients (8 of 28; 28.6%) delivered by cesarean section at term. The rest of the patients have been trying to conceive by IVF-ET or natural course.

Limitations, reasons for caution: The sample size was small, so further study with larger number of patients will be helpful to investigate the possibility of this result.

Wider implications of the findings: This modified adenomyomectomy was related to symptom relief of dysmenorrhea, menorrhagia and increasing pregnancy rate, implying that reduction surgery could be considered as a successful method for infertile women with adenomyosis who need fertility preservation. This is the first report on the clinical pregnancy outcome of uterus-sparing surgery in adenomyosis.

Trial registration number: N/A

P-779 The optimal number of embryo transferred for patients with didelphys uterus: following 115 cases after *in vitro* fertilization embryo transfer (IVF-ET)

Y. Yi[1], X. Li[2], Y. Ouyang[1], F. Gong[1], G. Lin[1], G. Lu[1]
[1]*Central South University, Institute of Reproductive and Stem Cell Engineering, Changsha, Hunan, China*
[2]*Reproductive and Genetic hospital of CITIC-Xiangya, Imaging Department, Changsha, Hunan, China*

Study question: To investigate possible optimal number of embryo transferred for didelphys uterus according to reproductive outcomes between singleton and twins pregnancies in this uterine morphology.

Summary answer: One good quality embryo transfer is recommended for didelphys uterus since twin's pregnancies dramatically increase risks of prematurity and low birth weight.

What is known already: Most literature on didelphys uterus were based on small sample or case studies which indicated prematurity rate was relatively higher in didelphys uterus compared with normal uterus. However, no studies analyzed the differences of reproductive outcome between singleton and twins pregnancy in didelphys uterus and investigated whether risks of obstetric outcome come from twins pregnancies to some extent because this anomaly were frequently accompanied with relatively small uterine cavity. No studies discussed the strategy on the number of embryo transferred to reduce these risks. Besides, infertile female have higher prevalence of didelphys uterus compared with the unselected population.

Study design, size, duration: From March 2003 to April 2015, 115 cases with didelphys uterus who experienced IVF-ET were retrospectively analyzed. There

were 76 cases achieved clinical pregnancy. One case had ectopic pregnancy. One case had triple pregnancy and two embryos demised spontaneously. Seven cases had twin's pregnancy firstly and then one embryo demised spontaneously. The rest cases were divided into singleton (52 cases) and twins (15 cases) pregnancy group according to the pregnancy number.

Participants/materials, setting, methods: Only good quality embryos were transferred including day 3 embryos which majority blastomere are regular size, fragmentation < 20% and blastosphere whose grade above 3BB (Gardner grading system). Comparison of pregnancy outcome, preterm delivery rate, cesarean section rate and birth weight were made between singleton and twins pregnancy groups. The clinical pregnancy rate and the number of gestation were calculated and recorded based on different numbers of embryo transferred.

Main results and the role of chance: The clinical pregnancy rate for patients with didelphys uterus was 66.1% (76/115). The miscarriage rate in first trimester (3.9% (2/52) vs. 0% (0/15)), second trimester (1.9% (1/52) vs. 6.7% (1/15)) and the live birth rate (94.2% (49/15) vs. 93.3% (14/15)) between singleton and twins pregnancy groups were not significantly different ($P = 0.483$). The cesarean section rate were both 85.71% in singleton (42/49) and twins (12/14) groups. However, the prematurity rate in twins pregnancy was significantly higher compared to singleton pregnancy (64.3% vs. 22.4%, Odds ratio: 6.21; 35.5 ± 2.7 vs. 38.3 ± 0.6 weeks of gestation). What is more, the birth weight in twins group was lower compared with that in singleton group (2.23 ± 0.46 vs. 3.11 ± 0.55 Kg). In twin's pregnancy group, there were two infant with perinatal death caused by pulmonary hypoplasia. When one (15 cases), two (73 case) or three (27 case) embryos were transferred, the clinical pregnancy rate were 66.7%, 65.8% (42.5% single pregnancy and 23.3% twins pregnancy) and 66.6% (40.7% single pregnancy, 22.2% twins pregnancy and 3.7% triple pregnancy) respectively.

Limitations, reasons for caution: Seven cases with twin's pregnancy had spontaneously one fetus demise but the pregnancy outcome, reason and potential clinical implication of one fetus demise were not analyzed. Further studies will be conducted on this phenomenon to figure out potential implication on the number of embryo transferred in uterine anomaly population.

Wider implications of the findings: One good quality embryo transfer is recommended for patients with didelphys uterus even probably for other uterine anomaly because one good quality embryo transfer would achieve the similar clinical pregnancy rate compared with multiple embryo transfer and reduce risks of prematurity and low birth weight from multiple pregnancy.

Trial registration number: None

P-780 Histeroscopic treatment for infertility women: Myosure

E. Lopez[1], C. Forero[1], F.J. Martinez[1], J. León[1], C. Vidal[1]
[1]CUHU, Reproductive Medicine, Huelva, Spain

Study question: The objective of this manuscript is to evaluate the fertility results and pregnancy outcomes in infertile women after treatment of intrauterine pathology with de Myosure tissue removal system.

Summary answer: Post-operative fertility was higher in women who suffered from myoma type 0 and was lower in women whose largest and intramural component.

What is known already: The association of subserous fibroids and intramural fibroids with infertility is controversial. But the role of submucous fibroids which are reported in 5%-18% of patients as a causal factor for infertility is likely.

A few retrospective studies published in 1990s have demonstrated successful reproductive outcome after hysteroscopic removal of submucous myomas in infertile women.

Study design, size, duration: A retrospective study was performed from June 2014 through September 2015. A total of 150 patients had undergone hysteroscopic myomectomy during the study period. Of these, 8 patients who were subfertile and fulfilled our criteria were included.

Submucous fibroids were classified based on European Society of Gynaecological Endoscopy into type 0-whole of fibroid inside the uterine cavity. Type 1-less than 50% extension of submucous fibroid into myometrium. Type 2-more than 50% extension into myometrium.

Participants/materials, setting, methods: For each patient operated in a context of infertility, we analyzed ovarian function and partner's semen. We examinate the uterine cavity by diagnostic hysteroscopy or hysterosalpingography. The following collected data was characteristics of myomas; tube appearance, permeability, and aspect of the mucosa. The variables collected were the age, duration of infertility; existence of menometrorrhagia, existence of uterine cavity deformation; number of myomas; type, size and location of the largest myoma.

Main results and the role of chance: Histeroscopic Unit only admitted in this study myomas discovered during the work-up for infertility The mean patient age was 32 years (range: 24–40 years). The mean duration of infertility was 42 months (range: 12–108 months). The mean follow-up was 26 ± 10 months. A total of 6 patients were symptomatic (75%). The most common symptoms were menorrhagia which was present in seven patients and dysmenorrhea/pelvic pain in five patients. During the process 4 of 8 (50%) patients needed the second morcellation. In the classification 50% were type 0, 20% type I and 30% type II. In process 2 (25%) patients achieved spontaneous pregnancy, 3 become pregnant with assisted reproduction, 2 by insemination and other by *in vitro* fecundation; who obtained a cornual pregnancy resolved through surgery and finally successful intrauterine pregnancy. Other 37% was until waiting to get the pregnancy. The average diameter of pathology removed was 3±0.7 cms for fibroids.

Limitations, reasons for caution: Possible biases related to retrospective studies and limited number of cases.

Wider implications of the findings: This investigation reveals the myosure as a technique histeroscopic to solve the uterine patology. The limited cases not allow to get important results. But myosure begin to appear as a alternative from the surgical procedure in the patients.

Trial registration number: Funding by Hospital. Hospital CUHU, Huelva, Spain.

P-781 Frequency of endometrial cancer and atypical hyperplasia in infertile women undergoing hysteroscopic endometrial polypectomy

Y. KURIBAYSHI[1], K. NAKAGAWA[2], R. SUGIYAMA[1], H. MOTOYAMA[1], C. USUI[2], Y. NISHI[2], H. JUEN[2], Y. KORO[1], R. HOBO[1], N. INO[1], K. VALCKX[1], M. INOUE[1], O. NISHII[3], S. AKIRA[4], R. SUGIYAMA[2]
[1]Sugiyama Clinic Marunouchi, Reproductive medicine and surgery, Tokyo, Japan
[2]Sugiyama Clinic, Reproductive Medicine, Tokyo, Japan
[3]Mizonokuchi Hospital, Teikyo University, Obstetrics and Gynecology, Kawasaki, Japan
[4]Nippon Medical School, Obstetrics and Gynecology, Tokyo, Japan

Study question: What is the frequency of endometrial cancer (EC) patients among infertile women undergoing hysteroscopic endometrial polypectomy due to endometrial polyps?

Summary answer: EC or atypical hyperplasia (AH) is found in 0.95% of infertile women undergoing hysteroscopic endometrial polypectomy with endometrial polyp.

What is known already: In Japan, the incidence of EC is reportedly ≤0.003% in women between 30 and 39 years old. The high-risk group for developing uterine EC shows an association with infertility. Endometrial polyps cause implantation disturbance, and so are usually resected irrespective of size. Two popular methods are used for extraction of endometrial polyps: blind dilatation and curettage; and hysteroscopic polypectomy. In general, blind dilation and curettage can miss endometrial pathology in approximately 50% of cases, so hysteroscopic polypectomy remains the gold standard for both diagnosis and treatment of endometrial polyps.

Study design, size, duration: A total of 1,049 infertile patients who underwent office-based hysteroscopic polypectomy at Sugiyama Clinic Marunouchi between July 2011 and October 2015 were eligible for this retrospective study. All patients had been diagnosed with endometrial polyp via hysterofiberscopy prior to operation.

Participants/materials, setting, methods: All patients underwent hysteroscopic endometrial polypectomy using a resectoscope (OES Pro, Olympus, Japan) with monopolar resection. Surgical specimens were examined histopathologically. Characteristics of patients diagnosed with EC from histopathological examination were evaluated retrospectively.

Main results and the role of chance: Median age of patients was 32 years (range, 19–50 years). According to histopathological examination, EC was found in 10 patients (incidence, 0.95%). The histological type of EC was as follows: endometrioid adenocarcinoma G1; endometrioid adenocarcinoma G2; endometrioid adenocarcinoma G3; and atypical hyperplasia.

Type of EC	Incidence, *n*
Endometrioid adenocarcinoma G1	3
Endometrioid adenocarcinoma G2	1
Endometrioid adenocarcinoma G3	2
Atypical hyperplasia	4

Median age of EC patients was 34 years (range, 28–41 years), and median body mass index (BMI) was 21.2 kg/m^2 (range, 16.7–29.9 kg/m^2). Nine EC patients were nulliparous, and all had undergone infertility treatment, with only one woman having delivered healthy babies. Ovulation disorder was noted in four patients, and obesity (BMI > 25 kg/m^2) in only one. Polycystic ovaries (PCO) were concomitantly observed in one patient. However, abnormal vaginal bleeding was not noted in any patients.

Limitations, reasons for caution: The incidence of EC in this study was markedly higher than that in the Japanese population. All patients in this study had undergone infertility treatment, and infertility itself represents a risk factor for developing EC. Several biases might thus have contributed to this incidence.

Wider implications of the findings: Hysteroscopic polypectomy should be performed when endometrial polyps are detected on investigational screening, and surgical specimens should be checked for the presence of malignancy.

Trial registration number: This study does not have RCT status, and therefore did not receive a trial registration number.

P-782 Three-month treatment with ulipristal acetate prior to laparoscopic myomectomy of large uterine myomas

C. Bondi[1], U. Leone Roberti Maggiore[1], F. Alessandri[2], P.L. Venturini[1], V.G. Vellone[3], S. Ferrero[1]

[1]IRCCS AOU San Martino, IST, Academic Unit of Obstetrics and Gynecology, Genoa, Italy

[2]IRCCS AOU San Martino, IST, Unit of Obstetrics and Gynecology, Genoa, Italy

[3]IRCCS AOU San Martino, IST, Department of Surgical Sciences and Integrated Diagnostics, Genoa, Italy

Study question: Which is the usefulness of preoperative treatment with ulipristal acetate (UPA) in patients undergoing laparoscopic excision of large uterine myomas?

Summary answer: A 3-month treatment with UPA prior to laparoscopy for large uterine myomas decreases intraoperative blood loss, hemoglobin drop, postoperative blood transfusion and length of surgery.

What is known already: Randomized controlled trials showed the efficacy of UPA in decreasing the volume of uterine myomas, in improving menorrhagia and iron-deficiency anemia. No previous study investigated the use of preoperative UPA in patients undergoing laparoscopic excision of uterine myomas.

Study design, size, duration: This was a retrospective analysis of a prospectively collected database. The study included all consecutive patients who underwent laparoscopic myomectomy at our Institution because of heavy menstrual bleeding caused by large uterine myomas. Patients included in the study underwent either direct surgery (group S, $n = 43$) or received 3-month preoperative treatment with UPA (5 mg/day orally, Esmya; Gedeon Richter, Budapest, Hungary; group UPA, $n = 34$).

Participants/materials, setting, methods: The study included premenopausal women undergoing laparoscopic myomectomy because of FIGO type 3, 4 or 5 myomas with largest diameter ≥10 cm and total number of myomas ≤3. The primary objective was to evaluate whether UPA decreases intraoperative blood loss. Secondary objectives were to compare changes between study groups in operative outcomes, incidence of complications, and to report adverse events, changes in preoperative hemoglobin levels and myoma volume caused by UPA.

Main results and the role of chance: Mean (±SD) intraoperative blood loss was lower in group UPA (504.7 ± 212.2 ml) than in group S (686.2 ± 315.6 ml; $p = 0.012$). The operative time was lower in group UPA (137.6 ± 26.8 min) than in group S (159.7 ± 26.8 min; $p < 0.001$) while there was no significant difference in the suturing time between the two study groups ($p = 0.076$). Hemoglobin drop was lower in group UPA (1.1 ± 0.5 g/dl) than in group S (1.3 ± 0.7 g/dl; $p = 0.034$). Six patients in group S and no patient in group UPA required postoperative blood transfusion ($p = 0.031$). Complications (hematoma, fever >38°C, urinary tract infection) were infrequent and not significantly different between the two groups ($p = 0.726$). Preoperative 3-month treatment with UPA caused a significant increase in hemoglobin levels (11.9 ± 1.6 g/dl) compared with baseline (9.1 ± 1.1 g/dl; $p < 0.001$) and a 31.8% (±10.7%) decrease in total myoma volume.

Limitations, reasons for caution: Firstly, this research is limited by the retrospective study design. Secondly, UPA was not compared with other hormonal therapies commonly used for the preoperative treatment of uterine myomas, such as GnRH analogues. Thirdly, the surgeons performing laparoscopic myomectomy were not blinded to the treatment received by the patients.

Wider implications of the findings: This study shows that a 3-month preoperative treatment with UPA before laparoscopic myomectomy for large uterine myomas is useful to reduce intraoperative blood loss, operative time, haemoglobin drop and the need for blood transfusions. Future studies should compare UPA with other preoperative standard treatments such as GnRH analogues.

Trial registration number: Not applicable.

P-783 Laparoscopic guided tubal catheterisation for proximal fallopian tube occlusion. A retrospective cohort study

J. Chu[1,2], A. Vidyasagar[1], I. Gallos[1], D.S. Prathiba[1], M. Rajkhowa[1], Y. Afifi[1], A. Coomarasamy[2], A. Eapen[2], L. Robinson[1]

[1]Birmingham Womens Hospital NHS FoundationTrust, Assisted Conception Unit, Birmingham, UK

[2]University of Birmingham, Institute of Metabolism and Systems Research, Birmingham, UK

Study question: What are the reproductive outcomes of infertile women with proximal tubal occlusion (PTO) following laparoscopy-guided hysteroscopic tubal catheterisation?

Summary answer: Women with proximal tube occlusion treated with laparoscopy-guided hysteroscopic tubal catheterisation at the Birmingham Women's Hospital have a 27.8% chance of natural pregnancy.

What is known already: Tubal disease is the cause of infertility in 30% of women unable to conceive naturally. The cause of tubal infertility can be infection, previous pelvic surgery and endometriosis. Prior to the widespread availability of *in vitro* fertilisation (IVF), tubal surgery was commonly performed. In the case of proximal tubal occlusion (PTO), tubal catheterisation (TC) was attempted. However, due to increase reliance on IVF, the availability of TC is now limited to selected gynaecology centres in the UK. In the UK, government funded IVF cycles are limited therefore TC remains an important management strategy.

Study design, size, duration: This is a retrospective cohort study of women with PTO as their main cause of infertility. The cohort underwent laparoscopy-guided hysteroscopic tubal catheterisation between March 2010 and March 2015. A postal survey was sent to all women in October 2015 to ascertain their reproductive outcomes following tubal catheterisation.

Participants/materials, setting, methods: Fifty-four women with PTO as the main cause of infertility underwent tubal catheterisation in a large teaching hospital between March 2010 and March 2015. Diagnosis of proximal tubal occlusion was confirmed pre-operatively by hystero-salpingogram or laparoscopy and dye testing. Demographic information and operative details were reviewed. All women were invited to complete a questionnaire regarding natural conception, need for assisted reproductive treatment and other reproductive outcomes.

Main results and the role of chance: The 54 women in our cohort study had a mean age of 32.9 years (SD 5.9) and Body Mass Index of 27.2 (SD 4.9). Twenty-three women (42.6%) had primary infertility and 31 women (57.4%) had secondary infertility. Thirty-two of the 54 women (64.8%) had unilateral tubal blockage and 22 (35.2%) had bilateral blockage. In 31 out of 54 (57.4%) women, successful catheterisation was demonstrated by a positive tubal dye test at the end of tubal catheterisation. No surgical complications were identified in the clinical records. Postal surveys were sent to all 54 women, 36 women responded (66.7%) and provided data regarding reproductive outcomes. The intra-operative catheterisation success rate was similar for those that responded to the survey and those that did not (55.5% vs. 57.4%, $p = 0.876$). Natural clinical pregnancy occurred in 10 out of 36 respondents (27.8%), with a live birth rate of 6 out of 36 respondents (16.7%). The median interval from tubal catheterisation to spontaneous conception was 197 days (IQR 91-273). Four women out of 10 achieving natural clinical pregnancy miscarried but none had an ectopic pregnancy. Fourteen of the 36 respondents required IVF treatment, with seven achieving a subsequent live birth.

Limitations, reasons for caution: This is a small cohort study of 54 women so the results must be interpreted with caution. Although the Birmingham Women's Hospital covers a diverse population the generalisability of the findings may be limited as this was a cohort study from a single centre.
Wider implications of the findings: In the UK, government funding for IVF is limited. In women who have PTO who have difficulty in self-funding multiple IVF cycle attempts, surgery for tubal pathology is an important alternative management strategy. Tubal catheterisation provides a low risk treatment option achieving almost comparable clinical pregnancy rates to IVF.
Trial registration number: The study was approved by the UK National Research Ethics Service Committee West Midlands – Black Country (15/WM/0199).

POSTER VIEWING SESSION

STEM CELLS

P-784 Human spermatogonial stem cells survive but show limited proliferation rate *in vitro* under mouse spermatogonial stem cell culture conditions

J.V. Medrano Plaza[1], C. Rombaut[2], A. Pellicer[1], E. Goossens[2]
[1]*Instituto de Investigación Sanitaria Hospital La Fe IIS La Fe, Gynevology and Assisted Reproduction, Valencia, Spain*
[2]*Vrije Universiteit Brussel VUB, Biology of the Testis, Research Laboratory for Reproduction, Genetics and Regenerative Medicine, Brussels, Belgium*

Study question: Are human Spermatogonial Stem Cells (hSSCs) able to proliferate *in vitro* in co-culture with inactivated somatic feeder cells under mouse SSC (mSSCs) culture conditions?
Summary answer: hSSCs are able to survive but do not proliferate *in vitro* in co-culture with inactivated somatic feeder cells under mSSC culture conditions.
What is known already: Previous studies based on conditions already employed for mSSC *in vitro* propagation and the different attaching properties of somatic and germ cells to create an *in vitro* system for the long term *in vitro* propagation of hSSCs. However, a recent report detected a limited ability of human germ cells to survive *in vitro* beyond 1 month and hypothesized that this was due to the higher proliferation rate of the somatic fraction. On the other hand, some reports indicate that human testicular cells sorted for the markers EPCAM+/HLA-, results in an enriched hSSC population.
Study design, size, duration: Time course study at 7, 14 and 28 days comparing the *in vitro* appearance, phenotype, and propagation rate of hSSCs. Testicular tissue from 3 human donors with prostate cancer was used to create *in vitro* cell cultures corresponding to the following treatment groups: 1) Unsorted human testicular cells, 2) Differentially plated human testicular cells, and 3) EPCAM+/HLA-enriched testicular cells in co-culture with inactivated testicular feeders from the same patient.
Participants/materials, setting, methods: Cryopreserved testicular tissue from human adult male donors with prostate cancer. Testicular cells obtained by mechanical/enzymatic digestion were FAC-Sorted and co-cultured with testicular feeder cells previously irradiated at 50 Gy. Analyses and characterization included hormone production/intake measurement, immunocytochemistry, TUNEL and RT-qPCR.
Main results and the role of chance: Putative hSSCs appeared in singlets, doublets or small groups of up to 8 cells *in vitro* only when testicular cells were cultured in StemPro medium supplemented with GDNF, LIF, bFGF and EGF. FAC-Sorting based on the EPCAM+/HLA-phenotype resulted in an enrichment of 27% VASA+/UTF1+ putative hSSCs, compared to 13% in unsorted controls. Co-cultured sorted cells with inactivated testicular feeders gave rise to a relative enrichment of hSSCs with an average density of 173 hSSCs/cm^2 after 2 weeks *in vitro*, compared to the culture of unsorted testicular cells (83 hSSCs/cm^2) and differentially plated testicular cells (50 hSSCS/cm^2). However, putative hSSCs rarely stained positive for the proliferation marker Ki67 and their presence was reduced until almost dissapear after 4 weeks *in vitro*. Sorting EPCAM+/HLA- cells and co-culturing with inactivated testicular feeders improved the germ cell/somatic ratio *in vitro* compared with previous reports. The mouse-based culture conditions supported the survival of hSSCs, but not their proliferation. This phenomenon is similar to the *in vivo* situation where the mouse testicular niche allows the survival but not the proliferation nor the maturation of hSSCs transplanted into the mouse seminiferous epithelium.
Limitations, reasons for caution: This study was performed with frozen/thawed testicular tissue from three aged donors with normal spermatogenic histology. However, a possible bias on the results due to the age of the donors cannot be totally discarded.
Wider implications of the findings: Fertility preservation strategies in boys include the amplification of hSSCs. Our results indicate that the already reported methodology for hSSC *in vitro* propagation is not sufficient to induce hSSC proliferation *in vitro*. Further research on the needs of hSSCs for their *in vitro* propagation is mandatory.
Trial registration number: Not applicable.

P-785 Transplantation induced pluripotent stem cells in situ improves fertility outcome impaired by intrauterine adhesions in mice

L. Yuan[1], J. Zhang[2], M. Chen[1], X. Zhang[1], C. Xu[1], L. Yao[1]
[1]*Obstetrics and Gynecology Hospital of Fudan university, Gynecology, Shanghai, China*
[2]*Minhang District Central Hospital, Department of Obstetrics and Gynaecology, Shanghai, China*

Study question: To investigate the therapeutic potentials of induced pluripotent stem cells(iPSCs) to treat intrauterine adhesions(IUA) and further explore the possible mechanism involved.
Summary answer**:** iPSCs may be a pragmatic solution for the treatment of IUA and heme-oxygenase-1(HO-1) gene plays an important role in regulating the therapeutic effect of iPSCs.
What is known already: Traditional treatment nowadays for IUA can only restore the shape of the uterine cavity but it remains difficult to repair the inadequate endometrium. While the application of iPSCs is widely popularized in many degenerative diseases by the means of differentiating stem cells into different cell types, its usage in treating IUA is still fragmentary.
Study design, size, duration: A cross sectional study was carried out to compare the efficacy of different treatment modalities in mouse IUA model among 5 groups (20 mice/each). Five mice from each group were sacrificed at various times following treatment (24h, 5d), in order to evaluate the change of acute and chronic inflammation on endometrium. The rest mice (n = 10 in each group) were mated with male mice to observe the subsequent pregnancy rate 28d after treatment.
Participants/materials, setting, methods: A mouse IUA model was established with dual injury of lipopolysacchairdes and mechanical injury. Different cells were infused in situ into the mice uterus after modeling, including PBS, MEF, iPSCs, iPSCs-ho1siRNA and iPSCs-CTsiRNA. Subsequent fertility outcomes were observed 28d after treatment, so were the degree of tissue edema and inflammation 24h and 5d after treatment. The presence of iPSCs was demonstrated by immunofluorescence and ER expression of the impaired endometrium was also detected by IHC.
Main results and the role of chance: Transplantation iPSCs in situ could significantly increase pregnancy rate and fetus number when compared with controls(PBS and MEF) ($P < 0.05$). Pathological studies showed that iPSCs could significantly ameliorated tissue edema and inflammation with the proof of having higher number of nucleus but less neutrophil than control groups 24h after treatment($P < 0.05$). Furthermore, iPSCs were detected in the impaired endometrium with red fluorescence 5d after treatment. This, coupled with the increased level of ER expression and number of endometrial gland, strongly indicated the functional improvement of impaired endometrium. However, when knocking down HO-1 expression, the effect of iPSCs was significantly weakened ($P < 0.05$).
Limitations, reasons for caution: As an animal study, the mouse model couldn't simulate all causes of IUA from the patients. The safety of offspring and the exact mechanism of how to effectively direct differentiating iPSCs to hormonal responsive endometrial cells are also needed to be delineated before clinical translation.
Wider implications of the findings: Our study highlights the potential role of iPSCs in promoting endometrial regeneration, which may offer the possibility not only to treat refractory IUA but also prevent IUA after uterine injury.
Trial registration number: None.

P-786 Identification of functional integrin heterodimers expressed on spermatogonial stem cells in mice

S.T. Lee[1], H.J. Park[2], J.E. Park[2], J.I. Yun[3]
[1]*College of Animal Life Science, Department of Animal Life Science and Division of Applied Animal Science, Chuncheon, South Korea*
[2]*College of Animal Life Science, Department of Animal Life Science, Chuncheon, South Korea*
[3]*College of Animal Life Science, Division of Animal Resource Science, Chuncheon, South Korea*

Study question: Which kind of integrin heterodimers was expressed on plasma membrane of mouse spermatogonial stem cells?
Summary answer: Mouse spermatogonial stem cells have integrin α6β1 and αVβ1 on plasma membrane.
What is known already: Generally, fate of spematogonial stem cells (SSCs) can be determined specifically by microenvironments surrounded with various extracellular matrix (ECM) components and integrins recognizing directly ECM proteins play an important role in transporting ECM-derived signals into cytoplasm, resulting in inducing a variety of biological functions such as cell attachment, self-renewal and differentiation. However, to date, studies on type of functional integrin heterodimers expressed on the undifferentiated SSCs remain unclear.
Study design, size, duration: We tried to investigate systematically what kind of integrin heterodimerssubunits are expressed transcriptionally, or translationally and functionally in the spermatogonial stem cells derived from testis of ICR mouse.
Participants/materials, setting, methods: Isolation of spermatogonial stem cells from testis were conducted by magnetic activated cell sorting (MACS) using Thy1 antibody. Subsequently, transcriptional and translational level of integrin α and β subunits in the isolated spermatogonial stem cells were measured by real-time PCR and fluorescent immunoassay, respectively. Moreover, functionality of presumed integrin heterodimers was confirmed by antibody inhibition assay.
Main results and the role of chance: Transcriptional levels of genes encoding total 25 integrin subunits were quantified, and integrin α1, α5, α6, α9, αV and αE and integrin β1, β5 showed higher expression levels than other subunits. In contrast, integrin α2, α3, α4, α7, α8, α10, αL, αM, αD, and αX, and integrin β2, β4 and β7 were weakly transcribed. When translational levels of the integrin α subunits showing high transcription level (α1, α5, α6, α9, αV and αE) were measured, integrin α5, α6 and αV were higher than integrin α1, α9 and αE. In case of integrin β subunit, β1 evaluated more expression than β5. Based on these results, we speculated that the undifferentiated spermatogonial stem cells derived from ICR mouse might express integrin α5β1, α6β1 and αVβ1 on plasma membrane. Subsequently, functional blocking of integrin α6β1 or αVβ1 in SSCs significantly inhibited attachment to laminin or vitronectin, whereas functional blocking of integrin α5β1 did not inhibit significantly attachment to fibronectin.
Limitations, reasons for caution: The results of this study was derived from only mouse with outbred strain. Therefore, studies on the expression of integrin hetrodimers in different strain mouse, other species and human should be conducted in the future.
Wider implications of the findings: This information will greatly contribute to constructing non-cellular niche supporting self-renewal of SSCs in the future.
Trial registration number: –

P-787 Study of the epigenetic cellular memory induced by morphine upon Epiblast-like cells (EpiLCs) differentiation

I. Muñoa[1], N. Subirán[2,3], J.A. Halsall[4], C. Ward[5], P. Garcia[6], B.M. Turner[4]
[1]*University of Basque Country, Physiology in the Faculty of Medicine and Dentistry, Leioa, Spain*
[2]*University of the Basque Country/University of Birmingham, Physiology/ Chromatin and Gene Expression Group, Leioa, Spain*
[3]*University of the Basque Country/University of Birmingham, Physiology/ Chromatin and Gene Expression Group, Birmingham, UK*
[4]*University of Birmingham, Chromatin and Gene Expression Group, Birmingham, UK*
[4]*Institue of Cancer and Genomic Science, Biomedical Research, Birmingham, UK*
[5]*Institue of Cancer and Genomic Sciences, Biomedical Research, Birmingham, UK*

Study question: To analyze the genetic expression changes induced by morphine during EpiLCs differentiation and to determine its epigenetic cellular memory
Summary answer**:** The Polycomb/H3K27me3 complex seems to be involved in the epigenetic memory induced by morphine, causing an inhibition of male reproductive processes during EpiLCs differentiation.
What is known already: The epiblast is derived from the inner cell mass in the mammalian blastocyst giving rise to the three primary germ layers: the ectoderm, the endoderm and the mesoderm. If there is a presence of external stimuli, in contact with the blastocyst before or during epiblast cells differentiation, it might affect to the developmental process. Due to the fact that morphine is the most active component of opium and its therapeutic value for pain relief, our aim is to elucidate the effect of morphine on differentiation and to identify the existence of a cellular memory produced by morphine upon EpiLCs differentiation.
Study design, size, duration: mESC, 24 h morphine treatment, *in vitro* EpiLCs differentiation (using activin A, bFGF and KSR).
Participants/materials, setting, methods: High density microarray, qRT-PCR, immunoblotting approaches.
Main results and the role of chance: EpiLCs where differentiated (Hayashi et al., 2011) from morphine treated and untreated mESC. After 24h morphine treatment we have evidenced a lower mESC cell amount, without altering the viability and the pluripotent status, suggesting that morphine affects the cellular cycle. We have carry out a transcriptome analysis by the microarray technique, to identify morphine target processes, in mESC, and EpiLCs. Specifically, 87 genes related to the function of the mESC cell membrane were altered in these cells. On the other hand, there was a 1,462 genes deregulation in EpiLCs, suggesting the existence of a cellular memory between mESC and EpiLCs. The ontology analysis on EpiLCs derived from morphine treated mESC, showed that there is down-regulation on genes associated to male reproductive processes, while those related to neural development functions are up-regulated. The transcriptome and qRT-PCR analysis also showed a down regulation on Ezh2 gene, which belongs to the epigenetic regulator Polycomb Complex, associated with inactive genes through the H3K27 histone methylation. Therefore, we have verified the down regulation of H3K27me3 in morphine treated mESC, by immunoblotting, suggesting that the complex Polycomb/H3K27me3 can be involved in the epigenetic memory induced by morphine during EpiLCs differentiation.
Limitations, reasons for caution: Complex data analysis by bioinformatic resources.
Wider implications of the findings: The potential implication of H3K27me3 in the epigenetic memory induced by morphine in differentiated EpiLCs, offers a new target to establish the basic knowledge to understand the mechanisms underlying the epigenetic cellular memory. The fact that reproductive processes are affected by morphine provides possible evidences for a transgenerational epigenetic inheritance.
Trial registration number: No trial registration number

P-788 Construction of endometrial-like epithelium using human endometrial CD146 positive cells *in vitro*

M. Fayazi[1], M. Salehnia[2], S. Ziaei[3]
[1]*Department of Medical Sciences, Najafabad Branch, Islamic Azad University, Najafabad, Iran*
[2]*Anatomy Department, Faculty of Medical Sciences, Tarbiat Modares University, Tehran, Iran*
[3]*Midwifery Department, Faculty of Medical Sciences, Tarbiat Modares University, Tehran, Iran*

Study question: Does human endometrial CD146$^+$ mesenchymal stem cells could construct endometrial-like epithelium *in vitro*?
Summary answer: The CD146 cells derived from human endometrium have the potential tobe used for *in vitro* construction of endometrial-like epithelium in a three-dimensional (3D) culture system
What is known already: It has been proposed that a 3D culture system using CD146$^+$ endometrial stem cells on collagen/matrigel scaffold and uterine smooth muscle cells could construct endometrial-like epithelium.
Study design, size, duration: This laboratory-based study used human endometrial and myometrial tissues from women at proliferative phase aged 30–40 years (n = 10) undergoing hysterectomy for non-endometrial and -myometrial pathologic conditions.

Participants/materials, setting, methods: Human endometrial cells were cultured to the fourth passage, then CD146+ cells were sorted using MACS. Then they were cultured in collagen/matrigel scaffold on the top of the myometrial smooth muscle cells for 10 days. At the end of culture period, the differentiation and formation of the epithelial-like cells were confirmed by ultrastructural studies and analysis of the expression of SPP1, MMP2, ZO-1, LAMA2 and COL4A1 genes by RT-PCR and CD9 protein by western blotting.
Main results and the role of chance: The results showed that the human endometrial mesenchymal CD146+ cells were able to produce endometrial glandular tube-like structures *in vitro*. Ultrastructural observation revealed the polarization of cells as epithelium by appearance of some projections on the apical basal lamina-like structures on the basal and tight junctions and desmosomes on the lateral surfaces of the epithelial-like cells. The expression of SPP1, MMP2, ZO-1, LAMA2 and COL4A1 gens and CD9 protein confirmed the formation of endometrial epithelial-like cells.
Limitations, reasons for caution: This study does not demonstrate the functional properties of the formed epithelial-like cells, it needs more study to evaluate the interaction of embryo with this endometrial like cells.
Wider implications of the findings: This is the first attempt to construct endometrial-like epithelium in a 3D culture system using human endometrial CD146+ mesenchymal stem cells. This 3D culture system may have important implication in cell therapy and in human implantation models studies.
Trial registration number: It is not a clinical trial

P-789 Uncovering the novel role of mTORC2 subunit of the PI3K/AKT/mTORC pathway in establishing naive pluripotency in human embryonic stem cells

S. Warrier[1], M. Van der Jeught[1], G. Duggal[2], J. Taelman[1], S. Lierman[1], S. Chuva De Sousa Lopes[3], A. Van Soom[4], L. Peelman[5], F. Van Nieuwerburgh[6], D. De Coninck[6], B. Menten[7], J. Van de Sompele[7], D. Deforce[6], P. De Sutter[1], B. Heindryckx[1]

[6]*Ghent University, Laboratory for Pharmaceutical Biotechnology, Faculty of Pharmaceutical Sciences, Ghent, Belgium*
[7]*Ghent University, Center for Medical Genetics, Ghent, Belgium*

Study question: How does the PI3K/AKT/mTORC pathway facilitate the induction of naive pluripotency in human embryonic stem cells (hESCs) converted in different naive conversion media?
Summary answer: Induction of naive pluripotency in primed hESCs occurs via activation of the mTORC2 subunit of the PI3K/AKT/mTORC complex, irrespective of the naive medium utilized.
What is known already: Efforts have been made to establish naive pluripotency in hESCs, such as by using naive conversion medium (NCM), naive human stem cell medium (NHSM) or reverse-toggle protocol (RT). Other published naive media rendered naive hESCs karyotypically abnormal or required ectopic transfection prior to exposure to the naive culture medium. Although the inhibition of MAPK/ERK, GSK3β and activation of LIF/STAT signalling is necessary to induce naive state, we recently demonstrated a novel role of PI3K/AKT/mTORC in naive hESCs converted in NCM media. However, the role of PI3K/AKT/mTORC in naive hESCs generated by other naive media has not been investigated so far.
Study design, size, duration: Unlike previous studies that compared different naive hESC conditions based on published datasets only, we carried out naive conversion of in-house derived primed hESCs using different naive media in the same lab, to avoid any bias. We induced the conversion of primed UG11-7 (XY) hESC line towards a naive state in NCM, NHSM or RT media in low oxygen conditions (5%) in the presence of mouse embryonic fibroblast feeder layer.
Participants/materials, setting, methods: Upon successful conversion of primed hESCs towards a naive state in NCM, NHSM and RT media, the naive hESCs from each condition were subjected to microarray analysis in biological and technical triplicates. The results were analyzed using the Qlucore Omics Explorer 3.1 software package. Genes were considered to be significantly differentially expressed if they had p-value ≤ 0.01 and fold change ≥|1.5|, i.e., expression levels between conditions had to be at least 50% different.
Main results and the role of chance: Genome-wide microarray-based transcriptional analysis revealed significantly increased expression of genes associated with mTORC2 complex including PROTOR1, MAPKAP1(SIN1), AKT1S1, DEPTOR and MLST8 in NCM-, NHSM- and RT-naive hESCs, whereas genes related to mTORC1 subunit were downregulated in these naive conditions. PROTOR1 is a known Rictor-binding subunit of mTORC2, facilitating activation of AKT1 via mTORC2 to aid in cell survival, further confirming the role of mTORC2 in inducing increased single cell clonogenicity in naive pluripotent hESCs (95%) compared to primed hESCs (25%). MAPKAP1 knockdown is known to be lethal to mouse embryo. AKT1 phosphorylation via mTORC2 facilitates cell proliferation and growth when expressed at higher levels compared to AKT2 and AKT3 which otherwise leads to mESCs differentiation. Remarkably, AKT1 continued to be highly expressed in all the three naive hESC conditions compared to AKT2 and AKT3, which further emphasizes the naive state of hESCs being induced via mTORC2 as the doubling time of naive hESCs, similar to naive mESCs, is reduced significantly (17 h) compared to primed hESCs (51 h). As well, AKT1 inhibits GSK3β via PI3K/AKT/mTOR activation. DEPTOR inhibition of mTORC1 leads to its overexpression on mTORC2, resulting in increased cell survival.
Limitations, reasons for caution: This study will benefit from in-depth transcription analysis for more naive hESC lines, male as well as female, to further validate the role of the PI3K/AKT/mTORC (mTORC2) pathway in naive pluripotency. Additionally, mechanistic studies involving the use of mTORC2-specific inhibitors and activators will also strengthen the novelty of our finding.
Wider implications of the findings: We demonstrate for the first time an unbiased approach to compare hESCs converted in different naive conditions by performing the study in one lab, using in-house derived hESCs. We reveal PI3K/AKT/mTORC (mTORC2) pathway as a novel naive pluripotency-related pathway in all naive culture media conditions.
Trial registration number: N/A

P-790 Inhibition of Rho-associated protein kinase (ROCK) in mouse embryos affects trophectoderm formation and blastocyst development, but still allows subsequent stem cell derivation

S. Ghimire[1], M. Van der Jeught[1], J. Neupane[1], P. De Sutter[1], B. Heindryckx[1]
[1]*University Hospital Ghent, Ghent Fertility and Stem cell Team G-FaST, Department for Reproductive Medicine, Ghent, Belgium*

Study question: Does Rho-associated protein kinase inhibition (ROCKi) affect the first lineage segregation in mouse embryos and still allow subsequent mouse embryonic stem cell (mESC) derivation?
Summary answer: ROCKi impairs trophectoderm (TE) cell formation in mouse embryos, still permitting successful mESC derivation. However, higher concentrations reduce both blastocyst development and subsequent mESC derivation.
What is known already: Hippo signaling regulates the first lineage segregation (TE and inner cell mass (ICM) formation) in mouse embryos. Yes-associated protein (YAP), a Hippo target, binds with Tead4 (TE marker) in nucleus, initiating Tead4 expression in the outer cells. YAP fails to enter nucleus in the inner cells repressing Tead4. ROCKi during mouse embryo culture activates Hippo signaling impairing TE proliferation and blastocyst formation. However, it is unknown whether mESCs can be derived from ROCKi embryos. From an ethical perspective, it would be valuable to enable ESC derivation from embryos that lack TE cells as they cannot develop further as individual.
Study design, size, duration: Zygotes were collected from B6D2/F1 mice. At two-cell stage, mouse embryos were exposed to ROCKi (Y-27632) (10 μM, 20 μM, 50 μM and 100 μM) and an equivalent amount of dimethylsulfoxide (DMSO) in controls. On the fourth day of treatment (~75h), blastocyst development was evaluated and all embryos (irrespective of whether they were blastocysts or not) were either fixed for immunostaining or plated for subsequent ESC derivation. This study was conducted in 295 two-cell stage mouse embryos.
Participants/materials, setting, methods: Blastocyst development from two-cell stage embryos was evaluated morphologically. Embryos were stained for Nanog (epiblast marker) and Cdx2 (TE marker). Positive cells were counted

using a Zeiss fluorescence microscope. mESCs were derived on gelatin-coated dishes using N2B27 medium supplemented with 1000U/ml leukemia inhibitor factor, 1 μM PD0325901 and 3 μM Chir99021. mESC derivation efficiency was measured based on the number of lines derived per total number of embryos plated. *P* values < 0.05 were considered significant.

Main results and the role of chance: Blastocyst development was similar to the control (95%) in presence of 10 μM (96.42%) and 20 μM (97.56%) ROCKi, but was severely inhibited in presence of 50 μM (21.42%) and 100 μM (0%) ROCKi (control: 85.36%). Most embryos that failed to form blastocysts displayed morula-like morphology and failed to form blastocoel cavity. Most embryos in 100 μM ROCK inhibitor had already started to degenerate on day 4. The number of Cdx2-positive cells (46.58 ± 14.91 (10 μM), 59.94 ± 11.04 (20 μM), 24.64 ± 16.14 (50 μM) and 10 ± 6 (100 μM)) was significantly reduced in embryos cultured in all concentrations of ROCKi compared to their respective DMSO controls (57.68 ± 13.19, 70.18 ± 14.77, 50.56 ± 21.16 and 50.56 ± 21.16). The number of Nanog-positive cells increased significantly with 10 μM (17.62 ± 5.39) and 20 μM (12.27 ± 4.95) ROCK inhibitor, whereas it remained unaffected with 50 μM (12 ± 6.90) and 100 μM (15.10 ± 5.53) ROCKi, compared to their respective DMSO controls (13.94 ± 4.22, 7.12 ± 2.44, 14.5 ± 5.29 and 14.5 ± 5.29). The total cell number was comparable in presence of 10 μM (74.87 ± 22.92) and 20 μM (83.33 ± 12.69) ROCKi (controls: 81.52 ± 15.33 and 81.5 ± 10.27). However, it was significantly reduced in 50 μM (41.17 ± 15.96) and 100 μM (30.47 ± 7.66) ROCKi (control: 72.18 ± 17.56). mESC derivation efficiency was 76.19% in control (no DMSO or ROCKi treated embryos) and 71.42% in 20 μM, 42.8% in 50 μM and 25% in 100 μM ROCK inhibitor treated embryos.

Limitations, reasons for caution: Although we found that ESCs could be derived from ROCKi treated mouse embryos showing no cavitation, it remains to be investigated whether those mESCs show similar self-renewal and pluripotent characteristics as mESCs derived from control embryos.

Wider implications of the findings: We found that ROCKi impaired TE formation in mouse, still yielding mESCs. As a next step, we will extrapolate these findings to human ESC derivation, where the derivation of hESC lines from non-viable embryos that lack TE cells and cannot form individual would be ethically less controversial.

Trial registration number: N/A

P-791 Assessment of pharmacological compounds during neural differentiation in human embryonic stem cells

H.Y. Kang[1], K. Song Ai[1], A. Jin Yong[1], H. Jeong Ung[1], L. Jae-Hwan[1], K. Kipung[1], L. Myoungho[1], N. Tran Dinh[1], A. Changhwan[1], J. Eui-Bae[1]
[1]*Chungbuk National University, College of Veterinary Medicine, Cheongju, South Korea*

Study question: Human embryonic stem (hES) cells can be used in screening of neural embryotoxic chemicals.

Summary answer: Differentiated hES cells are useful for assessment of cell viability or neurogenesis impairment of chemicals.

What is known already: Human embryonic stem (hES) cells have been used in evaluation of embryotoxic chemicals because they are generated in large numbers and differentiate into three germ layers following formation of embryoid bodies. Using pluripotency of hES cells that have a potential for differentiation, they are currently used in assessment of toxicity of a variety of compounds.

Study design, size, duration: We examined the effects of several pharmacological compounds on hES cells differentiation into neuronal cells up to 28 days.

Participants/materials, setting, methods: Three anticancer agents (cytosine arabinoside, 5-fluorouracil, and hydroxyurea) and two immune suppressing agents (indomethacin and dexamethasone) were evaluated through cytotoxicity using CCK assay and changes of neural markers using real-time PCR and immunocytochemistry.

Main results and the role of chance: When three anticancer agents, cytosine arabinoside, 5-fluorouracil, and hydroxyurea, showed strong cytotoxicity, two immune suppressing agents, indomethacin and dexamethasone, showed a high concentration of $IC_{50,}$ which has weak cytotoxicity. Furthermore, most chemicals induced a significant change in levels of neuronal specific markers, such as *NR4A2* (dopaminergic neuron), *SLC1A2* (glutamartergic neuron), and *CNP* (oligodendrocyte). In addition, we monitored the neuronal lineage markers, including *FABP* (Neuronal progenitor), *FOXG1* (mortorneuron progenitor), *OLIG2* (oligodendrocyte progenitor), *GAD1* (GABAneuron terminal marker), and *SLC17A6* (glutamartergic terminal marker). We also found that cytosine arabinoside acts to diminish β-tubulin III in hES cells under conditions of neuronal differentiation because β-tubulin III is detected as a specific marker in extensive neurons.

Limitations, reasons for caution: We focused on the inhibited viability and the differentiation into cells of the neural lineage of human pluripotent stem cells by pharmacological compounds.

Wider implications of **the findings:** These findings could extend our understanding of how differentiated hES cells may be useful in assessment of cell viability or neurogenesis impairment of chemicals that could have an impact on the embryonic stage and its relevance in relation to embryonic neurogenesis.

Trial registration number: CBNU-201308-LRETC-008-01

P-792 Can Wnt inhibition induce more favorable characteristics in primed hESCs for future clinical applications?

J. Taelman[1], M. Van der Jeught[1], S. Lierman[1], B. Heindryckx[1], S.M. Chuva de Sousa Lopes[2], P. De Sutter[1]
[1]*University Hospital Ghent, Department for Reproductive Medicine, GFAST, Ghent, Belgium*
[2]*Leiden University Medical Centre, Department of Anatomy and Embryology, Leiden, Netherlands*

Study question: Can Wnt inhibition induce more favorable characteristics in primed hESCs for future clinical applications?

Summary answer: The Wnt inhibitor IWP2 converts hESCs into a distinct pluripotent state that displays more homogeneous pluripotent colony formation.

What is known already: HESCs hold great promise for future therapeutic applications. However, their primed nature is known for its heterogeneous expression of pluripotency markers, more spontaneous differentiation and low cloning efficiency. Recently, successes were obtained in converting hESCs into a more homogeneous, mESC-like (naive') pluripotent state, characterized by single cell clonogenicity. Yet, it remains uncertain whether or not this complicates directed differentiation. An alternative state has been described recently in mouse epiblast stem cells and hESCs using the Wnt inhibitor IWP2, exhibiting low levels of heterogeneity and spontaneous differentiation.

Study design, size, duration: Two in-house derived hESC lines, one male and one female, were converted towards IWP2 and naive conditions in three replicates. Standard primed hESCs were used as a control. Conversions were performed thrice from consecutive passages. After three passages, gene expression was analyzed by RT-PCR and immunofluorescence.

Participants/materials, setting, methods: HESC lines were cultured on mouse embryonic fibroblasts according to standard stem cell culture conditions. At three consecutive passages, cells were seeded into naive, IWP2 and primed conditions. After three passages, cells were fixed for immunofluorescence for pluripotency genes (POU5F1 and NANOG) and differentiation markers (GATA4 and T). RNA was collected from parallel cultures, for gene expression analysis of the same genes.

Main results and the role of chance: Overall, both IWP2-treated hESCs were more homogeneous than the parental primed hESCs. Levels of spontaneous differentiation were lower in IWP2-treated hESCs then in the parental primed hESCs, in all three replicates. Furthermore, IWP2-treated hESC colonies were distinct from both the naive and primed state hESC colonies. In the female line, the pluripotency marker genes POU5F1 and NANOG were not significantly different in the IWP2-treated hESCs compared to the primed condition. GATA4 and T were expressed in primed hESCs, but absent in IWP2-treated hESCs. In the male line, POU5F1 and NANOG were expressed similarly in primed and IWP2 conditions. However, GATA4 was expressed in primed hESCs, but absent in IWP2-treated hESCs, whereas T was not be detected in any condition.

Limitations, reasons for caution: Two different hESC lines were converted in triplicate, but we only assessed short-term effects of the IWP2 treatment of the pluripotency state. It will be important to investigate long-term effects as well. Moreover, directed differentiation experiments need to be performed to assess efficiency and possible clinical relevance of IWP2-converted hESCs.

Wider implications of the findings: In case the directed differentiation experiments are successful, the unique features of the IWP2 condition (homogeneous pluripotency nature and less spontaneous differentiation) will allow a new state of pluripotency that is perhaps more suitable for future clinical applications.

[4]*Karolinska Institutet, Department of Medical Biochemistry and Biophysics, Stockholm, Sweden*
[5]*University of Basel, Department of Biomedicine, Basel, Switzerland*

Study question: What is the expression profile and which are the target genes of human *LEUTX*?
Summary answer: Recently discovered new *LEUTX* isoform encodes functionally active homeodomain-containing transcription factor expressed exclusively in human embryos. The experimental *LEUTX* targets overlap with human EGA genes.
What is known already: PAIRED (PRD)-like homeobox genes belong to a class of predicted transcription factor genes with incompletely known functions. Our recent study of human EGA focusing on transcription start sites (TSSs) in oocytes, zygotes, and isolated blastomeres from 4-cell and 8-cell embryos (Töhönen et al., Nat Commun 6:8207, 2015) revealed that many PRD-like homeobox genes are uniquely expressed in the early embryos. One of the previously unannotated TSSs implicated in human EGA marked the predicted PRD-like homeobox gene *LEUTX*.
Study design, size, duration: We cloned the full-length *LEUTX* with a complete homeodomain from human 8-cell stage embryos. The gene was further cloned into a bicistronic pFastBac vector co-expressing eGFP marker and transfected to a human embryonal stem cell line. Nine to 11 h after transfection, we analyzed gene expression in 50-75 FACS sorted cells using single-cell tagged reverse transcription (STRT) RNA-seq.
Participants/materials, setting, methods: Human 8-cell stage embryos destined to be discarded were donated for research by informed consent. The human ESC lines HS401, HS980, HS983a and H9 were maintained in culture. Methods used included cDNA cloning, overexpression in human ES cells, FACS, STRT RNA seq, qPCR and database surveys.
Main results **and the role of chance:** Our results revealed that high *LEUTX* expression is restricted to early embryos only and we confirmed that mouse lacks the orthologous gene for human *LEUTX*. The novel *LEUTX* isoform containing a full homeodomain, but not the previously predicted *LEUTX,* activates more than 2,500 TSSs ($p < 0.1$) and the targets show remarkable overlap (FDR = 0.05, Chi-square test) with the genes that we previously identified in human EGA.
Limitations, reasons for caution: Due to the lack of mouse ortholog and the limited availability of human embryos, the functional studies in model systems are limited.
Wider implications of the findings: A novel *LEUTX* isoform is suggested to play an important role in early embryo development and pluripotency.

Study question: We aim to examine the relationship between the differentiation stages of the human spermatogenesis and their transcriptomic activity in adult.
Summary answer: The dynamics of the germinal transcriptome has been observed along adult human spermatogenesis with a focus on primitive spermatogonia.
What is known already: Compared to mouse model, the identity of the stem cell pool in the human spermatogenic lineage is not well established. The molecular mechanisms governing human GSC germinal stem cell renewal and initiation of differentiation remain largely unknown.
Study design, size, duration: The various differentiation stages of human spermatogenesis were purified using a multi-parameter flow cytometry strategy with Vybrant, b-2microglobulin, a-6 integrin and Thy-1 markers. Using this strategy, three spermatogonial populations, one of which contains primitive spermatogonia and is enriched in spermatogonial stem cells, spermatocyte I, spermatocyte II and spermatids were sorted. A mix of somatic tissue was used as a reference. RNA was prepared and transcriptome was analysed using Affymetrix transcriptome array.
Participants/materials, setting, methods: Testicular biopsies were obtained from obstructive azoospermia patients exhibiting normal profiles of spermatogenesis in seminiferous tubules
Main results and the role of chance: According to PCA analysis, the transcriptome of the somatic reference is clearly distinct from transcriptome of the different germinal populations, showing the transcriptional specificity of the germinal lineage. We observe also a clear trend of the transcriptome to diverge according to the differentiation process. These comparisons reveal dramatic changes in gene expression profiles of each stage, exhibiting unique transcriptome profiles that underly the mechanistic differences between these steps. Premeiotic spermatogonial populations clustered closely together, and meiotic and post meiotic populations diverged. Transcriptomic signatures have been found for the different steps of spermatogenesis. We focused our analysis on the population of immature spermatogonia containing SSCs, and 551 genes (fold > 2, $p < 0.01$) were identified with enriched expression in this population compared with the downstream spermatogonial progeny.
Limitations, reasons for caution: Transcriptome
Wider implications **of the findings:** The characterization of the human spermatogonial stem cells and spermatogenesis should help to identify new molecular pathways and the genetic factors associated to infertility.
Trial registration number: Not applicable.
